This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world’s books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that’s often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book’s long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google’s system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google “watermark” you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can’t offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book’s appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google’s mission is to organize the world’s information and to make it universally accessible and useful. Google Book Search helps readers discover the world’s books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at [http://books.google.com/](http://books.google.com/)
A MANUAL
of
PHARMACOLOGY
and its applications to
THERAPEUTICS AND TOXICOLOGY

By
TORALD SOLLMANN, M. D.
Professor of Pharmacology and Materia Medica in the School of Medicine of Western Reserve University, Cleveland

SECOND EDITION, ENTIRELY RESET

PHILADELPHIA AND LONDON
W. B. SAUNDERS COMPANY
1922
PREFACE TO THE SECOND EDITION

PHARMACOLOGY comprises some broad conceptions and generalizations, and some detailed conclusions, of such great and practical importance that every student and practitioner of medicine should be absolutely familiar with them. It comprises also a large mass of minute details, which would constitute too great a tax on human memory, but which cannot safely be neglected. It is the ambition of this book to present both types of information without confusion. The matter in the larger print aims to give a connected and concise statement of the essentials of pharmacology. The smaller print need not be considered by the reader who wishes to obtain merely a general knowledge of pharmacology. It contains more detailed data for consultation. Side headings have been introduced liberally to facilitate this use. The bibliographic references are intended to put the student on the track of further details.

The volume can, therefore, serve both for study and reference. There may be some question as to the general advisability of combining text-books and reference books; but in Pharmacology this appears to be necessary, since every student may need more detailed information at any time.

Since the first edition of this work was printed, the development of pharmacology has been repaid and extensive, notwithstanding the war, and in some directions because of it. There has not yet been time thoroughly to digest all this material. However, it has been possible to make important additions and changes in all parts of the text; and to introduce fairly thorough discussions of new topics; such as the "war-gases;" the new antiseptics; cuprein derivatives; etc. These additions have enriched the bibliography by over twelve hundred titles.

CLEVELAND, OHIO.

A MANUAL
OF
PHARMACOLOGY

PHARMACOGNOSY

Definitions.—Pharmacognosy deals with the origin and the anatomic and chemic structure of crude drugs.

Materia Medica is an older, obsolescent title, which was used to include also the actions, uses and dosage. Organic Materia Medica is limited to the drugs derived directly from the vegetable and animal kingdoms.

Importance of Pharmacognosy.—An accurate knowledge of this branch is necessary to the pharmacist to insure the quality of his wares. It is much less important to the physician. However, it is useful to know the appearance, odor, taste, solubility, and perhaps the origin, at least of the more important drugs.

Vegetable Drugs.—The crude organic drugs are derived mainly from plants, either wild or cultivated; collected at the proper season to insure the maximum activity, and properly dried or otherwise prepared.

Parts Used.—The active principles are often diffused throughout the plant; but they are generally more abundant in one particular part, which is then used. The parts are designated by their usual botanic names. The following are the most important, with some characteristic examples.

Root (Radix).—The underground part of the plant, generally devoid of chlorophyll (green coloring matter), and which does not produce leaves (Dandelion, Belladonna, Ipecac, Rhubarb).

Tuberous Roots.—Roots swollen with accumulation of reserve food material (Sweet Potato, Aconite, Jalap). They are often called tubers; but true tubers (Potato) are similar formations on rhizomes.

Corm.—A thickened underground stem (Colchicum).

Bulb.—Very fleshy, closely crowded leaves, enfolding the underground base of the stem (Onion, Squills).

Rhizome.—Underground stems which bear leaves (Podophyllum, Hydrastis, Ginger, Aspidium).

Wood (Lignum).—The wood of trees, in fragments, chips or coarse powder (Quassia, Hematoxylin, Sandalwood).

Bark (Cortex).—The outer layer of the stem (Cinchona, Cascara, Wild Cherry), or of the root (Sassafras, Cotton-root). Sometimes only the inner bark is collected (Ceylon Cinnamon, Elm).

Leaves (Folia).—Digitalis, Uva Ursi, Belladonna, Senna.

Herb (Herba or Species).—The smaller leafy and flowering or fruiting stems (Peppermint, Cannabis Indica, Savin).
Flowers (Flores).—Chamomile, Arnica. Unexpanded flowers are: Cloves, Santonica.

Fruit (Fructus).—The ripened ovary, with any persistent parts of the flower, and containing the seeds (Pepper, Cardamom, Hops, Colocynth, Anise).

Seed (Semem).—The essential part of the fruit (Nux Vomica, Strophanthus, Physostigma, Mustard, Linseed).

Microscopic Structure of Plants.—This differs from the animal cells, especially by the thick cell walls, and by the frequent presence of protoplasmic enclosures, starch, fats, calcium oxalate, protein crystals, etc. The cell walls are chiefly responsible for the shape and physical properties of the cell. They consist primarily of cellulose, variously modified by certain allied substances (lignin in wood, suberin in cork). These are all insoluble in ordinary solvents and in the alimentary canal of man. They are therefore so much useless “ballast” in the administration of the drugs. The processes of pharmacy consist largely in isolating the active constituents from this useless material.

Pharmacognostic Importance of Microscopic Structure.—The appearance, size and arrangement of the cells and their inclusions (starch grains, etc.) is often the most important aid in identifying a drug, particularly when in the form of powder. The pharmacopeias therefore include microscopic descriptions, whenever these are important.

IMPORTANT PLANT CONSTITUENTS

Elementary and Proximate Constituents.—The elementary or ultimate, constituents of plants, as of animals, are mainly C, H, O, and N. The chemical compounds formed from these are called the proximate principles or constituents of the plant. These belong to the chemical groups of proteins, fats, carbohydrates, tannins, resins, alkaloids, glucosides, acids, terpenes, etc. Plants also contain inorganic salts.

Cellulose.—This is found in the cell walls. It exists in almost pure form in cotton. It is chemically an isomer of starch, having the elementary formula (C₆H₁₀O₅)n. It is insoluble in all the ordinary solvents, and is not affected by boiling water. It dissolves without change in Schweitzer's reagent (ammoniated solution of copper sulphate). In older cells it is often modified by the introduction of allied molecules: wood (lignin) or cork (suberin). Cork is very resistant to reagents and impermeable to water, and hence protects the plant against evaporation and chemic injury. The cellulose may also undergo a retrograde metamorphosis into gum or pectin.

Starch (C₆H₁₂O₅)n.—This is produced as one of the first stages in the assimilation of CO₂. It occurs in the form of granules, usually showing a laminated structure around a center (hilus). The character of this lamination, as well as the average shape and size of the granules, are important in distinguishing between different plants. Starch can be easily recognized by the blue color which it gives with iodin. It is insoluble in all the ordinary solvents, but with boiling water swells and forms a peculiar colloidal solution (paste).

Gums.—These are colloidal carbohydrates, swelling or dissolving in water to viscous adhesive fluids (mucilages or pastes). They are precipitated by alcohol. They are formed in the plant by the transformation of cellulose and cell contents, especially as the result of pathologic processes. Pectins are closely related substances, occurring in fruits, and
causing the boiled fruits to set into jelly. Gums and pectins do not color with iodin; they reduce copper only after inversion.

Sugar.—The various forms of sugars have a wide distribution in the vegetable kingdom. Some reduce copper in alkaline solution; others do so only after inversion. All turn the plane of polarized light. They are soluble in water; much less so in alcohol. The most important types are:

- **Glucose** (Dextrose and Levulose), C\textsubscript{6}H\textsubscript{12}O\textsubscript{6}; **Maltose** and **Saccharose**, C\textsubscript{12}H\textsubscript{22}O\textsubscript{11}; **Mannite** C\textsubscript{6}H\textsubscript{12}O\textsubscript{6}.

- **Glucosides.**—These are ester-like combinations of sugars with various other substances, frequently with phenols. Acids or appropriate ferments hydrolyze them into sugar and the other substance. Many do not contain nitrogen. Most glucosids are neutral or weakly acid; a few are alkaloidal. They are widely distributed in plants, and include active principles such as the digitalis constituents, saponins, tannins, etc.

- **Saponins.**—These are neutral, non-nitrogenous substances distinguished by foaming with waters, emulsifying oils, and laking red blood corpuscles. Many have the formula C\textsubscript{a}H\textsubscript{b}-aO\textsubscript{15}. Some are glucosids. Those which are markedly toxic are sometimes called **sapotoxins**. The saponins are also of wide occurrence.

- **Tannins.**—This term is applied to a group of phenol derivatives, distinguished by giving a bluish or greenish color with ferric salts. The greater number also form insoluble compounds with other metallic salts, with alkaloids, proteins, etc. This precipitation leads to an astringent action.

  Tannins occur in many plants, especially in the leaves and bark, and in pathologic formations (nut-galls). They are non-nitrogenous; some are glucosids. They are soluble in water and in alcohol; but since they form insoluble compounds with so many substances, they often occur in plants in granular form.

- **Phlobaphenes.**—Tannins are easily decomposed into resin-like substances called phlobaphenes. These exist naturally in plants, but are usually formed as artificial decomposition products in all extracts. They are dark-colored, soluble in alcohol and in alkaline liquids, insoluble in water.

  Tannins and phlobaphenes, as well as most other plant constituents, are easily converted into a group of substances called **humins**. These do not exist in living tissues, and arise on the death of the cells, by the action of air and moisture. They cause the brown color which plants assume on drying; they are also present in the brown bark.

  Tannins, phlobaphenes, and humins form a series, without sharp demarcation. They are rather resistant to the action of bacteria, and in this way protect plants against putrefaction.

**Alkaloids.**—These comprise many of the most active and important plant constituents. They may be defined as natural nitrogenous organic bases (generally tertiary amines); i.e., they are organic substances, containing nitrogen, of basic character, combining with acids without the elimination of hydrogen, forming well-defined and usually crystalline salts. The salts with halogens are called hydrochlorids, hydrobromids, etc. (not chlorides, etc.).

The names of alkaloids are often spelled with a final e, to distinguish them from neutral principals (thus morphine, an alkaloid; salicin, a glucosid). This distinction is rather arbitrary, and is not followed here.

**Discovery of the Alkaloids.**—This is an achievement of the 19th century (Morphin, by Bertler, 1805 to 1817; Strychnin, 1812; Quinin and Caffein, 1820; Nicotin, 1829; Atropin, 1833).
Occurrence.—Only a few alkaloids occur in the animal kingdom, the most important example being epinephrin, the active principle of the suprarenal gland. Alkaloidal principles are also formed by the action of bacteria, and are called piomains. Amongst the higher plants the occurrence of alkaloids is very common, the same plant containing usually several alkaloids, which are often formed from one another. They are often found in all parts of the plants, but sometimes they are strictly localized in certain portions.

The alkaloidal content of plants varies considerably according to the climate, culture and other conditions. Individual plants also show considerable variations (Sievers, 1913). They can be improved by selective breeding, although this is technically rather difficult (Sievers, 1916).

Some alkaloids contain oxygen, others do not. Those containing oxygen are solid and comparatively non-volatile, whereas those free from oxygen (nicotin and conin) are liquid and volatile.

Properties of Alkaloids.—All alkaloids have certain properties in common: bitter taste, alkalinity to litmus, nitrogen reaction; generally profound physiologic action, without postmortem lesions.

Solubility Characters.—Free alkaloids are soluble in ether, chloroform, and oils, much less soluble in alcohol, and comparatively insoluble in water. Alkaloidal salts, on the other hand, have just the opposite solubility: They are soluble in water and alcohol, insoluble in chloroform and ether. With the alkaloidal salts, the combined acid plays a prominent role in the solubility.

Precipitation Reactions.—Alkaloidal salts are precipitated by iodin, mercuric-potassic iodid (Mayer's reagent); phospho-molybic acid; picric acid; gold chlorid, platonic chlorid, etc. Many also precipitate mercuric chlorid, potassium bichromate, tannin, etc.

Color Reactions.—Many alkaloids give characteristic colors with concentrated acids, with or without the addition of oxidizing or reducing agents.

Chemic Constitution.—The structure of many alkaloids is well understood; others are still obscure. The greater number are fairly complex derivatives of pyridin (conin, nicotin); pyrrolidin (cocain, atropin); quinolin (quinin, cinchonin, strychnin, brucin); iso-quinolin (hydrastin, narcotin, cotarnin, berberin); morpholin or phenanthren (morphin, codein, thebain).

Neutral or Bitter Principles.—This class comprises a heterogeneous collection of substances, which have not been assigned to other classes. The principles usually have a bitter or sharp taste, and are usually crystalline and non-nitrogenous. A number are lactones, i.e., derived from alcohol-acids, by the elimination of H₂O.

Resins.—These are also a heterogeneous collection; including solid, non-volatile, amorphous substances of obscure composition, generally non-nitrogenous. The distinguishing character is their insolubility in water, and solubility in alcohol, most fat solvents (except petroleum ether) and strong alkalis. The resins are often contained in special vessels, from which they are usually obtained as exudations after incising the plant.

Mixed Resins.—When the resins occur mixed with essential oils, they are natural oleoresins; when mixed with gums, gum-resins. If they contain aromatic acids (cinnamomic, benzoic, etc., or essential oils), they are called balsams.

Resinoids.—These are artificially isolated principles soluble in alcohol and insoluble in water. They are generally mixtures, often containing true resins.
Volatile Oils (Essential Oils).—These are odorous principles, of the physical characters of fatty oils, from which they differ by being volatile and soluble in alcohol. They are responsible for the odor of plants. Chemically, they are mixtures of esters, aldehydes, alcohols, ketones, and especially the terpenes (Kremer, 1898).

The constituents may separate on cooling, the liquid part being called *eucalyptus*, the solid *mephrum*. Compounds are analogous substances, but solid at ordinary temperature. *Rubber* (casautchouc and gutta-percha) is related to the terpenes.

Plants also contain many other alcohols, aldehydes, organic acids, aromatic derivatives, etc.

Fats and Fixed Oils.—Typical fats (esters of fatty acids and glycerin) are abundant especially in seeds, occurring within the cells as drops or crystals. The fats are greasy liquids or soft solids; when heated, they undergo decomposition, denoted by acrid acrolein vapors. They are insoluble in water or glycerin, sparingly soluble in alcohol, and freely soluble in ether, chloroform, benzine (petroleum ether), carbon disulphide, turpentine, etc. (fat solvents).

Waxes.—These are more solid substances with the solubility characters of fats. Chemically, they are esters of fatty acids with alcohols other than glycerin.

Proteins.—These are, of course, represented in all vegetable cells, but are especially abundant in seeds, sometimes as crystals (aleurion). Several classes of the proteins are peculiar to plants.

Chlorophyll.—This, the green pigment of plants, is insoluble in water, soluble in alcohol and fat solvents. It is allied to blood pigment, but contains no iron. It is readily changed and discolored by reagents.

The chlorophyll occurs in the cells as granules (chloroplasts), made up of a colorless, spongy, protein groundwork, containing in its meshes the chlorophyll pigment. The latter consists really of a mixture of green and yellow colors (chlorophyll and xanthophyll). These chlorophyll granules are found mainly in the higher plants, and serve in the presence of light to assimilate CO₂, and consequently to form starch, etc. During the process of drying, especially if this occurs slowly, the pigment is acted on by acids, etc., developed under these conditions, and undergoes various changes, usually becoming brown.

Other Pigments.—Plants are rich in colors, belonging to various chemic groups, often unidentified. Many alter with changes of reaction. The brown coloring matter of barks, etc., is allied to the tannins and phlobaphens.

Carotin.—This is the principal yellow pigment of plants. It is practically non-toxic or poisonous injection, and also with intradermic tests (Wells, H. G. and Hederburg, rnt.)

Enzymes.—Different plants contain almost every imaginable kind of ferments, a few being used in medicine.

Extractive Matter.—This term is applied to the mixture of unidentified organic constituents; especially to the colloidal smery mass which remains after evaporating any extract from which the important constituents have been removed.

Mineral Salts.—These are fairly abundant in plants, constituting the ash which remains on incineration. Ca and K are especially important.

These salts seem to be combined largely with the protoplasm, and exist partly dissolved, partly as crystals. Growing tissues are always richer in salts than those fully developed.
PHARMACEUTIC STANDARDS

Objects.—Pharmacy deals with the preparation and compounding of drugs for the purpose of administration. It has for its objects the separation of the active principles of drugs, their combination, and their presentation in a pleasant form.

The Need of Pharmacy.—The necessity for such an art will be readily understood. Drugs may be divided according to their origin into mineral, vegetable, and animal drugs. The last two are often too bulky to be conveniently used, and the substances which determine their action are often in such a condition that they can not readily be administered in the body, and so cannot fully develop their action. One drug alone may not meet all the indications in a disease, and when several are given it is necessary to combine them in such a way that they may not interfere with one another, either chemically or mechanically. Lastly, having chosen and prepared the drugs in a proper manner, and having decided how to combine them, it is highly desirable to give them in such a form as will be least objectionable to the taste, smell, or sight of the patient.

Official Drugs.—A certain degree of uniformity in the strength and preparation of pharmacetical products is absolutely indispensable. Accordingly, practically all civilized countries have standards established by law, to which drugs and preparations in the shops must conform. The book in which these standards are published is usually called the Pharmacopoeia. Preparations listed in these official books are termed "official." A pharmacopeia, therefore, is an official book of standards for official drugs.

International Uniformity.—The first effective step in this direction was taken by the Brussels Conference of 1906, the "International Conference for the Unification of the Formulas for Potent Medicines." This conference drew up a list of the potent drugs for which uniformity was most important, and established standards of strength for them and their preparations. These have been adopted essentially by most of the civilized nations. These formulas of the Conference are designated as "I.A." (International Agreement) by the B.P.; as "I.P." (Protocol International) by the U.S.P.

Scope of the Pharmacopoeias.—These usually aim to include only "standard drugs," i.e., those of established value. There is a healthy tendency to restrict the admission of complex mixtures.

Galenic Preparations.—"Galenicals" are, strictly speaking, medicines prepared after the formulas of Galen. The term is now used to designate standard preparations containing one or several organic ingredients, as contrasted with pure chemic substances.

Proprietary Drugs.—Drugs which are protected by a monopoly—by patents, trade marks, secrecy, etc.—are generally not admitted into the pharmacopoeias, and are therefore non-official. They are thus not subject to legal control, and are often advertised under extravagant, misleading and false claims. However, some of the most valuable drugs are proprietary, and many are marketed in a strictly legitimate manner. The pharmacopoeias will doubtless give increasing recognition to patented drugs that are really valuable, non-secret, and otherwise unobjectionable.

Patent Medicines.—This term is to applied proprietary drugs that are advertised, directly or indirectly, to the laity. They are not usually patented, as the name would imply, but they are usually preferred by patients upon secrecy or price, and are easily advertised. The medical profession is generally opposed to patent medicines as a class, and to lay advertising in particular. The impossibility of controlling the irresponsible claims which are usually made in advertisements to the public, the well-known dangers of suggesting by descriptions of symptoms to the minds of the people that they are suffering from the many diseases described, the dangers of the unconscious and innocent formation of a drug habit, and the evils of harmful self-medication, including the dangers
of the spread of many infectious and contagious diseases when hidden from the physician, and similar well-known considerations, are the reasons for discouraging, in the interest, and for the safety, of the public, this reprehensible form of exploitation” (N.N.R.).

The United States Pharmacopeia.—This is issued decennially; the revision started in 1920 being the “U.S.P.X.” It furnishes mainly the standard definitions, tests and formulas. It is a legal standard.

The U.S.P. was first published in 1820. It is revised by a Pharmacopeial Revision Committee, appointed by the United States Pharmacopeial Convention which consists of delegates from pharmaceutical and medical organizations. The current committee of revision consists of 50 members, headed by an executive committee.

The British Pharmacopeia.—The B.P., fifth edition, was issued in 1914. It resembles the U.S.P. in scope and arrangement.

The B.P. is published by the General Medical Council, and revised at irregular intervals.

National Formulary (N.F.)—This is a collection of formulas for less important preparations, issued by the American Pharmaceutical Association. It is also a legal standard.

New and Non-official Remedies (N.N.R.)—This contains descriptions of the characters, actions and uses of those proprietary drugs that are marketed in a proper manner. It is issued by the American Medical Association and revised annually by its Council on Pharmacy and Chemistry.

Dispensatories.—These are commentaries which enlarge and explain the official texts, and generally also describe unofficial preparations. The National Dispensatory and the U.S. Dispensatory are principally used in the U.S. The British Pharmaceutical Codex (B.P.C.), and Hager’s Praxis are similar works.

Useful Drugs.—This is a small manual issued by the American Medical Association which contains only the most useful drugs with such information as is of especial interest to physicians.

Physicians’ Epitome of U.S.P. and N.F.—This is another A.M.A. publication, giving a brief but critical abstract of all U.S.P. and N.F. preparations.

PHARMACEUTIC METHODS

In the making of pharmaceutical products different methods must be used, depending upon the physical and chemic nature of the crude drug, and upon the character of the desired product.

These may be roughly classified into those used in the making of many different preparations—general methods—and those used in only a limited number of cases—special methods.

The methods may be studied in the order in which they are usually applied to the drug.

PREPARATORY PROCESSES

Desiccation or Drying.—This is usually the first operation to which the crude drugs are subjected after their collection. It serves a threefold purpose: It reduces the bulk, assists preservation, and facilitates comminution.

Formerly the drying was done by spreading or hanging the drugs in airy lofts. At present they are usually placed on perforated trays in special drying closets and heated artificially (steam, etc.). They are often cut into smaller pieces before this drying. The degree of heat must not be so high as to injure the sometimes very unstable ingredients. The U.S.P. designates 32 to 39°C. as “gentle heat.”
COMMUNION.—The next step is comminution, or reducing of the substance to smaller pieces.

This is usually done by machinery. Crude vegetable drugs are first sliced or chopped, often before drying. They are then bruised by pounding in a mortar and finally ground, the finer grades of powders often several times, the grinding surfaces being brought closer together each time. The mills for this purpose are constructed on the same general principles as flouring mills, employing stones, rollers, etc. The details of the process used depend upon the physical character of the drug.

On the small scale, drug mills, constructed more or less on the principle of the coffee-mill, are used for fibrous, and mortar and pestle for friable drugs. Mortars are made of iron, wedgewood, porcelain, and glass.

Pulverization is comminution to a powder.

Trituration is the process of rubbing (not pounding) a substance to a powder in a mortar.

Some points deserve special mention. Often a substance will not powder by itself, but will do so when mixed with another substance—e.g., sugar of milk. This is called "pulverisation by intervention." Sometimes it is well to moisten the drug—e.g., camphor with alcohol, nux vomica with steam, etc.

Fineness of Powder.—In the process of percolation, presently to be described, it is often essential to use a powder of a certain degree of fineness. The powders are therefore sifted, and are classified according to the size of the meshes of the sieve through which they pass, thus:

No. 80 = 80 meshes to linear inch, very fine.
No. 50 = 50 meshes to linear inch, fine.
No. 40 = moderately fine.
No. 20 = moderately coarse.
No. 20 = coarse.

Since the different structures in a crude drug do not powder with equal readiness, it is essential that the whole of the drug to be powdered should be passed through the sieve, else the different portions will not have the same composition.

Levigation.—This is employed to obtain very fine powders of insoluble substances, by making them into a thick paste with water, and rubbing this between polished slabs.

Intration is used to separate fine insoluble powders by suspending them in water and decanting.

PROCESSES OF SEPARATION

For the separation of the desired ingredients from the inert material three methods are in vogue, depending upon the nature of the active constituents. If volatile constituents are to be separated, this may be readily done by the application of heat—distillation and sublimation. If they are not volatile, the separation is usually effected by exposing the drug to the action of some solvents in which the desired principles are soluble, and the undesired constituents are insoluble. In certain cases some mechanical means are sufficient, as in the separation of fixed oils from seeds, etc., by pressure.

Separation by Means of Heat.—This may be used whenever the substances to be separated have different boiling-points, and are not themselves destroyed by the necessary degree of heat. The methods vary according to whether the fixed or the volatile portion is desired, and, if the latter, according to whether it is liquid or solid.

Desiccation, Torrefaction, Carbonization, Ignition.—With all these, the object is to drive off some volatile constituent from a solid, the fixed residue being the portion desired.

When the heat employed is of such degree as not to change the chemic composition, the process is spoken of as desiccation.
Torrefaction.—The process of roasting; the object being to employ such a degree of heat as will alter some of the constituents without affecting others. The roasting of coffee is a familiar example.

Carbonization.—The heating of organic substances under exclusion of air. The object is to destroy the chemic composition without oxidation; carbon results in the process (vegetable or animal charcoal).

Ignition.—This is the process of heating a substance strongly, usually in a crucible, with full access of air, so as to effect complete oxidation; nothing but the ashes remain.

Evaporation consists in vaporizing the solvent from a solution, the object being the concentration of the dissolved substance.

Since the rapidity of the evaporation, aside from the quantity of heat applied, depends upon the extent of the liquid exposed to the air and to the heat, dishes as flat as possible are chosen. For ordinary pharmaceutical and chemical purposes, those made of porcelain are of most frequent service. Vessels made of glass, iron, platinum, etc., find application in special cases. The heat may be applied directly, say by means of a Bunsen flame, only a piece of wire gauze or a plate of asbestos or iron being interposed. This method can be used only where there is no danger of injuring the solution by excessive heat, either the substance being incapable of change, or the solvent sufficient in amount so that the temperature can not rise much beyond its boiling-point. If this is not the case, some method must be used of regulating the amount of heat applied, and this is done by applying the heat indirectly through a bath. This consists of an outer vessel filled with water (steam), oil, sand, or air.

The rapidity of evaporation may be considerably increased by stirring, thus exposing a constantly renewed surface to the air.

In cases where the evaporation must be carried on at a temperature below the boiling-point of the solvent, this may be done either by evaporation over H₂SO₄, or in a vacuum, or by passing a current of dried air through the liquid.

Sublimation.—The process of separating a volatile from a non-volatile solid by heat.

This may be done in a distilling apparatus, provided that the cooling tube has sufficient lumen to prevent its clogging by the condensation of the sublimate. The apparatus is, however, usually modified. A simple illustration of this process is the old method of manufacturing benzoic acid from gum benzoin, a paper hood being used as condenser.

Distillation.—The process of separating a volatile liquid from a less volatile liquid or solid. (The difference between sublimation and distillation consists in this, that the product is solid in the former, liquid in the latter.)

Although distillation is such a ready and simple means of separation that one would think it must have been discovered at a very early time, such does not appear to have been the case. We find the first record of it in the writings of the fourth century alchemists.

Fractional distillation is the process of separating a mixture of liquids of different boiling-points by distillation.

Destructive distillation is the name applied to the process of heating a substance so strongly as to decompose it, and collecting the volatile products arising from this decomposition: i.e., in the case of organic bodies, tar.

Solution.—This consists of incorporating a solid into a liquid in a state of "molecular subdivision."

That is, the molecules of the solid disperse themselves in the liquid and become so widely separated that no solid particles are by any means discernible. In other words, the solid is liquidified and its molecules intermingle with those of the solvent.

A single solution is one occurring in the manner described, the change in the solid being physical. When a chemic change takes place, the process is called chemic solution (such as the solution of a metal in an acid).

A solution is capable, under given conditions, of dissolving but a limited amount of a given solid. A solution which contains as much of the solid as the liquid can dissolve under these conditions is called a saturated solution. The condition which has the greatest influence upon solubility in the temperature. A liquid can usually dissolve
the more of the solid, the higher the temperature. There are, however, a few exceptions to this rule.

If a solution saturated at a high temperature is allowed to cool, the originally dissolved substance will be in excess of saturation. Under certain conditions it may still remain in solution at the lower temperature, this being a supersaturated solution. Ordinarily, however, the excess will separate, usually in crystalline form. This process is called crystallisation. It is frequently used as a means of purification.

A solution which contains less of the solid than it is capable of dissolving is an unsaturated solution. A solution which is saturated with one substance is still capable of dissolving others.

Solution is effected by placing the solvent in contact with the substance to be dissolved. The process may be hastened by applying heat, or by exposing the largest possible surface to the action of the solvent. The latter may be done by using the substance in a pulverized condition, and by constant stirring. With circulatory solution, the substance is suspended near the surface of the solvent. As this takes up the substance, it gains in specific gravity, and hence sinks to the bottom, a new portion of liquid taking its place. The same object may be secured by a process analogous to percolation, the powder being placed in a funnel partly occluded by a pledget of cotton, etc., and the solvent allowed to percolate through it.

The process of solution applied to crude drugs has for its purpose the separation of the active ingredients from the insoluble inert material. The object is to dissolve out the greatest possible amount with the least possible menstruum. This accomplishes two results: We obtain a strong extract, and we waste neither drug nor menstruum. There are a number of methods of accomplishing this, each with its advocates. They are combinations of two extremes: maceration and percolation. Neither of these is commonly used alone in this country, the practice being to combine one with the other.

Maceration is by far the simpler process. It consists in simply leaving the solvent in contact with the drug under suitable conditions for a sufficient length of time.

When maceration alone is employed, a given quantity of the drug is put in a bottle or other suitable vessel with a definite proportion of the solvent (called menstruum) and left a certain time, usually a week or two. The liquid is then strained off, the residue (marc) is expressed and the mixed extract filtered. The details of the process are influenced by the fineness of the powder, the time of maceration, and the temperature. Different names are given to the process according to the temperature at which it is carried out. Maceration proper = room temperature; 30° to 40° C. = digestion; boiling = decoction. Possible injury to some constituents by heat, or evaporation of a constituent or of the solvent, are objections to the application of heat in certain cases.

This process of maceration is the one almost exclusively employed in Europe, and it offers certain advantages, not the least being its simplicity and the constant results which it gives. Its main disadvantages are the required time and the loss of the extract retained in the insoluble residue or "marc." Certain drugs are physically unfit for percolation, since the moistening causes them to form into a tough mass, as good as impenetrable to the solvent.

The loss of menstruum does not, of course, weigh when an aqueous solvent is used and only small quantities are prepared. Hence maceration is used in making infusions and decoctions.

Percolation consists in passing a solvent through a thick layer of the powder to be exhausted. This exposes a large surface of the latter; the nearly saturated solvent flows off and fresh unsaturated portions continuously replace it, insuring very rapid solution.

The principle of the method is to pack the powder into a tall vessel, with an opening at the bottom, and to let the solvent trickle through it. Usually the process is preceded by a short maceration.

The U. S. Pharmacopoeia defines percolation as consisting in "subjecting a substance or a mixture of substances, in powder, contained in a vessel called a percolator, to the
PHARMACEUTIC METHODS

Solvent action of successive portions of a certain menstruum, in such a manner that the liquid shall traverse the powder in its descent to the receiver, shall be charged with the soluble portion of it, and pass from the percolator free from insoluble matter. The details are as follows:

The powder, the fineness of which depends upon the nature of the drug and is directed for each case by the Pharmacopoeia) is moistened in a jar with some of the menstruum. This moistening is for the purpose of swelling the drug, for if this took place in the percolator, the drug would become so firmly impacted that the menstruum could not penetrate through it; or it could even burst the percolator. The moistened powder is then passed through a coarse sieve and transferred to the prepared percolator, which it should fill about two-thirds. The choice of the shape of the percolator and the manner of its use are important. The shape of the percolator depends upon the nature of the drug. Should the drug have a tendency to swell, particularly if they are in fine powder or if a weakly alcoholic menstruum is used, a conical percolator is employed; otherwise, the cylindrical.

Arrangement of Percolator.—The percolator is prepared in the following manner (Fig. 1): Into the small end there is inserted a cork perforated by a short glass tube which projects about 1 cm. inside the percolator. The other end of this tube is attached to a piece of rubber tubing, about one-fourth longer than the percolator, and this to a U-shaped glass tube. This is held to the percolator by a rubber band in such a way that it can be raised and lowered. The percolator is then set in the stand. A pledget of absorbent cotton is loosely packed in the neck of the percolator, and this is covered by a layer of clean sand, and over this goes a well-fitting disk of filter-paper. Then the moistened drug is pressed in—and this is the part of the process which requires the greatest skill and judgment, and on it depends the success of the product. It should be done very evenly, else the menstruum will choose the path of least resistance and some portions of the powder will be entirely exhausted whilst others are still scarcely affected. The fineness of the packing is also of great importance; if not firm enough, the menstruum will run through too rapidly and the percolate will consequently be weak. If too firm it can not run at all; and if any swelling occurs the percolator will be broken. Drugs in coarse powder should be packed more firmly than fine powders. An alcoholic menstruum requires firmer packing than a watery one.

The packing being completed, the menstruum is poured on until it stands an inch or two above the drug; the percolator is then covered and set aside for maceration for a specified time, the tube being raised so that no liquid flows out. When the time of maceration is completed, the tube is lowered and fixed at such a level that the outflow proceeds at the rate of 2 to 3 drops per minute. New menstruum is poured on in the measure that the old flows out. Care should be taken always to maintain the layer of liquid above the powder; ebbs and flows may appear in the latter, necessitating repacking.

The process is continued, in the case of tinctures, until a certain volume of percolate is obtained. The quality of the percolate will, of course, depend upon the care and skill of the operator, and the product is apt to vary. Maceration would, therefore, be a better process for tinctures.

This difficulty is avoided in the case of extracts, for here the percolation is continued "until the drug is exhausted;" i.e., until the active ingredients have become completely dissolved out. This is recognized by testing the last portions of the percolate in the appropriate manner, such as Mayer’s reagent for alkaloids, water for resins, etc. A drug is usually more rapidly exhausted of its active ingredients than of its coloring-matter, so that the last portions of percolate may be colored and yet devoid of activity.

The choice of a menstruum must be determined by the nature of the constituents, so as to extract all the active ingredients and the minimum of inactive. Alkaloids and resins require strong alcohol; gums, weak alcohol; licorice, alkaline alcohol; sanquine and ergot, acidiﬁed alcohol; gentian and quassia, water plus alcohol enough to keep.

Pharmaceutical Solvents.—The most useful are the following:

Water or Glycerin.—Dissolve salts (including those of alkaloids), sugar, gums, tannin, acids, alkalies, etc.

Dilute Acetic Acid.—Especially for alkaloids.
Alcohol.—Dissolves alkaloidal salts, neutral principles, resins, volatile oils. Precipitates gums and most inorganic salts.
Ether, Chloroform, Acetone.—Dissolve free alkaloids, neutral principles, resins, volatile and fixed oils, and fats.
Petroleum Benzine.—Solvent properties as the preceding, except resins.
Aromatic Spirits of Ammonia.—Dissolves resins and organic acids.
Expression.—The process of separating a liquid from a solid by pressure.

Its principal employment in pharmacy is for the recovery of tinctures from the “puddles” or other liquid retained by the drug residue after maceration and percolation. It is also a process of separating fixed oils.

The drug is put in a coarse strong cloth and subjected to pressure in a press. These are of various patterns; screw, lever, hydraulic, or centrifugal. The pressure must be applied gradually to prevent the bursting of the cloth. Small quantities can often be pressed sufficiently by putting them into a cloth and tightly twisting the end.

Straining or Colation.—The process of separating coarse solid particles from a liquid by pouring it through a cloth or strainer.
Filtration.—The process of separating solid particles (fine or coarse) from a liquid by pouring it through a finely porous material, such as filter-paper.

There are two principal methods of folding a filter—plain and plaited. These two filters have different uses. The plaited filter offers a much larger surface for filtration and is therefore more rapid; it is the form usually employed in pharmacy. The plain filter, on the other hand, facilitates washing and removal of the precipitate, and is of more frequent use in chemistry.

Other materials are sometimes employed instead of paper. A very useful filter for large quantities of liquid is made from felt. A plug of glass-wool or asbestos placed in the tube of the funnel is especially useful for strong acids or alkalies. A cell of porous clay is also employed, as in the various forms of the Chamberland filter. With this a vacuum is indispensable.

Dialysis.—This is sometimes used to separate crystalloids (alkaloids, salts, etc.) from colloids (extractives).

Decolorisation.—It is often desirable to remove the coloring-matter from a solution. This may sometimes be accomplished by choosing appropriate solvents. More often, however, the solution is filtered through recently calcined animal charcoal. This very often retains some of the active constituents as well as the coloring-matter.
Clarification.—The process of rendering turbid mixtures clear and transparent, by removing the suspended solid. When filtration does not suffice, the object is accomplished by agitating the mixture with insoluble powders (talcum, phosphate of lime, aluminum hydrate) or by adding egg-albumen and boiling; or sometimes by the centrifugal machine.
Sterilization.—The destruction of bacteria and their spores is accomplished by the various customary methods.

Glass and metal utensils may be sterilized by dry heat of 150 to 170°C for two hours; by superheated steam of 115 to 120°C for fifteen minutes; heating in a current of steam for thirty minutes or boiling for fifteen minutes, especially in 0.1 per cent. sodium bicarbonate. This kills all non-spore-bearing organisms.
Solutions that are not readily decomposed by heat may be boiled in a current of steam for one-half or better one hour.
Solutions that are readily decomposed by heat are either prepared aseptically or filtered through porous bones.
Emulsions in glycerin or oil are prepared aseptically, the solvent being first sterilized by heat.

PHARMACEUTIC ASSAYING

Different samples of vegetable drugs may vary widely in the quantity of active constituents which they contain. These variations are very undesirable from a thera-
Yeast standpoint, especially when they occur in potent, so-called "leaky" drugs. Inorganic drugs or other definite chemic compounds are not subject to this variation; but in many cases the removal of the last traces of innocuous impurities would greatly increase their cost without adding to their therapeutic usefulness. The pharmacopoeia has therefore aimed to furnish quantitative methods of estimation, assays, wherever possible, and to establish practical standards to which medicinal substances must conform. With inorganic drugs, it states the permissible quantity of innocuous impurities (usually less than 2 per cent.). With crude vegetable drugs, it states the lowest permissible percentage of active ingredient, wherever practical methods for their determination are available. Assayed galenic preparations are directed to be diluted so as to contain a definite proportion of active constituents, corresponding to the minimum permitted in the crude drug. These preparations should therefore be preferred to the crude drug whenever accurate dosage is desired.

The assay of inorganic drugs involves the well-known methods of ordinary quantitative analysis, volumetric processes being preferred. Special tests are furnished for determining the permissible limits of accidental impurities, and the presence of harmful substances, such as metals.

A series of volatile oils are assayed for their most important ingredient. Fats and fixed oils are tested for their "iodin absorption" and "saponification values," resins for the "acid number," some vegetable products for their ash. These tests serve mainly for identification and the exclusion of willful adulterations.

Pepin is assayed for its digestive power for proteins, pancreatin for starch. In resinous drugs, such as Jalap, Scammony, or Guaiac, the proportion of ether- or alcohol-soluble matter is determined.

The most important class of assays refers to drugs containing alkaloidal principles, utilizing the method of immiscible solvents, as in toxicologic analysis. This rests on the fact that free alkaloids are generally soluble in chloroform or ether, whilst their salts are insoluble in these, but soluble in water. In principle, alkaloids are extracted by chloroform or ether, or a mixture of both, in alkaline reaction. This solution is then shaken in a separator with acidulated water, which converts the alkaloids into salts and dissolves them, leaving the impurities behind. For further purification, the watery solution is again rendered alkaline and extracted with chloroform or ether. This, in evaporation, leaves the fairly pure alkaloid which may be weighed, or titrated, by dissolving it in a known amount of acid, and titrating back with alkali. Each cubic centimeter of acid corresponds to a definite quantity of each alkaloid. It is important to observe the directions minutely to obtain reliable results. The process for extracts and fluidextracts differs merely in details (the percolation being omitted, etc.). Tinctures are first concentrated by evaporation.

This method estimates the sum of all the alkaloids present in the drug, and suffices when the important one predominates very largely over the others. When this is not the case, it is necessary to confine the assay to the particular alkaloid desired, generally a very difficult matter. In Hydrastis, advantage is taken of the comparatively greater solubility of hydrastin in ether; in Opium, of the comparative insolubility of the morphin in this solvent. In Nux Vomica, the brucine is removed by oxidizing it with nitric acid.

Bio-44444 - Drugs which depend for their activity on neutral principles are often assayed in a chemic assay; there being no reliable chemic method for estimating the constituents of Aposyrum, Cannabis Indica, Convallaria, Digitalis, Ergot, Scilla, etc. Attempts have been made to supply this deficiency by physiologic standardization—estimating the strength of a preparation by comparing its effects on animals with those of a standard product. A just fatal dose is generally the best criterion for quantitative work. Individual differences of susceptibility and absorption in different animals can be largely eliminated by using an extensive series of animals. The expense and labor is scarcely warranted by the results, except in a very few cases, for instance with Digitalis. Qualitative physiologic tests of drugs of very uncertain activity, such as Cannabis Indica or Ergot, are more simple. The U.S.P. describes the most important bio-assays, but usually leaves their employment optional with the manufacturer.

CLASSES OF PHARMACEUTIC PREPARATIONS

The pharmaceuticals are grouped into certain definite classes, established by long usage, such as Waters, Spirits, Tinctures, Extracts, Pills, Plasters, Ointments, etc. The student should learn to distinguish clearly between these preparations, according to the definitions given below.
WATERY SOLUTIONS

These include the Waters, Liquors, Muclilages and Syrups. Their advantage lies in the fact that water is a cheap solvent of very wide applicability, itself devoid of any therapeutic property. In the case of substances which are insoluble in it, it can not of course be employed. The greatest drawback lies in the fact that watery solutions of organic substances tend to spoil rapidly by the development of bacteria and infusoria. Solutions of chemic substances are less subject to this change, as they do not furnish a pabulum, and are often themselves antiseptic.

Aqua, Waters (singular, Aqua; abbreviated, Aq.).—Clear aqueous solutions of volatile substances. Two very dissimilar classes of preparations come under this heading:

Aqua Aromaticæ, Aromatic Waters, U.S.P. (Flavored Waters).—Saturated solutions of volatile oils (Aqua Cinnamoni, etc.). These are alone included under Aqua in the B.P. They are prepared either by distilling the plant or oil with water (B.P.); or by triturating the oil with an absorbent substance (talc, etc.) until it is finely subdivided, and then extracting this with water.

The quantity of active substance in them is just large enough to give them a pleasant flavor without imparting to them any noticeable therapeutic properties. The absence of alcohol makes them good solvents for salts, which are generally insoluble in this liquid. Hence their main use is as a pleasant vehicle (a vehicle being the substance which serves for the conveyance of another substance).

The dose of flavoring waters is practically unlimited (15 c.c., 4 drams, U.S.F.); except Aqua Amygdalæ Amare, 4 c.c.

Waters, as a rule, do not keep well. Their keeping qualities may be improved by adding to them some of the oil of which they are solutions. This floats on the surface, and in this way excludes air and bacteria, and at the same time insures permanent saturation.

The second class of Waters (included under Liquores by the B.P.) are fairly strong solutions of gases (ammonia, etc.) prepared by passing the gas into water. Their doses are relatively small.

Liquores (Liquor, Liq.); Solutions.—Aqueous solutions of solid chemic salts or hydrates, made either by dissolving the pure salt directly in water by trituration or heat; or, more often, by chemic decomposition (simple and chemic solution). (The British Pharmacopeia includes solutions of gases under this heading.)

The advantage of the solutions consists mainly in the convenience of measuring the relatively large volumes of the solution against weighing the small quantity of salt. Water is chosen as the solvent because salts are but little soluble in alcohol, and because the therapeutic qualities of the latter are not desired.

Solutions, when used for special purposes, receive special names, thus: Injectiones (Hypodermice; Urethrales), Collyria (Eysewaters), Lotions (Washes), Gargarismæ (Gargles), etc.

Injectiones Hypodermicae (B.P.) (Inject. Hyp.).—These are watery solutions of active drugs, intended for subcutaneous administration, and of such strength as to be used in the dosage of 0.3 to 0.6 c.c., 5 to 10 minims. They are sometimes preserved sterile by the addition of phenol or salicylic acid. Manufacturers also market a variety of unofficial hypodermic solutions in aseptic ampouls, i.e., small sealed glass vials containing a single dose of the sterilized solutions.
Mucilages (Mucilage; Muc.); Mucilages.—Aqueous solutions of gummy substances. They are used as vehicles and demulcents. Since gums are insoluble in alcohol, mucilages are incompatible with this substance. They should be recently prepared because they are very apt to mold.

Mucilages are made by either hot or cold process: the former being solution by heat the latter by percolation. Heat should be used only when necessary (tragacanth), as it usually causes discoloration of the product.

Syrups (Syrupus; Syr.); Syrups.—Dense saccharine solutions of medicinal substances. The syrup serves mainly as a vehicle and preservative. The dose of flavoring syrups is practically unlimited (15 c.c., 4 drams, U.S.P.).

Simple syrup is a practically saturated solution of cane-sugar, containing 85 Gm. in 100 c.c., U.S.P. (66.7 Gm. of sugar in 100 Gm. of syrup, B.P.). Syrups are usually prepared by first making an infusion, and dissolving in this the sugar, either by heat or percolation, according to whether or not the drug is injured by a high temperature. In special cases modifications may be introduced. Some syrups are prepared by mixing the juice extract and syrup. Honey is sometimes used instead of cane-sugar, making a class of preparations called melitids. If acetic acid is added to this, we have ozymelitids. Confections (Confectio; Conf.) are thick medicated jams. They were formerly very popular, but have now been almost abandoned. Electuaries were similar but somewhat thinner preparations.

Elixirs (Elixir; Elix.); Elixirs.—Sweetened aromatic alcoholic liqueurs, used as flavoring vehicles, similarly to the syrups. Their content in alcohol (about 25 per cent.) is apt to lead to abuses, which must be kept in mind.

The official Aromatic Elixir is flavored with orange peel, lemon, coriander and anise. This, mixed with licorice, constitutes Elixir Adjuvans. Glycerites (Glycerium, U.S.P.; Glycerinum, B.P.; Glycerinum).—Solutions in glycerin. Glycerin is a good solvent for many substances. It keeps well, and is useful especially for external application on account of its adheriveness. Glycerin is also less irritant than alcohol and devoid of the pharmacologic action of the latter agent.

ALCOHOLIC SOLUTIONS

Alcohol is a specific solvent of certain substances (volatile oils, alkaloids, resins). In prescribing, these should not be mixed with an aqueous solution. Alcohol is also a good preservative; but it has distinct therapeutic qualities, which may or may not be useful.

Spirits (Spiritus, genitive Spiritus; Sp.).—Alcoholic solutions of volatile drugs. They are all fairly strong. They are prepared by simple or chemic solution or by distillation. Flavoring spirits contain 10 per cent. of the respective volatile oils. Their dosage is 1 to 2 c.c., 15 to 30 minims. Spirits other than flavoring vary in strength and dose.

PREPARATIONS MADE BY EXTRACTION

In these, only a part of the crude drug is dissolved. They comprise the aqueous Infusions and Decotions; and the alcoholic Tinctures and Fluid and Solid Extracts.

Infusions (Infusum; Inf.).—Aqueous solutions of the soluble principles of vegetable drugs, obtained by brief maceration in hot or cold water,
Decoctions (Decoccum; Dec.)—Analogous preparations, in which the ingredients have been boiled with water for at least fifteen minutes.

Infusions and decoctions are especially useful when it is wished to extract some principle which is more soluble in water, or when the therapeutic effect of alcohol or the mechanical incompatibility of alcohol with salts is to be avoided. There are some inconveniences connected with their use: They take some time to prepare. Like all watery solutions, they spoil quickly, and must, therefore, be made fresh. The decoction can only be used if there are no delicate constituents to be destroyed by boiling.

The solvent being so very cheap and having no action, it is usual to make decoctions considerably weaker than tinctures. In prescribing infusions or decoctions of potent drugs, the proportion should always be stated by the prescriber. When the strength is not stated, the pharmacist is supposed to use 5 per cent. of the drug. The dose of non-poisonous infusions and decoctions lies between 15 and 120 c.c. (3/4 to 4 ounces).

Type Formulas (U.S.P.).—Infusia.—1,000 c.c. of boiling water are poured on 50 Gm. of the coarsely comminuted drug, the vessel is covered tightly, and allowed to stand for half an hour in a warm place. It is then strained with expression, and enough water is poured through the strainer to make the infusion measure 2,000 c.c.

Decocia.—50 Gm. of the coarsely comminuted drug and 1,000 c.c. of cold water are boiled in a covered vessel for fifteen minutes, cooled to about 40° C., strained and expressed, and cold water added through the strainer to make the decoction measure 1,000 c.c.

Preservatives.—The amount of preservative must be added to a watery solution to insure its keeping qualities varies with its nature, and in the same direction as the amount of "extractive." The proportions generally necessary are: Alcohol, 20 to 25 per cent.; glycerin, 10 per cent.; sugar, 66 Gm. to 100 c.c. of finished product.

A bibliography of the deterioration of drugs and pharmaceutical products is given by Eberhardt and Eldred, 1914.

Tinctures (Tinctura; Tr.).—Alcoholic or partly alcoholic solutions of the useful constituents of such drugs as are not wholly soluble in the menstruum.

Exceptions of this definition are tincture of iodin, tincture of chlorid of iron, and tincture of tars, in which the solution is complete.

The drug-strength of the tinctures varies from 0.4 to 50 per cent.; but those containing potent drugs conform to an international standard of 10 per cent.

The tinctures are in many respects the most useful therapeutic preparations: The dose is relatively large and uniform (about 2 to 4 c.c. for the non-toxic); the quantity of solvent is sufficiently large to keep the principles in solution; the use of heat in the preparation is avoided.

The greater number of tinctures are prepared by percolation; a few by maceration. The menstruum is alcohol or alcohol and water; acetic acid or glycerin are added in a few cases; aromatic spirit of ammonia is used in the ammoniated tinctures.

Type-process for Percolation Tinctures (U.S.P.).—The powdered drug is moistened with the menstruum, transferred to a percolator without pressing, and allowed to stand covered for six hours. It is then packed firmly, and menstruum poured on to more than cover the powder. When the liquid begins to drop, the lower orifice of the percolator is closed, and the maceration prolonged for twenty-four hours. The percolation is then allowed to proceed slowly, gradually adding sufficient menstruum to the percolator until the percolate measures the required volume.
Type-process for Maceration Tinctures (U.S.P.).—The drug is macerated in a moderately warm place with the menstruum, using four-fifths of the final volume. This is continued, with frequent shaking, for at least three days. It is then filtered, the filter being washed with menstruum sufficient to make the required volume.

Dissolved tinctures are tinctures from which the tannin has been removed (as by powdered skin). They do not precipitate with iron salts.

Ethereal tinctures are made with etherial spirit, a mixture of 7 parts of ether and 3 parts of alcohol.

Green Tinctures.—Since some drugs are supposed to lose part of their activity by drying and keeping, a class of tinctures made from the freshly collected green drugs has been introduced under the name of Tinctura Herbium Recensium. The directions are to macerate 500 Gm. of the fresh herb with 1,000 c.c. of alcohol for fourteen days, to express and filter. These preparations are justly unpopular. They are of very moderate efficacy, since the natural moisture of the plant is variable. Again, they can be prepared only in the localities where the plants are native and where there often are no reliable facilities for their manufacture. These remarks apply equally to the Juice (Succus; Succ.) of the British Pharmacopoeia, made by using 1 part alcohol and 3 parts of the freshly expressed juice.

Wines (Vinum; Vin.).—These are tinctures in which wines have been substituted for alcohol. They have a more pleasant taste, but inferior keeping qualities, and are very little used.

Ecto (Ect.) are medicated vinegars, prepared by maceration with dilute acetic acid.

Fluidextracts, U.S.P.; Liquid Extracts, B.P. (Fluidextractum; Fidect. — Extractum Liquidum; Ext. Liqu.).—These are liquid alcoholic extracts, 100 c.c. representing approximately 100 Gm. of the drug. The menstruum is in certain cases modified by the addition of glycerin, acetic acid, etc. They are the most concentrated fluid preparations, and were supposed to possess considerable advantages, but many are of doubtful value.

The simple ratio of drug-strength has no special advantage in therapeutics, and has led to serious abuses such as the practice of preparing tinctures, infusions, etc., by the dilution of the fluidextracts. This is highly reprehensible, since these dilutions often differ materially from the orthodox preparations.

Concentration may sometimes be desirable to reduce the bulk of the dose, but it is often secured at the cost of efficiency. The heat which must necessarily be used in their preparation is never beneficial. Precipitates are apt to form on standing, and while these are often inactive, they may contain the active principles. They are also much more subject to precipitation on mixture with other liquids, and the dose is usually so small that they require some such admixture.

Fluidextracts are usually prepared by percolation, the first four-fifths of the percolate being set aside, the remainder evaporated to the consistency of a soft extract, dissolved in the reserved portion, and menstruum added to make the required volume.

Type-processes for Fluidextracts.—The following are described by the U.S.P.:

Type A.—The powdered drug is moistened and macerated with the menstruum as described under tinctures, the maceration being prolonged to forty-eight hours. The percolation is then started, and continued by the addition of menstruum, until 850 c.c. of percolate have been collected for 1,000 Gm. of drug. This is reserved and percolation continued, with additional menstruum, until the drug is exhausted. These later percolates are evaporated to a soft extract, below 60°C., dissolved in the reserved portion, and diluted with menstruum to make 1,000 c.c.

Type B.—This is employed when two successive menstrua are used, the first containing glycerin, acid, etc. In this case, the powdered drug is moistened and macerated with the first menstruum. The percolation is then started, and continued with the plain alcoholic menstruum. Otherwise, the process is identical with Type A.

Type C.—Fractional or Divided Percolation.—This is used for drugs containing constituents that are volatile or injured by heat. It may also be used in place of Type A. The drug is divided into three portions of 500 Gm., 100 Gm. and 200 Gm. The first portion is then moistened and macerated, as usual. The first 200 c.c. of percolate are
reserved; and the percolation then continued, collecting five additional portions of 300 c.c. each.

The second 300 Gm. portion of drug is moistened with the first 300 c.c. percolate of the preceding percolation; and macerated and percolated, as usual. The first 300 c.c. of percolate are reserved; and the percolation continued with the successive portions of the percolate from the first drug, until exhausted. These weaker percolates are collected in 300 c.c. portions.

The third 300 Gm. portion of the drug is moistened with the first 200 c.c. percolate of the second drug, macerated and percolated with the successive weak portions of the percolate of the second drug, until 300 c.c. are obtained. This is mixed with the reserve portions of the two first drugs.

Type D.—In this, the drugs are exhausted with water and preserved by the subsequent addition of alcohol. 1,000 Gm. of the ground drugs are mixed with 5,000 c.c. of boiling water and macerated for two hours. They are then transferred to a percolator, gradually adding boiling water until the drug is practically exhausted. The percolate is evaporated on a water-bath to the specified volume. It is then cooled, and sufficient alcohol added to make 1,000 c.c.

Solid Extracts (Extractum; Ext., U.S.P. Extractum Siccum; Ext. Sicc.; B.P.).—Must not be confused with the fluidextracts. They are solid or semisolid preparations obtained by evaporation of solutions of the medicinal principles of drugs. Some of the solid extracts are dry, others of a "pulular" consistency, i.e., like a pill-mass. They are convenient for administration in solid form, e.g., in pills, ointments, plasters, etc. Nearly all the potent, and most of the other, extracts are adjusted to four times the strength of the fluidextracts.

"Powdered Extracts" are dried, and mixed with sufficient diluent (milk-sugar) to give them the same strength as the solid extracts. Most extracts are prepared by percolating and subsequent evaporation; the last and weaker portions of the percolate being evaporated first, to avoid the deleterious actions of prolonged heat on the main portion. Some of the extracts are obtained by evaporating the fluidextract. The menstruum is sometimes water, or alcohol, or a mixture of both; acetic acid being added in some cases. The finished product is assayed, if possible, and adjusted to a definite standard by the addition of sugar of milk.

Artificial resins are precipitates obtained by mixing alcoholic solutions with water. Where they constitute the active principle, this is a convenient method of isolating it in a concentrated although somewhat impure form. Their strength is fairly constant. They are practically identical with the eclectic "resinoids."

Oleoresins (Oleoresina, Oleores), are extracts containing the resinous and oily constituents of the drug; obtained by evaporating ethereal, acetone or alcoholic percolates.

MIXTURES

Mixtures, in the wider meaning of the word, are fluids resulting from the mixture of fluids with other fluids or with solids. They comprise: Liniments, Mistures, Emulsia.

Liniments (Linimentum, Lin.).—These are solutions of irritant drugs in oily, soapy or alcoholic vehicles, intended to be rubbed on the skin as counterirritants.

Mixtures (Mistura; Mist.).—In the narrow meaning of the term, these are generally suspensions of a solid in a liquid, sometimes by the use of a gummy substance; for heavy powders can not be evenly distributed in a light liquid without this aid. The B.P. also includes some emulsions under this title.
Emulsions (Emulsion; Emul.).—These are mixtures of a milky appearance, made by suspending fats, oils, or resinous substances in aqueous liquids by the intervention of some viscid, usually gummy, substance.

The object of emulsification is to break up the insoluble oil into very fine particles and to envelop each of these in a coating of the emulsifying agent, which will keep them from reuniting. This allows of dilution, of the admixture of other substances, and it facilitates absorption.

Milk is a natural emulsion in which the butter-fat is kept suspended by the casein. It may be taken as a type to which artificial emulsions must conform. The globules must be uniform and of about the same size as those in milk.

Emulsions may be divided into the following classes:

- **Natural emulsions**, such as are found ready formed in nature. Instances of these are milk, the yolk of egg, and some plant juices.
- **Gum-resin and seed emulsions**; that is, emulsions made from such substances as contain their own emulsifier. Examples of such gum-resins are ammoniac, asafetida, and cypress. The drugs are reduced to a coarse powder and water is added gradually. Seeds which yield such emulsions are poppy, hemp, and almond.

In artificial emulsions an emulsifier must be added. A variety of substances may be used for this purpose, especially gum acacia, tragacanth, yolk of egg, Irish moss, soap bark, and extract of mallow. The substance most commonly employed is gum acacia. This emulsifier is incompatible with large quantities of alcohol, borax, tincture of iron, or glicerine. It may be used by either the Continental method, where a nucleus is first formed from gum, oil, and water, and to which the remainder of the water may then be added; or by the English method, where a mucilage is first made, to which the oil and water are added in alternate small portions.

The Continental method deserves the preference. To form a nucleus there should be used for each part of oil 1/4 to 1/3 part of acacia and 1 part of water. Stir the oil with the acacia in granular powder, then add the water at once. The mixture of the oil and the gum must not be allowed to stand too long before adding the water, otherwise it will separate. In the English method the acacia, the amount of which should be half that of the oil, is rubbed up with an equal volume of water and then small portions of oil and water are added alternately. If this addition should be done too rapidly, there is danger that the emulsion will separate or "crack." This does not necessarily spoil it, for it may be re-emulsified by adding it to a fresh portion of acacia and repeating the process.

In making medicated emulsions the ingredients should be mixed in the following order: First the nucleus, then the flavoring, then the syrup, and, lastly, the water in which the solids have been dissolved.

In yolk emulsions, the yolk of egg is used in place of the nucleus in the Continental method. The yolk is triturated in a mortar and the oil and water are added alternately in small portions. One yolk suffices for from 1 to 2 ounces of oil. The yolk emulsions are incompatible with the same substances as gum emulsions and do not keep nearly as well.

Soap bark has saponin for its emulsifying agent. It is not incompatible with any of the above-named substances, but possesses very decided therapeutic properties, which preclude its use in many cases. It is used in the proportion of 1 part of the tincture to 8 parts of the oil. Place the tincture in a dry bottle, add the oil in portions, and shake after each addition. Finally add the water. Crude saponin (0.5 to 1 of oil) can also be employed.

Extract of malt emulsifies its own weight of oil. It is used as the nucleus in the Continental method.

Solutions of alkalis may also be used for emulsification, since they form soaps, but they are usually not desirable.

---

SOLID PREPARATIONS

These comprise the Powders and the various dosage forms, PILLS, etc., for internal use; and Ointments, Plasters, for external applications. Powders (Pulvis; Pulus, Gen., Pulveris) are finely powdered drugs intended for either external or internal administration.

When intended for internal use, they are generally folded in papers (chartula; chartil). It must be borne in mind that hygroscopic (deliquescent) substances, such as potassium acetate or citrate, can not be prescribed as powders, nor such substances as become a fluid when mixed (e.g., camphor and chloral).

In making compound powders, one should begin with the smallest ingredient and add the others in the order of their amount, triturating thoroughly after each addition. In dividing the powder, it is not always necessary to weigh out each powder. The object is often accomplished with sufficient accuracy by flattening the powder on a piece of paper, squaring off the edges, and dividing into a number of equal parts by means of a spatula. In the case of more bulky powders, such as Seidlitz powders, measures are used.

When intended for external use, as for dusting powders, extreme fineness is the main desideratum. They should in this case be mixed with a spatula and not in a mortar, since the former insures greater smoothness.

Triturations (Trituratio; Trit.).—These are powders obtained by triturating the active substances with some inert material such as sugar of milk. Their advantage lies in the greater ease in weighing out a comparatively large amount of substance. When no special directions are given, triturations are made of a strength of 10 per cent. The triturations of elaterin is the only one official.

Etereosacchara are triturations of volatile oils with sugar in the proportion of 1:30. They are used for the purpose of flavoring other powders.

Effervescent (Ef.) Salts.—These are dried salts, mixed with sodium bicarbonate and tartaric acid, etc., so as to evolve carbonic acid when they are dissolved in water. This aids in disguising the taste.

DOSE FORMS

Pills, capsules, tablets, lozenges, cachets, etc., are used to divide the drug into definite doses, to avoid the inconveniences of dry powders, and to reduce the bulk. Care must be used in prescribing the dosage forms so as not to make them too large to be swallowed.

The administration of drugs in compact solid form delays solution and absorption. This is especially true of old pills, in which the excipient may become so impervious that they pass unchanged into the feces; but it applies also to many tablets. A mere delay in solution may be an advantage if an intestinal action is to be procured; but difficulty soluble substances (salol, bismuth, etc.) should not be administered in these compact forms. Corrosive substances are also unsuited for solid administration.

Pills (Pilula; Pil., U.S.P.).—These are defined as spherical or elongated masses of medicinal substances, of such size as to be convenient for swallowing; that is to say, containing up to 5 gr. (0.35 Gm.) of active substance. If the pill is of larger size, it is called a bolus. Very small coated pills are spoken of as granules. The quantity of drug in the official pills is adjusted so as to make the average dose two pills.

Pill-Masses (Massa; Mass., U.S.P. Pilula; Pil., B.P.).—These are soft solid preparations of such consistency that they can be formed into pills. A pill consists of the active ingredient and of the excipient (cohesive).

In order to make pills, the substance is first made into a mass by means
of this excipient. The mass must be sufficiently soft to admit of molding, but on the other hand it should be sufficiently consistent not to lose its shape. It should neither harden nor soften nor crumble on keeping.

The quantity of drug in the B.P. pills is adjusted so as to make their dose, with few exceptions, 0.25 to 0.5 Grm. 5 to 8 gr. (The exceptions are Pl. Phosphor; Pl. Ferr.; Pl. Plumbi c. Opio; Pl. Saponis Co.).

Excipients.—Syrup, glycerin, acacia, vegetable extracts (Extr. Gentiane), and a great variety of other substances are used, according to the characters of the active drug. The choice may usually be left to the pharmacist.

Modi Excipients.—Glycerite of acacia or tragacanth, thick flour paste, glycerin, syrup, confections, or extracts.

Modi Excipientis.—Acacia, tragacanth, starch, album, licorice powder, soap.

For chemicals which are destroyed by organic substances the best excipient is formed by a mixture of petrolatum and kaolin.

Absorption Influenced by Excipients.—These, being coloidal, all delay absorption somewhat. For iodid pills, Rieben, 1907, found the greatest delay with waxy and oily excipients, the least with vegetable extracts and syrups. Silver-foil coating produced considerable delay.

Preparation of Pills.—The ingredients are first triturated to a fine powder. In case crystalline salts are used, these must be desiccated. The excipient is then added in small portions and thoroughly triturated with the powder until the proper consistency is obtained. If accidentally too much excipient is added this can be remedied by the addition of some inert powder, such as starch, gum acacia, or powdered licorice.

The mass having been formed by thorough trituration, it is placed on a glass or porcelain slab marked with equal divisions. It is well to put a little dusting-powder on the slab to prevent the mass from sticking to it. The best dusting-powders are starch, hycopodium, or licorice, according to the color of the pill-mass. This mass is then rolled out by means of a broad spatula into a cylinder of uniform diameter, and this is cut with a sharp knife into the requisite number of equal parts. These are formed into spherical shape by rolling them between the thumb and the first two fingers. The pill may be rendered more perfect by placing the pills with a liberal amount of dusting-powder in the lid of the pill box and gently rolling them with the ball of the thumb.

Pill-coatings.—Pills are often coated with sugar, gelatin, chocolate, etc., to disguise their taste while being swallowed. The coatings tend to interfere somewhat with absorption.

In coating with sugar, the pills are moistened with a thick syrup and rapidly rotated and dried in a current of warm air until they acquire a sufficiently thick coating and a fine polish. The latter is often enhanced by a little wax. For a gelatin coating they are dipped into a strong hot solution of gelatin, which is allowed to harden in the air. When it is desired to exclude the air from the pills, they are sometimes varnished by dipping them into an ethereal solution of tolu. This is the official process for keeping phosphorous pills. A still finer polish may be given to pills by coating them with silver nit, which is done by shaking them in a box with silver foil.

Enteric Pills.—These are pills coated with some substance (keratin, salol, stearic acid, or formaldehyde-hardened gelatin), supposed to protect them from the gastric juice, but which dissolves in the intestines. They would be useful when the drug is intended to act only after passing the stomach. Unfortunately, they fail to accomplish their purpose, for soluble drugs diffuse through them rapidly (Lmosser, 1912).

Improved directions for the salol-coating of pills are given by Peacock, 1915; for stearic acid by Toplis, 1915. The latter claims that the stearic coating apparently fulfills its purpose.

Keratin (a protein derived from horn, goose, quill, etc.) was tried extensively; but it is not recommended, since commercial specimens are largely soluble in artificial gastric juice (Packner, 1917).
FORMALDEHYDISED CAPSULES.—These are prepared by immersing the filled capsules in water containing 1 per cent. of absolute formaldehyde, and drying. The capsules should become insoluble in acid-pepsin solution, but remain soluble in 0.5 per cent. sodium carbonate. The degree of insolubility is governed by the duration of the immersion. If they are to be used on the next day, the immersion should last six minutes; but these will have become quite insoluble in the carbonate after they have been kept a week. With immersion of thirty seconds, the capsules will be properly hardened only after storing them for two weeks; but they will preserve their proper solubility in carbonate for one year (Scoville, 1915).

CAPSULES.—These are small containers, usually of gelatin, intended to be filled with the drug and swallowed. Those used for powders are hard, and consist of a body and a cap. In filling these capsules, the powder is divided into the requisite number of parts, forced into the body with a spatula, and the caps placed on. Soft capsules are used for oils, etc. These are sealed with a drop of melted gelatin. These soft capsules may be made to hold as much as 4 Gm. Hard capsules should not hold more than 0.3 Gm. or at most 0.5 Gm. A somewhat larger amount may be used by making the powder into a pill-mass. The purpose of capsules is to disguise the taste of the substance.

CAPACITY OF CAPSULES FOR DRY POWDERS.—The capsules are marketed by numbers, which have about the following average capacity (Caldwell, 1913); probably differing somewhat, however, for the various makes:

<table>
<thead>
<tr>
<th>Size of capsules</th>
<th>Capacity in minims</th>
<th>Average capacity for most powders</th>
</tr>
</thead>
<tbody>

</table>

Parkes, Davis & Co. state the capacity of their capsules as: No. 0, 12 minims; No. 1, 9 minims; No. 2, 6 minims; No. 3, 4.75 minims; No. 4, 3 minims; No. 5, 2 minims.

PILL-MASSES IN CAPSULES.—Capsules can be made to hold larger quantities of powders when these are made into pill-masses. A wax-mass may be used for solidifying creosote or volatile or fixed oils, so as to make them suitable for capsules. Such a mass may be prepared by mixing 3 parts of castor oil with 1 part of melted beeswax (N. S. Davis, 1910).

WAFFERS are thin sheets formed of a dried flour-paste, in which the powder is enveloped. They are immersed in water and swallowed. They possess the advantage that larger quantities of the drug (up to 2 Gm.) may be administered.

CACHETS are wafers, molded into concave circular forms.

TROCHES OR LOZENGES (TROCHICUS, TROCH.).—These are made by punching or cutting out circular or oblong disks from a mass made up from the active substance, sugar, and mucilage or fruit base. They are then dried in the air. They are usually intended for solution in the mouth, especially for throat medication.

TABLETS (TABELLA, TAB.).—These are small disks composed of medicated powders. Tablet triturates are prepared from the powdered drug and milk-sugar or sugar, made into a paste with alcohol, and pressed into molds. Compressed tablets are formed by strong dry compression. These forms are used similarly to pills, and dissolve more readily, especially the triturates. By suitable choice of ingredients, they may be made very ac-
PHARMACEUTIC PREPARATIONS

Acceptable to children (Tabella Dulces, "Candy medication" Fantus, 1912-1914).

Variability of Commercial Tablets.—Commercial tablets are often unreliable. Variations of 10 per cent. may be excusable, but Kebler, 1914, found that nearly a fifth of the samples bought varied by 20 per cent. or more; and this even with toxic substances.

Hyopdermic tablets are similar to the tablet triturates, especial care being exercised to secure quick solution.

Lamelle (B. P.) (Lam.) are thin gelatin disks, softened with glycerin, and impregnated with substances acting on the pupil. They are intended to be placed under the epi-

Suppositories (Suppositorium, Supp.).—These are suitably shaped masses of solid, medicated usually fatty substances, intended for introduction into the rectum, vagina, or urethra (Fig. 2). They take the place of ointments for local treatment where these can not be readily applied.

![Fig. 2.—Different forms of suppositories (R. Blair). Natural size. The largest is for use in the vagina; the cylinder is a urethral suppository or bougie; the others are various shapes and sizes of rectal suppositories.](image)

Suppositories are made by incorporating the medicinal substance into a suitable base, and molding into masses of suitable shape and size. The ideal base is one which, whilst solid at the ordinary temperature, is melted by the heat of the body. Such is cacao-butter (Oleum Theobromat). Glycerinated gelatin or a soapy base is also sometimes used, especially with urethral suppositories for which cacao-butter would be too brittle. Rectal suppositories are usually made with sufficient base to weigh 1 or 2 Gm.; vaginal, 4 Gm.

Urethral suppositories are pencil-shaped, pointed at one end, and measure 7 or 14 cm., weighing 2 or 4 Gm.

Theobroma suppositories are made either by the hot or cold process. The hot process consists in melting cacao-butter at a temperature not exceeding 45° F. and adding the active substances, then pouring the mixture into cold molds. In the cold process the active substances are triturated with grated cacao-butter with the addition of a small amount of castor-oil, sufficient to make it into a suitable mass, which is then rolled out and divided as for pills. They may also be formed by pressure.
**Suppository capsular,** whether of gelatin or of cocoa-butter, largely defeat the object for which suppositories are employed. They are, however, more convenient to prepare than the suppositories, and may suffice when the object is merely internal medication. **Glycerine** is made into a suppository by means of a very hard soap formed from stearic acid and sodium carbonate.

**Ointments** (*Unguentum, Ung.*) are soft fatty masses intended for external application. They consist of the active ingredient and the base.

Ointments are prepared by fusion, mechanical admixture, or chemic reaction. In mixing ointments by fusion, that constituent of the ointment which has the highest melting-point is first melted, and the others are then added in the order of their melting-points. The active substance is added last, to obviate the prolonged action of heat upon it. The mechanical admixture is usually done on a slab or in a mortar. It is needless to say that powders must be in the finest stage of subdivision. If the quantity of powder is large, it is usually first mixed with some of the melted ointment.

**Ointment Bases.**—The base of ointments is formed by lard, by petrolatum, by wool-fat (lanolin) or by various mixtures, such as the "simple ointment," consisting of 4 parts of lard and 1 part of white wax. The choice of the base depends on the object for which the ointment is employed, whether absorption, protection, or local action is desired. **Petrolatum** (vaselinum), which consists of the less volatile parts of petroleum, is simply protective, or useful as a vehicle for substances intended to have a mere local action, since it is not absorbed. **Lanolin** (Adexam Lane Hydrosus) consists of a mixture of cholesterol-like substances obtained from sheep's wool. It does not become rancid, and mixes with its own weight of water. This latter property is of advantage when it is desired to use crystalline salts in ointment form, since these can be incorporated in the form of solution, making a much smoother ointment. **Lard** is the cheapest ointment material; but it rapidly becomes rancid. This tendency can be diminished by the incorporation of antiseptic substances. Official Benzoated Lard is an attempt in this direction.

Emollient or soothing, and antiseptic ointments should not be absorbed, and are, therefore, best made with petrolatum. Stimulating and absorptive ointments are intended to penetrate, and therefore require lard or lanolin. With astringent ointments, the base should vary according to the intended depth of action (Corlett, 1910).

**Oleates** (*Oleum, Oleat.*)—These are solutions of metals or alkaloids in oleic acid. They are used similarly to ointments.

**Cerases** (*Ceratum, Cerat.*)—These are preparations similar to ointments but made of a firmer consistency by the addition of wax.

**Plasters** (*Emplastrum; Emp.*)—These are made by spreading on a thin cloth or leather support a mass or base which is hard at an ordinary temperature, but is softened and rendered adhesive at the temperature of the body. They are applied as adhesive or for counterirritation. A rubber composition is the base for most modern plasters.

Plasters are now usually obtained from manufacturers, and are but rarely made to order. The typical old plaster, had for its base diachylon, Burgundy pitch, or other resins. Diachylon is a lead soap made by precipitating soap with lead acetate. This alone, or with the addition of a little rubber and petrolatum forms the base of the other official plasters. The base is fused and the active ingredients incorporated into it by stirring.

To spread the plaster, the cloth, cut to the proper size and shape, is tacked on a board and the mass is heated and spread evenly with a trowel or spatula. A margin 5/8 in. wide must be left to allow of handling. To avoid the irritation resulting from the confinement of the secretions of the skin, plasters are now frequently made porous. Isinglass plaster is made by spreading a thick solution of isinglass on silk.

**Charte** are medicated papers, i.e., pieces of paper covered or impregnated with a medicinal substance. Charta Sinapis is used as a plaster, Charta Potassii Nitratis for fumigation.

**Colloodia** (*Colleodium, Colled.*)—Solutions of pyroxylin (gun-cotton) in a mixture of ether and alcohol, or in acetone. By the evaporation of the solvent they form a film on the skin, and thus act like plasters. Colloedia must not be brought near fire.
SOLUBILITIES

Poultries (Catalepsia, Catapl.).—These are used mainly for the purpose of supplying heat. Linseed poultice may be taken as a type: it is prepared by pouring a cup of linseed meal into 21/2 cups of boiling water, stirring constantly. The mush is spread thickly on a piece of flannel, folded so as to form a sack, and applied as hot as can be conveniently borne. Other pasty materials (flour, clay, etc.) are also used.

SOLUBILITIES

It is well to have a general idea of the solubility of the substances usually prescribed. The subjoined compilations will be found useful in this connection. A knowledge of analytic chemistry and of incompatibilities can be utilized here, for a substance appearing as a precipitate is, of course, relatively insoluble.

GENERAL SOLUBILITY OF COMMONLY USED SALTS IN WATER

I. Arranged by Acids.—

Group A: Salts Mostly Soluble.—

1. Acetates and Nitrites: all soluble (except bismuth subnitrate).
2. Halogen group (= iodids, bromids, and chlorids): Soluble, except Ag; Hg (ous); Pb; Bi.
3. Sulphates: Soluble, except Pb, Sr, Ba; Ca sparingly soluble.

Group B: Salts Mostly Insoluble.—

1. Arsenites
   Arsenates
   Carbonates
   Hydrates (Ca sparingly soluble)
   Oxides
   Oxalates
   Borates
   Phosphates

   Insoluble, except those of alkali metals.

II. Arranged by Base.—

The salts considered in this table are: Acetates (Ac). Halogens (H), Oxids (O), Sulphates (SO₄), Phosphates (PO₄), Oxalates (Ox), Carbonates (CO₃), Sulphids (S), Nitrites (NO₂), Citrates (Ci). Hydrates agree with oxids.

Those of the above salts which are not mentioned with the respective base are insoluble.

2. Lithium: Soluble, except O and CO₃, sparingly soluble, and PO₄, insoluble.
3. Mg, Al: Soluble: NO₃, Ac, H, Cl, SO₄, S.
4. Ca, Ba, Sr: Soluble: NO₃, Ac, H, Cl, S; sparingly: O.
5. Zn, Mn, Ni, Co, Fe | Soluble: NO₃, H, Cl, SO₄ (mercuric iodid H₄[ic.] Cu, Sn)
   H₄[ic.] Cu, Sn is insoluble.
6. Ag: Soluble: NO₃, SO₄.
7. Pb: Soluble: NO₃, Ac.
8. Bi, Sb: Only soluble in form of double organic salts, e.g., Bismuth and Ammonium Citrate; Antimony and Potassium Tartrate.
Strength of Watery Solution, in which commonly used salts may safely be prescribed. (It must be remembered that where several salts are prescribed in the same mixture, the solubility of each is apt to be lowered.)

The following table gives the amount of very commonly used drugs which can be safely prescribed in water enough to make 100 c.c. These should be memorized:

50 per cent., or grams: \( \text{=} \frac{3}{4} \text{iv in water q.s. 3} \text{j} \) Tannin; Antipyrin; Acetate, Citrate, Salicylate, Iodid or Bromid of Potassium or Sodium; AgNO₃; ZnSO₄; Chloral Cocain Hydrochlorid.

5 per cent., or grams: \( \text{=} 25 \text{ grains in water q.s. 3} \text{j} \) Alum; Carbolic Acid; Borax; KClO₃; NaHCO₃; HgCl₂; Tartar Emetic; Potassium Bisulphate; Citrated Caffein; the majority of the soluble salts of alkalies, earths, and metals.

(b) Smaller Quantities:\n
Boric Acid, 4; Morphin Sulphate, 4.5; Quinin

4 to 0.1 per cent.

Hydrochlorid, 3; Quinin Sulphate, 0.13; Strychnin Sulphate, 2.

Solubility in Different Media.—As a general rule, inorganic substances are more soluble in water than in alcohol.

Basic alkaloids are insoluble in water, more soluble in alcohol. Alkaloidal salts are soluble in either alcohol or water. Gums are soluble in water, insoluble in alcohol. Resins and essential oils are the reverse.

(In making mixtures, it must be remembered that spirits, tinctures, and fluidextracts all contain alcohol.)

Glycerin stands intermediate between alcohol and water as a solvent. The following substances are: Much more soluble in glycerin than in water; Boric acid, alum, phenol, mercuric chloride.

Terms Used in Defining Solubility.—The following terms (Wilbert, 1909) are employed in "Useful Drugs" to describe the approximate solubility, which is often sufficient for prescribing. Substances that are soluble in less than 1 part of solvent = very soluble. From 1 to 10 parts of solvent = freely soluble. From 10 to 100 parts of solvent = soluble. From 100 to 1,000 parts of solvent = slightly soluble. From 1,000 to 10,000 parts of solvent = very slightly soluble. From 10,000 to 100,000 parts of solvent = nearly insoluble. More than 100,000 parts of solvent = practically insoluble.

Official Solubilities.—The U.S.P. and B.P. state the solubility of articles, as grams of substance to cubic centimeters of solvent; i.e., a solubility of 1:10 means that 1 Gm. of substance requires 10 c.c. of solvent for solution, at the standard room temperature, 35°C., 77°F., U.S.P.; 15.5°C., 60°F., B.P. The standards given in this book are those of the U.S.P. In percentage solutions, 10 per cent. signifies that 100 c.c. of solution contain 10 Gm. or c.c. of the substance.

**Incompatibility**

This is a subject usually very confusing to the student, since it consists of what appears at first sight a vast array of details. However, it rests only upon an application of the ordinary chemic reactions, and when the latter have been mastered, the subject is comparatively easy and simple. It may be laid down as a general rule that substances are incompatible if they are used in testing for each other or if they form antidoes.
Incompatibility

In the following compilation it has been attempted to arrange the incompatibilities into general groups.

In this generalization, it is not feasible to take account of individual exceptions. Care has been taken to err on the safe side. It is much more important for the physician to remember that mercuric chloride is generally incompatible with alkaloids, than it is to know that it may be prescribed with some.

Definitions.—Incompatibility is said to exist when the constituents of a mixture interfere with one another in a way not intended by the prescriber.

If an interference is intentional, it is called an intentional incompatibility. If a chemical change occurs, the incompatibility is called chemical.

When it consists in a precipitation of the substance by a change in the solvent, or when a chemic incompatibility does not interfere with the active substance, but produces an unsightly appearance, the incompatibility is pharmacologic.

If the interference is with the solubility, or if liquefaction or deliquesence occurs, the incompatibility is mechanic.

When without causing any chemic changes it interferes with the physiologic action of the ingredients, it is therapeutic.

Chemical Incompatibility.—This may result in explosion, precipitation, or the production of new substances with undesired properties.

Explosives.—Powerful oxidizing agents are apt to explode when mixed in concentrated form with easily oxidizable substances.

The most important oxidizing agents are: chronic acid; concentrated nitric acid and nitrates; permanganates; chlorates; peroxides.

The most important oxidizable substances are: All organic substances; Sulphur, sulphides, sulphites, and hyposulphites; Iodin and iodides; Phosphorus, phosphites, and hypophosphites; Reduced iron.

Explosions may also result from mixing iodin with ammonia or turpentine; and chlorine with ammonium chloride.

Explosions occur only when the substances are dry or at least concentrated, and when they are heated or perciused.

Dilute solutions may be mixed without danger if not heated. Glycerin, phenol, and in some cases alcohol, behave like dry solids.

Permanganate of potash or chronic acid or nitrate of silver decompose organic substances even in solution, but in this case without explosion.

Poudres may be mixed without concussion, but even this should be avoided, since conditions favorable to explosion may arise after they leave the hands of the dispenser.

Pills containing these easily decomposed substances are best made with inorganic excipient (clay and vaselin).

Substances containing loosely combined oxygen may explode on concussion or heating when no reducing substances have been added; this is due to their containing dust or other organic matter. They should therefore be handled with care.

Gradual Evolution of Gas.—This occurs especially on mixing acids with carbonates or sulphids; also when mixing strong acids with alcohols (= esters), or with chloride (= Cl); also on mixing strong HCl and HNO3. Formaldehyde effervesces copiously with oxidizing substances, even in solution (hydrogen peroxide).

Incompatibility by Precipitation.—Alkalies precipitate earths, metals and alkaloids from their salts. Under alkalies may be included oxides, hydroxides, carbonates, phosphates, borates, arsenates and arsenicites.

Chlorides, bromids and iodids precipitate salts of Ag, Pb, and some alkaloids. Iodid also precipitates mercuric salts, redissolving in an excess.

Sulphates precipitate Pb, Ca and the other earthy metals, except Mg.
**Manual of Pharmacology**

**Salicylates, phenol and tannin** precipitate or color iron salts. Tannin also precipitates most other metals, alkaloids, and some glucosides and neutral principles. Salicylates precipitate quinin.

**Salts of metals** are precipitated by alkalies, sulphids, tannin and proteins. They precipitate some alkaloids and acacia. **Mercuric salts** are often incompatible with other metals. **Silver and lead salts** are precipitated by chlorids, bromids, and iodids. **Stibir salts** are also incompatible with organic substances. **Iron salts** are colored by tannin, salicylate and phenol.

**Calcium salts** are precipitated by alkalies, phosphates and sulphates; **Magnesium salts** by alkalies and phosphates.

**Alkaloidal salts** and synthetic bases (antiyprin, etc.) are precipitated by alkalies, tannin, iodin, potassium-mercuric iodid, and some by iodids or metallic salts.

**Acacia** is precipitated by alcohol, borax, Tr. Ferri Chlor.

**Production of Substances with Undesired Qualities.**—**Iodids** liberate iodin on the addition of acid and oxidizing agents, including H₂O₂, nitrates, salicylic acid, etc. They oxidize mercurous to the dangerous mercuric salts.

**Chlorates** liberate chloride with concentrated acids.

**Chloral** liberates chloroform with alkalies.

**Glucosids** (f.i., glycyrrhizin) are destroyed by acids.

**Pharmaceutical Incompatibilities.**—**Alcohol** should not be added to:

- Acacia, gelatin, proteins, emulsions, strong salt solutions.
- **Water** should not be added to:
- Alcoholic liquids in general (such as tinctures, spirits, fluidextracts, with some exceptions); or to ethereal liquids (oleoresins), or oils.
- **Phenol** should not be mixed with colloidion.
- **Liquefaction** occurs when chloral is rubbed with camphor, menthol, phenol, salol, etc. Any of these, when rubbed together, or with coal-tar antipyremics, are apt to liquefy.

**Especially Incompatible Drugs.**—The following are most likely to give incompatibilities, and any combinations should therefore be scrutinized with special care: Acids, alkalies and carbonates; permanganates; iodids. Mercury, iron, silver and lead salts; tannin; alkaloids.

**Metrology**

A ready working knowledge of weights and measures is indispensable in prescribing.

Formerly every country, even every State, and some cities, had their own system of weights and measures, resulting in endless confusion and loss of time. This state of affairs still exists to some extent. In the United States and Great Britain no less than five different systems are in common use. It is a hopeful sign that the United States and British Pharmacopeias and the U. S. government medical services employ the metric system. This system originated in France near the close of the 18th century. It has been adopted in science to the exclusion of all others, and possesses a number of advantages which should cause all other systems to be discarded. This is the ultimate tendency, and the student is urged to learn the doses and practice prescription-writing in the metric system. Since, however, the common systems are still used in many hospitals and journals, these must also be mastered, and the conversion of the systems practiced.

**The Metric System.**—This is based on the decimal system, and has for the unit the measure of length, the meter (M.).
This was intended to be a natural unit, viz., the ten-millionth part of the distance from the pole to the equator of the earth at a particular meridian. Subsequent measurements have given a slightly different value to this distance. The meter is therefore an arbitrary standard—the length of a platinum bar, the original of which is preserved in Paris.

The meter is divided into 10, 100, and 1,000 parts, called respectively decimeter (dm.), centimeter (cm.), and millimeter (mm.). The thousandth part of a millimeter is a micron (μ).

The contents of a cube whose edges measure a decimeter, or 10 cm., form the unit of capacity, the liter (L). The thousandth part of this is a cubic centimeter (c.cm., or, briefly, c.c.; also termed a "mililiter" or "mil"). The unit of weight is given by the weight of a liter of distilled water at 4°C. Its name is this is the kilogram (Kg.). A thousandth part of this is a gram (Gm.). A quantity ten times the unit is expressed by prefixing the Greek numeral Deca; one hundred times, Hecto; one thousand times, Kilo. The tenth part of the unit is expressed by prefixing the Latin numeral deci; one-hundredth, centi; one-thousandth, milli.

Thus:

- 1,000 Gm. = Kilogram (Kg.)
- 100 Gm. = Hectogram (Hg.)
- 10 Gm. = Decagram (Dg.)
- 1 Gm. = Gram (Gm.)
- 0.1 Gm. = decigram (dg.)
- 0.01 Gm. = centigram (cg.)
- 0.001 Gm. = milligram (mg.)
- 0.0001 Gm. = microgram (μg.)

In quantities including several denominations only one unit is used: thus, 1,234 Kg. would be read as 1,234 Gm.; 0.0002 Gm. as 2 mg., etc. The quantities are always denoted by Arabic figures placed before the appellation. Fractional parts are always converted into decimal fractions.

In continental Europe the liquid measure is very little used in pharmacy, liquids being usually weighed.

Milliliter.—The B.P. designates the cubic centimeter as milliliter, and employs the following divisions and abbreviations. Their use does not seem advisable, as they tend to introduce complications and confusions that may retard the final adoption of the metric system.

1 Liter (Lit.) = 1,000 Gm. of water at 4°C.
2 Milliliter, ml. = 1 Gm. of water at 4°C.
3 Deciliter, dl. = 0.1 Gm. of water at 4°C.
4 Centiliter, cl. = 0.01 Gm. of water at 4°C.

Common Systems of Weights and Measures.*—The denominations are the following:

**APOTHECARY’S OR TROY WEIGHT (USED IN PRESCRIPTIONS)**

- Grain (gr.)
- Scruple (G) = 20 gr.
- Dram (dr.) = 1 scruple, 60 gr.
- Troy ounce (oz) = 8 scruples = 480 gr.
- Troy pound = 12 oz = 5,760 gr.

(*Some authors begin all the abbreviations with capitals; others employ capitals for the units; gram, liter and meter, and their multiples; and small letters for fractions (as in the above lists). The latter plan has some advantages. Those in square brackets are practically obsolete. *Also spelled dracon.* At 4°C and in vacuo.)
MANUAL OF PHARMACOLOGY

AOVIRDUPOIS OR IMPERIAL WEIGHT

(A SYSTEM USED IN COMMERCE)

Grain = same as Troy grain.
Ounce (oz.) = 437 1/2 grains.
Pound (lb.) = 16 oz. = 7,000 grains.
Ton = 2,000 lb.

UNITED STATES APOTHECARY'S OR WINE MEASURE
(USED IN UNITED STATES FOR BOTH PRESCRIPTION AND COMMERCIAL PURPOSES)

Minims (M or min.) (approximately equal to 1 drop or to 1 grain of water—more exactly, 0.05 grain).
Fluidram (fl. dr.) = 60 M.
Fluidounce (fl. oz.) = 8 fl. $3 = 480 M (fl. $ of water under standard conditions weighs 456 1/2 grains).
Pint (pt., or Octarius, O) = 16 fl. $3 = 5,680 M.
Quart (qt.) = 2 pta. = 16 fl. $3.
Gallon (gal., or Congius, C) = 8 O = 128 fl. $3 = 61,440 M.

A gallon holds 231 cubic inches.

Another system of liquid measure is in use in Great Britain, and must not be confused with the American system. It is the IMPERIAL MEASURE

Minims (min.) = 0.96 M.
Fluiddrachm (fl. dr.) = 60 min. = 0.96 fl. $.
Fluidounce (fl. oz.) = 8 drachms = 0.96 fl. $.
Pint (O) = 20 fluidounces = 1.2 O.
Gallon (C) = 8 pints = 1.2 C.

In writing the apothecaries' measure in prescriptions, the figures are written in the Roman system and placed after the appellation. Thus, gr. xx, not 20 gr. The ones are always dotted, and the last one is formed like a j: thus $5ij, $5ij, etc. The fl. before the sign is often omitted with liquids.

Fractions are written as common fractions: gr. $1/2$, not gr. o.1.

Popular Measures.—These are formed of utensils commonly found in the household, and are, of course, inexact. They should be displaced by graduated medicine glasses, which can be obtained cheaply. Spoons are supposed to be filled so that the fluid stands level with the rim.

The usually accepted equivalents of these measures are:

1 drop (gtt.) = 1 minim$^1$ = 0.05 c.c.
1 teaspoon = 1 fl. $3$ = 4 c.c.$^1$
1 dessertspoon = 2 fl. $3$ = 10 c.c.
1 tablespoon = 4 fl. $3$ (1/3 $3$) = 15 c.c.
1 wine-glass = 2 fl. $3$ = 50 c.c.
1 sea-cup = 4 fl. $3$ = 125 c.c.
1 tumbler = 8 fl. $3$ = 200 c.c.
1 knife-pointful (tableknife) = 15 to 30 gr. = 1.0 to 2.0 Gm.

$^1$ At 4°C. and in metric.
$^2$ The size of a drop varies according to the nature of the fluid and of the container; there may be from 50 to 150 to a fluid drachm. The International Protocol authorized a standard dropper, designed to deliver exactly 20 drops per cubic centimeter of water.
$^3$ Really from $1/4$ to $3/4$ fl. $3$.
$^4$ As a matter of fact, the actual capacity of teaspoons averages 5 c.c., when filled level (Wilbert, 1903).
Advantages of the Metric System.—These will now be manifest.
1. The metric system is widely used, and is understood throughout the civilized world.
2. There is a simple relation between linear, solid, and liquid measures.
3. The decimal feature simplifies multiplications, since only a change of a decimal point is required to change one denomination into another. It is also much easier to write the quantities. Calculations involving specific gravity are also much more easily made.
4. The adherents of the common system claim that it is more convenient for dosage. There may be some truth in this, for the grain, minim, and dram happen to be more convenient doses than the gram or cubic centimeter. This advantage, however, is insignificant.

Equivalents of Metric and Common Systems.—Doses and formulas may be calculated from one system into the other. For this, it is only necessary to remember that 1 Gm. = 15.4 gr. However, this always entails the possibility of some error in reckoning, which may have serious consequences. The student is therefore advised to learn the dosage in both systems, and to construct prescriptions directly in whichever system is chosen. If a transposition must be made, the following approximate equivalents (which should be thoroughly memorized and practiced) are sufficiently exact for prescription purposes; and being simpler, they are less apt to lead to arithmetical errors, than the exact equivalents.

**APPROXIMATE EQUIVALENTS**

<table>
<thead>
<tr>
<th>1 Gm.</th>
<th>15.4 grains or minims.</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 c.c.</td>
<td>15.4 grain</td>
</tr>
<tr>
<td>1 milligram</td>
<td>15.4 grain</td>
</tr>
<tr>
<td>1 Liter</td>
<td>1 quart (+)</td>
</tr>
<tr>
<td>1 Kilogram</td>
<td>2.2 lb.</td>
</tr>
</tbody>
</table>

**Dosage Equivalents.**—In memorizing "average doses" even this degree of approximation is needlessly complicated. The following table gives the most convenient figures:

<table>
<thead>
<tr>
<th>Above 1 Gm.</th>
<th>Above 13 Gr.</th>
<th>0.1 to 0.75 Gm.</th>
<th>15/8 to 1 Gm.</th>
<th>20 to 50 mg.</th>
<th>54/5 to 1 gr.</th>
<th>Below 2 mg.</th>
<th>Below 3/4 gr.</th>
</tr>
</thead>
<tbody>
<tr>
<td>150</td>
<td>0.750</td>
<td>0.500</td>

<td>(1/4)</td>
<td>0.0001</td>
<td>(1/16)</td>
<td>(1/128)</td>
</tr>
<tr>
<td>75</td>
<td>0.375</td>
<td>0.100</td>
<td>0.008</td>
<td>(5/16)</td>
<td>0.0001</td>
<td>(1/32)</td>
<td>(1/256)</td>
</tr>
<tr>
<td>70</td>
<td>0.350</td>
<td>0.075</td>
<td>0.007</td>
<td>(5/32)</td>
<td>0.0001</td>
<td>(1/64)</td>
<td>(1/512)</td>
</tr>
</tbody>
</table>

1 An example will make this clearer: Take 40 Gm.; in the United States system this must be written 3 1/2 Gm. xvi. Should it be necessary to calculate five times this quantity, one multiplication will suffice with the metric system: 5 X 40 = 200 Gm. But with the Apothecaries' system, the operation would be much more complicated: 5 X 3 1/2 Gm. xvi = 3 Y 3 x 1/2 Gm. lxxxi

This must be reduced:

<table>
<thead>
<tr>
<th>3 Y = 3 Y</th>
</tr>
</thead>
<tbody>
<tr>
<td>3 x 1/2 Gm. lxxxi = 3 Y 3 x 1/2 Gm. xvi</td>
</tr>
</tbody>
</table>

Answer = 3 Y 3 1/2 Gm. xvi
### Exact Equivalents

</tbody>
</table>

### General Toxicology

Toxicology is the science of poisons. The details of the actions and symptoms will be considered in connection with the individual poisons; but certain matters of general application may be discussed here.

**Definition of Poison.**—A poison (from potion, a draught), by the broadest definition, is a substance the administration of which is injurious to health. However, injurious mechanical, physical, or bacterial agencies are not commonly classed as poisons; nor are the substances which produce injurious effects only in very large doses (say over 50 Gm.). It is very difficult to give a definition which will not be ambiguous in some cases (see, *i.e.*, the collection of definitions by Murray and Frame, 1914). The following covers most of the points which must be considered in classing a substance as a poison:

A poison is any substance which, acting directly through its inherent chemic properties, and by its ordinary action, is capable of destroying life, or of seriously endangering health, when it is applied to the body, externally, or in moderate doses (to 50 Gm.) internally.

**Etiology of Poisoning.**—Poisoning may result through criminal or suicidal intent, or through accident.

The statistics of the relative frequency of the different forms of poisoning vary from year to year, and with each country. A classified list of deaths from poisoning in the U.S. registration area is given by Wilbert, 1916. Suicidal poisoning is probably the most frequent, nearly a half of the suicides in the United States being due to poisoning. It is calculated that here five-sixths of all suicidal cases are due to phenol. There is, however, a fashion in poisons, as in other things. This is greatly fostered by the notoriety which the newspapers often give to these cases.
Acknowledgment of Toxins and Classification of Poisons.—Suspicion of poisoning is aroused if a person, previously in good health, manifests any sudden marked pathologic symptoms, which become rapidly worse. The suspicion becomes more firm, if the phenomena appear a short time after swallowing some substance which may perhaps have an unusual odor or taste; if they agree in character with those produced by some group of poisons, and if they do not agree with any other disease.

Symptomatic Classification of Poisons: The following classes are generally recognized.

1. Irritants.—These produce inflammation; if they are taken by the mouth, there is pain throughout the alimentary canal, vomiting, purging, delirium, coma. So many poisons are to some extent irritant, that these symptoms are very commonly present.

2. Heave Poisons.—These act on the neuromuscular apparatus, and include most of the poisons which are fatal in minute doses. They are subdivided into: Convulsants, which cause spasms; Somnificants, causing sleep and coma; and Cardiac poisons, which stop the heart.

3. Blood Poisons.—Those which alter the hemoglobin or blood corpuscles. These include the toxic gases, the nitrites, etc. Their action is generally characterized by cyanosis.

It must not be supposed that the action of a poison is confined generally to one class of structures or functions. All functions suffer directly or indirectly, and whatever the class to which the poison belongs, the final cause of death is, in almost all cases, paralysis of respiration, preceded by the phenomena of asphyxia. In virtue of the latter, or through other causes, the urine often contains sugar.

The irritants, and especially the corrosives, produce lesions which can be demonstrated at autopsy. With other poisons the post-mortem examination is generally impossible. The spectrum of the blood shows characteristic changes with some poisons; it can also cause excruciating discompositions of the skin. Anthracotic poisons delay the purification of the body, so that mummification may result. Convulsive poisons quicken the onset of rigor mortis.

Duties of the Physician in Cases of Poisoning.—These are twofold: to save life or suffering, and to forward justice. The former object requires the removal of the poison, the administration of chemical antidotes, and the treatment of the symptoms.

For the detection of the poison, and to aid in fixing the guilt on the proper person, the physician must carefully observe the symptoms, take possession of any suspected material, medicine, vomit, etc., and in case of autopsy, preserve the stomach and its contents, the intestines and contents, blood, liver, kidneys, and portions of other organs, separately, without antiseptics, in clean, hermetically closed, glass vessels, which should be sealed with wax. An exact written record of all the observations should be made as soon as possible.

The symptoms in cases of suspected poisoning are rarely sufficient to affirm the presence or nature of a poison, although they may be of great aid to the analyst. The final proof rests generally on the results of the chemical examination.

So much depends on this analysis, that it should never be undertaken by anyone who has not had extensive experience in this class of work, and who has not the necessary apparatus and the treatment of the symptoms.

1. If any appear strange that poisons which possess a pronounced and disagreeable taste could be used for criminal poisoning, except with infants; but a moment's thought will show that if a叠 of potassium cyanide, mixed with coffee, is placed in front of a person, the odor of the potassium cyanide will be perceptible for 10 to 15 minutes. I have had two cases of suicide by potassium cyanide, the cyanide having been placed in a glass vessel and consumed by the victim.

2. Even chloroform and alcohol can be isolated for a long time (30 to 90 days) from human subjects. In such cases, however, the symptoms, if corrosives (Phosphorus, Cyanide, Poisonous, etc.) are used, the symptoms may be very characteristic.

3. In cases of poisoning by alkaloids, the symptoms may be very characteristic.

4. In emergency, a rare or specially marked coin, or a key, may serve to impress the seal.
sary facilities. It lies entirely outside of the scope of the practicing physician. The latter should, however, be familiar with the general outline of the process used for isolating poisons; and with such chemic tests as may be quickly applied. These tests an often valuable for diagnostic and therapeutic purposes. The physician is also expected to give expert testimony on toxicologic questions, and to do this intelligently, he must have at least an elementary knowledge of toxicologic analysis, such as is furnished in the following section.

Some poisons can be demonstrated much better by tests on animals than by any chemic tests. For this object, they should be isolated in as pure a form as possible by the methods laid down in this section. The application of these life tests, fall peculiarly into the province of the pharmacologist.

**OUTLINE OF TOXICOLOGIC ANALYSIS**

**Precautions.**—The first duty of the analyst is to guard the material confided to him from the willful or accidental introduction of poisons. For this purpose, precaution must be taken that no other person has access to the material; and every reagent and apparatus must be tested personally.

As a rule, the different organs must be kept strictly separated throughout the analysis. It will depend on circumstances whether the analysis of the individual organs is made at the same time, or successively. If the latter is decided on, the largest organ, or the most likely to contain the poison, is examined first. It may be advisable, however, to mix a weighed quantity (one-fourth or one-third) of the comminuted organs, and to use this mixture for the first analysis.

Since the material to be analyzed is limited in amount, and can not be replaced, the examination must be arranged in such a way that as many tests as possible can be made successively on a single sample of the material. An economy of time and material is also secured by obtaining, as quickly as possible, some idea of what poisons may be present. This may be done by some easy preliminary tests, or by using so-called "group-reactions" which, if negative, will exclude a number of substances. The symptoms may also have furnished important hints, but should never prevent the complete examination of the substance.

During the isolation and the preliminary search for the poison, only the most important tests should be applied. When the poison has been isolated, however, it should be subjected to every known test. A sample of the isolated poison should be preserved in stable form.

**Preliminary Examination.**—The systematic examination is begun by a careful inspection of the portions of the alimentary canal. These are opened, and extended on an inverted evaporating dish, mucous surface upward. Pathologic lesions are looked for, as also particles of the poison which may be adherent. A magnifying lens should be employed. (Granules of arsenic have often been isolated in this way.) The contents of the alimentary canal, or vomited matter, are subjected to a similar close inspection. The odor should be carefully observed. During this examination, the reaction to litmus paper should be noted (caustic acids or alkalies).

Each organ is then hashed, carefully weighed, and replaced in hermetic sealed jars.

**Isolation of the Poison.**—No routine schema of analysis will fit all cases, since each presents its own problems. However, the following illustrates the usual procedure.

**Division of Material.**—Ordinarily, each organ, after comminution, is divided into the following portions carefully weighed: One-third is reserved for control; one twentieth for preliminary tests. The remainder is divided into four parts, used respectivly for the search for volatile, fixed organic and inorganic poisons, and for reserve

---

1 This section should be studied in connection with the practical exercises. Gadamer's "Lehrbuch der chemischen Toxikologie" is an excellent reference book.

2 As soon as the absence of volatile poisons has been proven, the contents of the jars may be covered with 95 per cent. alcohol.
Volatile Poisons.—A portion of the material is acidulated with tartaric acid (adding water if necessary), and distilled from a flask or retort connected with a Liebig’s condenser. It is advisable to pass a slow current of live steam through the mass. The distillation is continued until about two-thirds of the liquid have been collected, in three portions. The odor is noted (volatile oils, chloroform, ether, etc.), and the characteristic tests applied for phosphorus, phenol, cyanides, alcohol, chloroform, chloral, etc.

Phosphorus.—A preliminary test for this element must be made with silver nitrate and acetate papers before the distillation is begun. If this test indicates its presence, the condenser is set vertically downward, and the distillation is carried on in a darkened room. All air is expelled from the apparatus by a stream of carbon dioxide. This is then shut off, and replaced by live steam; the flask being heated at the same time. If phosphorus is present, a luminous ring appears in the tubes or condenser, shifting its position when the heat applied to the flask is altered ( Mitscherlich’s noted). The appearance of this phenomenon proves the presence of phosphorus absolutely.

There are, however, a number of substances which interfere with the formation of this ring. Almost any volatile substance may do so; turpentine, chloroform, ether, alcohol, and alcohol is often present, as it is usually given as an antidote. The absence of the ring does not, therefore, prove the absence of phosphorus. The distillate will contain phosphorus in the lower stages of oxidation, as phosphorus or hypophosphorous acid. The best way to prove phosphorus in this is to add some bromine water to the distillate and to evaporate to dryness. This results in phosphoric acid, which may be demonstrated by magnesium mixture or ammonium molybdate. The quantitative determination of phosphorus is not important; because if it is present at all, it is present as a toxic agent.

Cyanides.—Mere traces of hydrocyanic acid in the distillate are not proof of poisoning, since these may have been introduced in the way of food (almonds or other seeds). A qualitative estimation, by means of silver nitrate, may be necessary. The qualitative test also requires two further precautions:

With the method which we have given, ferrocyanides might also be decomposed and give rise to hydrocyanic acid; and since ferrocyanides are not toxic, this would lead to wrong conclusions. To eliminate this, the original liquid is filtered and the Prussian blue test applied to it directly. Mercaric cyanid does not yield its hydrocyanic acid in this treatment. If it is suspected, the material must be treated with hydrogen sulphide, followed from Alkaline Solutions.—It is sometimes recommended to add water to the residue in the retort, to make it alkaline with sodium carbonate, and to distill again. The distillate contains ammonium, amines, chloroform (if chloral was present), and the volatile fraction. This step may generally be omitted, as these poisons are discovered in other parts of the process; or a small sample may be heated in a test-tube with sodium carbonate, and the odor noted.

Extraction of Fixed Organic Poisons.—The extraction, separation and purification of these poisons are based on their special solubility in certain solvents. As a rule, they are fairly soluble in acidulated water and alcohol. The neutral principles are removed from the acid water by the addition of water, the water solution by ether or chloroform. The alkaloids are dissolved by these substances only after the addition of an alkali.

In brief outline, the suspected material is first extracted with boiling acidulated water and alcohol. The acid watery extract is then treated with ether, which dissolves neutral principles and various impurities, but which leaves the alkaloids. These are extracted later by fresh ether, after rendering the solution alkaline.

---

1 See below for special arrangement to be used when phosphorus is present.

2 Alcohol is only important if it is present in large amounts. Smaller quantities may be present incidentally or as an antidote.
Various methods are in use. The most practical is that of Stas-Otto, slightly modified:

§1. The poisons are first brought into solution by boiling the material, if solid, with about 5 parts of water for fifteen minutes (or the residue remaining after the distillation of the acid solution may be used). The mixture is cooled and strained. This removes fat, coagulable protein, fiber, etc.¹

§2. The strained solution is evaporated at a low temperature to a syrupy consistency, and boiled with twice its volume of alcohol, for fifteen minutes. The evaporated alcohol is replaced. It is then filtered, and the filter washed with alcohol. This removes salts, non-coagulable proteins, etc.

§3. The alcoholic filtrate is diluted with an equal volume of water and filtered. This removes resins, fats, etc. (The residue may be examined for cathartic resins and croton oil.) (For further purification, the filtrate may be again treated by §§2 and 3.)

§4. The filtrate, which should have an acid reaction, is now shaken in a separatory funnel with 10 c.c. of ether. This is drawn off, and the same process is repeated twice. The ether removes neutral principles, picro acid, and salicylic acid. It is filtered and allowed to evaporate in a glass capsule, and the residue is purified and tested for these acids, for caffeine, cantharidin, colchicin, digitalin, picrotoxin, and the coal-tar antipyretics.

§5. The watery solution, remaining from the extraction with ether in the last paragraph, is now made fairly alkaline with sodium carbonate (to liberate the alkaloids) and again extracted with ether, as in the last paragraph. From this alkaline solution, the ether removes all alkaloids except morphine. The etheral layer is filtered and evaporated, the residue is purified, and tested, first by potassium mercuric iodide, then for physostigmin, aconitine, colchicin, conin, veratrin, strychnin, brucin, atropin, cochin, narcotin, emetin, and acornit.

§6. To isolate the morphine, the watery liquid remaining in the last paragraph, is made acid, then alkaline by ammonia, and shaken at once with acetic ether, or with hot amyl alcohol.

§7. To test for aconite acid, the original substance is partly dried, extracted with 3 c.c. of hydrochloric acid and 30 c.c. of boiling alcohol, for half an hour, filtered, evaporated, extracted with water, and tested. Sambuconin and Mecaconic Acid must also be extracted by special methods.

Dragendorff's Method.—In this, a more extensive separation of the poisons is obtained, by multiplying the solvents and operations. The preliminary treatment is as per §§1, 2, and 3. The acid solution is then exhausts successively by petroleum ether, benzene, and chloroform; and then in alkaline solution by the same sequence of solvents, and finally by amyl alcohol.

Kippdenberg's Method.—This possesses the advantage of separating the poisons in a purer form from the start, but it involves technical difficulties. It depends on the insolubility of the tannates of proteins in glycerin, whilst the organic poisons are soluble in this medium. The solid material (say 100 Gm.) is digested for two days at 40°C. with 10 Gm. tannin, 1 Gm. tartratic acid, and 100 Gm. glycerin. The mass is expressed; the residue is washed with tannic glycerin. The fluids are diluted with water, heated to 50°C., and filtered. The filtrate is then extracted twice with petroleum ether, which removes mainly fats. The glycerin layer is then extracted as in the Stas-Otto method (§§4 and 5), but using chloroform in place of ether.

For the purification of the alkaloids, the residue, left by the evaporation of the chloroform, is dissolved in aceticulated water, neutralized, and at once precipitated by sodium-potassium-iodid. The precipitate is collected on a small filter, washed with cold water, dried, and dissolved in hot acetone. The filtered acetone solution is treated first with alkali, then with acid, then with water; the acetone is expelled on a water-bath, and the remaining watery solution is decolorized by sodium hypochlorite. The solution is then made alkaline with sodium carbonate and extracted with ether or chloroform.

Physiologic Tests.—The poisons isolated by these methods are often not sufficiently pure to give the typical chemic tests; furthermore, certain of the tests are closely simulated by ptomains. This holds true also of the physiologic tests, i.e., the effects on animals. The only way to distinguish with certainty between these is to use both the chemic and the physiologic tests. For, as far as is known, there are no ptomains which give both the chemic and the physiologic tests of one alkaloid.

The physiologic tests can generally be obtained with fairly impure preparations. They are most typical in the case of strychnin, atropin, physostigmin, aconite, digitalis group, picrotoxin, veratrin, cantharidin, croton oil. The subject is elaborated in Fuchner's "Nachweis von Giften."²

¹ It is understood that the remaining mass should be washed, in every instance of filtration or straining.

² Nachweis von Giften.
Isolation of Fixed Inorganic Poisons.—The residues of the preceding operations may be used for the search of these poisons. The usual methods of inorganic analysis are followed; but it is superfluous to test for non-poisonous constituents.

The absence of many metallic poisons can be quickly shown by Reinsch’s test. This does not, however, dispense with further tests. Only an outline can be given here:

A: Destruction of Organic Matter and Solution.—Method of Persius and Bufo.—

Organ or syrropy residue, up to 500 c.c. to 500 c.c. of arsenic-free HCl (1:2) in liter flask; heat lakewarm. Add 4 to 6 Gm. KCIO₄ in 0.5 Gm. portions, till dissolved. Evaporate to about 100 c.c. (no free Cl). Dilute to 200 c.c. Add 2 c.c. dilute H₂SO₄. Stand overnight. Filter. Filtrate = B. Residue = K.

B: Filtrate B.—Pass through filter, add water to just 500 c.c. Use 50 c.c. for Marsh’s test (see L). If A is present, use balance for quantitative (see C). If not, evaporate until sample, dissolve in 10 c.c. water, add NH₄OH; blue = Cu.

C: Heat balance of filtrate B to 80°C. and pass arsenic-free H₂SO₄ for two or three hours, until cool. Heat again, and repeat. Stopper and set aside in warm place for twenty-four hours. Precipitate may contain As, Sn, Hg, Hg, Pb, Pb. It may be used for the quantitative estimation of As, or for further identification by D. Filtrate = I. D (H₂S precipitate of C).—Wash with H₂S water, warm with 4 c.c. ammon. sulphide, 4 c.c. ammonia, 8 c.c. water. Filter. Filtrate = E. Insoluble = F.

E (Filtrate of D).—Evaporate to dry; heat with HNO₃ till pure yellow; heat to expel HNO₃; add Na₂CO₃ and NaNO₃; fuse; extract with boiling water; add 2 Gm. Na₂C₂O₄. Filtrate contains As and may be used for quantitative. The insoluble = Sn.

F (Insoluble of D).—Oxidize residue and filter in capsule with HCl and KCIO₄; filtrate; dilute; heat; pass H₂S; filter; wash precipitate with warm HNO₃. Filtrate = G. Precipitate = H.

G (Filtrate of F).—Add 10 drops dilute H₂SO₄; evaporate; take up with water. Residue = Pb. Filtrate = Cu. (Apply tests.)

H (Precipitate of F).—Oxidize with aqua regia; evaporate; filter; dilute; test for Hg. I (Filtrate of C).—Use half for zinc, half for chromium.

Zn: Neutralize with KOH; acclimate with H₂C₂O₄; precipitate with H₂S; wash precipitate with H₂C₂O₄ in H₂S water (1:5); incinerate precipitate and filter; dissolve is dilute HNO₃, plus a little HNO₃; evaporate dry; dissolve in H₂O; test for Zn.

Cr: Evaporate to just moist; mix with KNO₃; dry; fuse; dissolve; test for chromate.

K (Residue of A).—Fuse with KNO₃, Na₂CO₃, and Na₂H₂BO₃. Suspend in H₂O; pass O₂; boil; filter. Dissolve precipitate in dilute HNO₃. Test this solution for Ag, Sn, and Pb.

Marsh’s Test (see B).—Produce hydrogen in flask by acting on pure zinc with arsenic-free HCl; pass through CaCl₂, through tubes drawn out at several places. Heat to redness at the thick portion of a segment. (This blank test should be continued for six hours.) If no mirror appears, introduce the suspected solution. Black mirror occurs with arsenic or antimony. They may be distinguished as follows:

TREATMENT OF POISONING

Whilst every case of poisoning demands to be treated by itself, yet certain general principles are all but universally applicable. These are the more important since the nature of the poison is so often unknown.

1H₂S purified by passing through water, calcium chloride, and a tube, 30 cm. long, filled with amorphous layers of glass-wool and calcium oxide.
The peculiarities of poisoning to deserve especial attention is the rapid course. This demands that whatever measures are taken, they must be taken quickly. The physician should therefore be thoroughly familiar with the general rules of treatment, so that no hesitation or delay occurs. On this account also, the antidote nearest to hand should be used in preference to one which can only be obtained with delay, even if the latter should be theoretically preferable.

The treatment of poisoning is directed against the cause and the symptoms. The former consists in removing the poison, or in rendering it harmless. Since neither of these objects can usually be attained absolutely, both are generally attempted at once.

**Removal of the Poison.**—The measures directed to this end vary with the site to which the poison was applied.

On the skin and on accessible mucous membranes this will be accomplished by a thorough washing with water. This will also be useful by diluting the poison. If the poison is only sparingly soluble in water (as phenol) alcohol may be employed. Soap may be useful, but should be avoided if the poison is an alkali. The appropriate chemical antidote should also be added to the wash water (for acids or bromin: Soap or Linimentum Calcis; for alkalies: vinegar or lemon juice). The poisons which are important in these situations are all irritants, and the further treatment consists in the application of oils or salves.

If the poison has been applied hypodermically or to wounds, the systemic effects may be lessened by preventing or retarding the absorption of the poison. The absorption may be delayed sufficiently so that the drug is excreted as fast as it is absorbed, and doses which would otherwise be fatal may then cause no effect. The best means for this purpose is a firm ligature applied centrally to the wound. Where this is not feasible, sucking, cautery, or excision may be practiced.

If an irritant poison has been taken by the mouth, the oral cavity and the pharynx demand the same treatment as would the skin.

With gaseous poisons, the treatment consists in free ventilation of the lung, using artificial respiration, and oxygen, if necessary.

**Removal from the Alimentary Canal.**—This should be attempted, in case of poisoning by mouth, unless the symptoms are already so far advanced as to make it useless. Even if the poison has been administered some time before the treatment is begun, or if it has been given hypodermically, the alimentary canal should be cleansed, since many poisons (notably morphin) are excreted by this channel, and then again reabsorbed. The only contraindications to the emptying of the alimentary canal are: extensive corrosion, and advanced strychnin poisoning. Great caution and careful judgment are required in these cases.

The measures for the removal of poisons from the alimentary canal consist in emptying the stomach and intestine. A cathartic, however, need only be administered after the acute manifestations are past. Oily cathartics should usually be avoided, and enemata are useless. The best purgatives in poisoning are the cathartic salts (15 to 30 Gm. of Magnesium sulphate).

**Evacuation of the Stomach.**—Vomiting often occurs spontaneously, but even in this case, more active measures are generally required. These consist in the administration of emetics, or in lavage.

**Lavage** deserves preference, if it can be used. It cleanses the stomach much more effectually, particularly of small insoluble adherent particles;
it is less depressant to the patient; and it permits the convenient use of
chotic antidotes. It is indispensable with depressant poisons which
paralyze the vomiting center (such as deep morphin or chloral poisoning).

The complicated stomach pump has been generally abandoned for the more con-
venient stomach tube. In emergencies, 6 feet of rubber gas tubing, with a funnel
attached, answers very well. The tube should not be inserted down, but should be
rately pushed to the pharynx, where the pharyngeal muscles will grasp it and push it further.
Can should be taken to avoid overdistention of the stomach; it is better to use small
quantities of fluid frequently. Against organic poisons, a 0.5% solution of potas-
sium permanganate may be used. If there is trismus, or the patient resists, the
tube may be passed through the nose.

Emetics have the advantage of greater convenience, and avoid strug-
gling. They should be repeated every fifteen to thirty minutes, if
necessary.

Apomorphine—[5 mg. (grain ½) x in 1 per cent. solution = 0.5 c.c. or
in hypodermically. This is the only emetic which can be given by
the skin, and is therefore particularly useful if the patient resists. It
is prompt and certain, but rather more depressing than the following
emetics.

Copper Sulphate or Zinc Sulphate.—These act promptly and with a
minimum of depression, but should not be given if the poison is a corrosive.
Zinc sulphate is less irritant than the copper, and nearly as efficient;
6 Gm. may be given in a glass of water. The dose of copper sulphate
is 0.5 Gm. at once, or three doses of 0.5 Gm., fifteen minutes apart. If
it is ineffective it must be removed by lavage.

Ipecac.—A teaspoonful of the powder in water, or a tablespoon of the wine. Un-
certain, and produces considerable depression.

Muriat.—A teaspoonful stirred in a tumbler of warm water. This is the most
useful of these emetics, but useful in emergencies.

Neutralization of the Poison—Chemical Antidotes.—The object of these
is, to render the poison incapable of acting, or of being absorbed.
They accomplish this by enveloping the poison with an impenetrable
casing, or by precipitating it, or by destroying it. Since these antidotes are
hindered in their action by the presence of food, and since the pre-
cipitates are not perfectly insoluble, it is well to combine them with lavage
or enemas, adding the antidotes to the wash water, or giving them in
the interval between vomiting; they must be repeated frequently.

Demulcents (raw eggs, acacia, boiled starch or flour, milk, ad libitum).
These act by lessening absorption; by allaying inflammation; and in the
case of metals, by precipitation.

Precipitants.—The most universally applicable of all precipitants
is tannin (a teaspoonful of tannic acid, or preferably, very strong hot
tea, ad libitum). The efficiency will be increased by the addition of
sodium acetate or bicarbonate, and diminished by alcohol and acids,
since the precipitates are soluble in these media.

From the experiments of Kieder (1892), on tannin, and Sollmann (1901), on tea,
it may be deduced that these are useful against: Apomorphin, Cinchona alkaloids,
Ipecacuanha, Strychnin, Veratrin, Digitalis, Antipyrin, Cochinex; and the metals: Pb.
Ag, Al, Ca, Cu, Ni, Ur, Za, Fe.

Sporadically useful against: Cocain, Brucin, Aconitin, Lobelin, Nicotin, Pilocarpin,
Codine, Muscarin, Physostigmin, Solanin.

Practically useless against: Atropin, Conin, Morphin, As, Sh, Hg.

Of other, specific precipitants, the following should be remembered:
For

Alkaloids.—Tincture of iodin, 15 drops in half a glass of water.

Metals (especially mercury).—Raw eggs.

Arsenic.—Arsenic antidote (see Index).

Barium.—Sulphates (Glauber’s or Epsom salt).

Oxalates.—Calcium (limewater, chalk, whiting).

Phosphorus.—Copper sulphate or Oxidized (old) Turpentine. (The former envelopes the phosphorus with an insoluble coating of metallic copper.)

Antidotes Which Destroy the Poison in the Alimentary Canal.—

(These, for the most part, will not be useful after the poison is absorbed.)

Acids.—Alkalis (burnt magnesia, soap, chalk, baking soda).

Alkalis.—Weak acids (vinegar, lemon juice).

Organic Poisons (Alkaloids, Glucosids, etc.) and Phosphorus.—Oxidizing agents, especially Potassium permanganate, 2 grains (a pen-knife-point full in emergency) to the tumbler, repeated as often as it is vomited; or for lavage, a liter of 0.05 per cent. Care must be taken that no undissolved crystals are administered. In case of snake bite, the powdered permanganate may be rubbed into the wound, after free incision.

Hydrogen peroxid is another useful, though less powerful oxidant.

Hydrocyanic Acid.—Permanganate, arsenic antidote, hydrogen peroxid, and thiosulphate of sodium (Hypo).

Antidotes Which Destroy Absorbed Poisons.—To be effective, these must be given hypodermically or intravenously. The best known examples of this class are the antitoxic sera. The following are also useful: Sodium thiosulphate against hydrocyanic acid; and sodium carbonate against mineral acids.

Removal of Poisons after Their Absorption.—This can be attempted by increasing the excretions, but is usually not very successful. The elimination by the alimentary canal has been discussed. The principal remaining channels are the urine and sweat, of which the former is more important.

Diuretics.—Water, especially as weak tea or carbonated drinks; theobromin; potassium acetate (irritant diuretics should be avoided).

The usefulness of diuresis for the removal of poisons is at best very limited, even for such substances as strychnin (Hatcher). With tetanus toxin, intravenous hypertonic saline solution or glucose failed to prolong the life of the animal, even when used under the most favorable conditions (Sansum, 1918).

Antispasmodics.—Hot drinks; heat; pilocarpin (if not contraindicated by pulmonary edema).

Infusion of Normal Saline Solution (1 Liter of 0.9 per cent. injected under the skin of the subclavicular region) increases elimination by all channels. Bleeding may be resorted to in some cases. Up to a liter of blood may be drawn, a double quantity of salt solution being injected.

Symptomatic Treatment.—The symptoms produced by poisons can often be lessened or removed by the use of drugs having an opposite action. These physiologic antidotes may not really abolish the action of the poison; they may only mask its symptoms. But by tiding the patient over the dangerous period, and by preventing exhaustion, they may be potent means of saving life. It must be remembered, however, that large doses of the antidotes often cause effects similar to those of the poison, which may add to the fatality of the latter. They must therefore be used in appropriate small doses.

It is not purposeful to enter in this phase into the special physiologic antidotes, but we shall take up only those measures which are generally useful.

These measures are directed, in the order of their importance, to: sup-
porting the respiration, heart, and vasomotor tone; to lessen cooling, pain, convulsions and coma.

Respiration.—This is usually the first function to fail, and this accelerates the other actions of the poison through the convulsant and paralytic effects of asphyxia, and by preventing the destruction of poisons through oxidation. For these reasons, it is well not to wait with the supporting measures until the respiration has actually failed, but to begin as soon as it shows signs of weakening. The measures consist in direct or reflex stimulation of the respiratory center; in artificial respiration; and in the administration of oxygen.

Reflex stimulation of the respiratory center is the quickest, but can not be kept up as long as the direct stimulation. It may be secured by inhalation of ammonia water or smelling salts, or by aromatic spirits of ammonia (half a teaspoonful in a glass of water); the alternate application of heat and cold (whipping with wet towels); friction with alcohol; hypodermic injection of camphorated oil, whiskey, or ether; mustard plasters; faradization.

Direct Stimulation of the Respiratory Center.—By strong hot coffee, strychnin (0.002 Gm.) or atropin (0.001 Gm.). The respiration may also be raised by improving the circulation. Saline infusion is useful.

Artificial Respiration.—This should be applied whenever the above measures are ineffectual.

Very prolonged and violent artificial respiration may injure the lungs. It should also be remembered that artificial respiration is apt to induce apnea, so that the patient does not breathe spontaneously simply because there is not enough CO₂ in the blood to stimulate the respiratory center. If the heart is strong, the artificial respiration should therefore be intermittently occasional for a short time.

Oxygen.—This is useful if an asphyxiant gas is the cause of the poisoning.

Heart.—Attempts to revive or even to support the poisoned heart directly have not been very successful. The best results are obtained by the injection of normal saline, possibly with the addition of some epinephrin (1:100,000). Digitalis is usually unsuccessful. Strong rhythmical pressure (rate of 100 per minute) over the cardiac region of the chest, may be helpful. A dilated heart can sometimes be revived by withdrawal of blood.

Vasomotor Stimulation.—This is usually accomplished by the reflex stimulants mentioned under respiration. Lowering of the head and bandaging the extremities is often sufficient.

Cooling.—This is prevented by the application of external heat; pain by morphin, or if local, by cocaïn; convulsions are controlled by the cautious inhalation of chloroform; coma by reflex stimulants, coffee, and atropin.

Methods of Administering Antidotes.—Physiological antidotes should be given hypodermically or intravenously, if possible. This obviates the loss of the antidote through vomiting, and the action is more prompt and more certain.

If the circulation is low the absorption of hypodermic injections may also be slow. It is therefore well thoroughly to massage the site of the injection, and if the circulation has almost stopped, to employ vigorous rapid rhythmical compression of the heart (this maintains a fairly efficient artificial circulation even after the heart has stopped beating).
Résumé of the General Treatment of Poisoning—Promptness is of vital importance. The physician should be familiar with antidotes; he should have these antidotes readily accessible; he should plan his treatment on his way to the patient. If he finds the condition of the patient dangerous, he should at once proceed to relieve the symptoms. Otherwise he should first administer the chemical antidote and evacuate the stomach; apply heat; attend to the respiration, to pain, to any other symptoms; give a diuretic, and, finally, a cathartic.

Antidotes for First Aid.—Every physician (and every drug store) should keep the following antidotes together, in a specialatchel ("Antidote-Bag") so that they can be readily transported. The dose should be written on each container. Amyl nitrite pears; Apomorphine tablets, 2 mg.; Atropine tablets, 1 mg.; Caffeïn-sodium benzoate Chloroform; Cobalt hydrochlorid tablets, 0.03 Gm.; Tincture iodin; Copper sulphate, powdered; Lime Water; Magnesia, calcined; Potassium permanganate, 1 per cent. solution (to be diluted twenty times); Sodium sulphate; Spir. Ammon. Arom.; Strychnin sulphate tablets, 2 mg.; Whiskey; also a hypodermic syringe in good order, and a stomach-tube with funnel.

The following should be demanded at the house of the patient: Boiled water; Coffee (strong, hot, and black); Eggs; Hot-water bags; Milk; Mustard; Salad oil; Salt; Soap; Starch, boiled; Tea, Vinegar.

PRESCRIPTION WRITING

Parts of the Prescription.—A prescription is an order for medicine sent by a physician to a pharmacist. It consists of the following parts (in this order):
1. Superscription—The heading (B).
2. Inscription.—The ingredients and their amounts.
3. Subscription.—The directions to the dispenser.
4. Signature.—The directions to the patient.

The prescription should also bear the signature of the physician, the date, and the name of the patient.

The Inscription may consist of but one ingredient. If several are used, they should be placed in the following order:

Basis: the principal substance.
Adjuvant: the substance which is used to aid the action of the basis.
Corrective: whose purpose it is to modify or correct an undesirable action of the basis.
Vehicle: the indifferent substance used to dilute the active ingredients.

The following is the type of a complete prescription:

S. Teaspoonful1 every hour in half a glass of water.

Dr. X
Jan. 1, 1905
For Mr. V.

1 Plural, "teaspoonfuls"
The names of the ingredients and the directions to the pharmacists are generally written in Latin, usually with abbreviations; but they may be written in English. With liquid mixtures, the directions to the pharmacist may often be confined to M. (misco, mix).

The directions to the patient (signature; abbreviated Sig. or S., for "signa," sign) are always written in English, so that the patient can read them. The directions should be explicit, and should include everything which it is necessary for the patient to know. The habit of giving verbal instructions to patients and of having the medicine labeled "use as directed" should be discouraged. The patient or relatives, when the prescription is given to them, are usually in a more or less excited frame of mind, and can not be relied upon to remember what is told them. Medicines intended for external application should be plainly labeled to that effect, and when a medicine contains poison, it should be so labeled, except when there is special objection to this.

The custom of having prescriptions "refilled" obtains in many localities. If the physician wishes to avoid this, he may write "non repetatur" on the prescription.

When the patient is very poor, the druggist may be invited to charge the lowest terms by writing P. P. (Pauperissimus) under the prescription. It is, of course, not just to do this if the physician himself receives a regular fee.

Prescriptions for Habit Forming Drugs.—The federal law requires that prescriptions for cocaine, or for opium or its alkaloids or derivatives, must contain: the signature of the physician in full; his address; his registry number; and the name and address of the patient.

Such prescriptions cannot be "refilled." If their administration is to be continued the physician must write a new prescription.

Forms of Administration.—If the medicine is to be used internally, it may be prescribed as:

Solution.—If the ingredients are soluble in water, alcohol or glycerin. Mixture or emulsion, i.e., suspended by acacia, if insoluble in water.

Powder.—If the substance does not have a very bad taste. These are preferred to the following preparations if the dose is bulky, or if the substance is to be dissolved in water before swallowing.

Pills, Capsules, etc.—If the substances are solid or semisolid, and possess a disagreeable taste; or if they are to act locally on the alimentary canal.

If the medicine is intended for external use, it may be prescribed as:

Plaster.—If the action is to be prolonged and superficial.

Ointment.—If the action is to be deeper, or briefer.

Lotions or Injections, Eye-waters, Gargles, Etc.—If it is soluble in water.

Liniment.—If it is soluble in oil or alcohol.

Size of Prescriptions.—Fluids should be prescribed so as approximately to fill the bottles in current use (15, 30, 60, 125, 150, 200, 400 c.c.) (½, 1, 2, 4; 6; 8 and 10 ounces):

For the dressings and eye-waters, the usual amount is 15 to 30 c.c. (½ to 1); for teaspoon doses, 30 to 125 c.c. (1 to 4 ½); for gargarisms and injections, 60 to 150 c.c. (2 to 6 ½); lotions, 120 to 200 c.c. (4 to 8 ½); tablespoon doses, 150 to 400 c.c. (6 to 16 ½). Pills are prescribed in numbers of 5 to 25; powders, 2 to 12; ointments, 10 to 30 Gm. (½ to 1 ½).
The Need of Practice in Prescription Writing.—The art of prescription writing presents considerable difficulties to the student. Nevertheless the principles upon which it is based are few, simple, and easily memorized. When asked for them, the student usually has no difficulty in answering the questions. The difficulties appear when he tries to put these principles into practice. But it is the same with any other art: nothing but practice will give expertness.

The student who would master this subject must not rest content with doing the few exercises which can be given him in class. As he studies each drug, or as he reads up the treatment of diseases, he should himself compile such prescriptions as the subject suggests. This will not only aid him in prescription writing, but in pharmacology and therapeutics as well. It is only in this way that he can acquire the necessary self-confidence and skill. In this home practice, method and detail should be cultivated, for in these lies the secret of the art. The following rules may prove helpful:

Routine Construction of Prescriptions.—When writing a prescription for a given condition, put down, first, the name of the best remedy. Ask yourself whether there is any other drug which may be employed to aid or usefully modify this. Put this down also.

Then consider in which form the medicine should be administered, whether as liquid, powder, salve, etc. This will usually determine which preparation of the ingredient is to be employed. Put this down also.

Then ask yourself what may be added to render the mixture agreeable to the patient. Add the vehicle. When this is written, all the ingredients will be represented.

Now look over this carefully and see that there are no incompatibilities and that the constituents are soluble if the mixture is to be a liquid. Write the directions to the dispenser. Assure yourself that the prescription is grammatically correct (especially the endings).

Decide how many days the mixture is to be taken, and how many doses a day (on the basis of sixteen hours to the day). Decide whether the dose of the total mixture is to be a teaspoonful, tablespoonful, etc. By multiplying the total number of doses with the size of the single dose, ascertain the approximate size of the mixture. Round this off to a convenient figure. Multiply the single dose of each ingredient by the total number of doses (again reducing the quantities to round numbers, unless the constituent is very active). Check the doses. Write the directions to the patient. Consider whether a non repetitur is advisable. Affix your signature, the date, and the name of the patient. This finishes the prescription. Look over the result carefully in the same order.

It would seem almost superfluous to mention that it is extremely essential in writing prescriptions to use as legible handwriting as possible. It is astonishing, in view of the dire results that may follow, how often this self-evident rule is disregarded. The same remarks apply to abbreviations. While it is justifiable to employ abbreviations even extensively, it is necessary to make these in such a way that they can not possibly be misinterpreted. It is, therefore, advisable to employ the official abbreviations which are given under the "Preparations."

An efficient aid in acquiring practice in writing prescriptions is to look over a druggist's prescription file, when this may be done.

The copying of a prescription, ingredient for ingredient and dose for dose, is as much empiricism as the use of any other ready-made compound. The physician should be well enough educated to devise his own

---

One may also write the quantity for a single dose, and state in the subscription the number of doses desired: "Take doses in 20, XX" (make so such doses).
PRESCRIPTIONS

Prescriptions and to select such ingredients as will best suit the special needs of the case in hand.

Simplicity in Prescription Writing.—Formerly the ingredients of a prescription were almost numberless. This was in the time of empiricism, and was simply an application of the idea that in a large mixture of substances there would probably be one which would do good. This was the so-called "shot-gun prescription." At present the tendency in prescription writing is to make the prescription as simple as possible. This avoids incompatibilities, and, what is more important, makes the action of the medicine more easy to watch and control. Especially, one should avoid to combine, in the same prescription, drugs which differ markedly in quickness of action, absorption or elimination; or habit-producing drugs with others that will presumably be used for long periods.

If the prescription includes a number of mixtures, each containing several ingredients, such as the numberless preparations now put on the market by many firms, the result is, of course, as much a "shot-gun" prescription as if the prescriber had enumerated all the ingredients.

Pharmacology (Doses).—The dosage of drugs must be adapted to the individual patient. The Pharmacopoeia states "Average Doses" (adult) for each preparation that is likely to be used internally; but these are not intended to be binding on physicians. They are, however, convenient approximations for memorizing. The metric and apothecaries' doses in the U.S.P. are not intended as mathematical equivalents, but represent rather the quantities that would be used by prescribers in these systems.

The doses of crude drugs are given mainly as a basis for calculating the preparations.

Maximal Doses.—The pharmacist is supposed to check the quantities of the ingredients, and not to dispense a prescription containing an unusual dose of a powerful poison without convincing himself that the physician prescribed this intentionally. While this does not in any way lessen the responsibility of the physician, it is a safeguard which deserves all encouragement. To avoid delay, it is customary to mark large doses in such a way that the pharmacist will have no doubt that they are intentional. Thus:

Tr. aconiti, 3f or 3f.; or 3f Q. R. (quantum rectum), the last being the best.

Most foreign pharmacopelias (but not the U.S.P. or B.P.) give tables of "Maximum Doses," not with the purpose of restricting the physician, but as a guide to the pharmacist. The latter is not permitted to dispense doses larger than these, unless the physician indicates specifically (as explained above) that the larger doses are intentional. The maximum doses in this book are taken from the compilation of the U.S.P. Digest, 1917, pp. 40-42.

Table of Maximal Doses.—An extensive table based on the data of foreign pharmacopelias is given by Wilbert, 1917 (U. S. Hyg. Lab. Bull. 107, p. 23).

PRESCRIPTION LATIN

It is customary, but not compulsory, to write the inscription, and often the subscription, in Latin. It is assumed that the student who intends to use this language is fairly familiar with its grammar. The following is intended merely to recall some of the more important facts.
Advantages of Latin.—The use of the Latin names of drugs is generally urged because they are more definite and concise, and less liable to change than common names; and because they serve to keep the patient in ignorance of the nature of the drugs. This is sometimes desirable, /t/, to guard against drug habits. However, the official English names are equally definite; and as either names are usually abbreviated, there is little difference. As a matter of fact, less than 5 per cent. of the U.S.P. “Latin” names are really Latin (Oldberg, 1910). In the directions to the dispenser, Latin has no advantage, except in the brevity of the customary abbreviations. Indeed, unusual Latin terms are apt to lead to mistakes. The discarding of Latin in prescription writing is being actively discussed (Fanus, 1916).

Grammatic Rules.—The superscription, R (recipe: “take thou”), requires the name of the substance to be in the genitive, if the quantity is given, the quantity itself being in the accusative (the latter is, of course, very rarely written out in full). When the quantity is not given, the name of the substance is to be placed in the accusative. Adjectives agree with their nouns in gender, number, and case. These rules will generally be understood by translating into English: e.g., Take thou of tincture of aconite 1 ounce.

The following rules for the formation of the genitive case will be found valuable (“Mann’s Manual”):

**Rule 1.** All nouns ending in a, form the genitive in e; as Quinina, Quinquina. Exceptions: Aspidosperma, Physostigma, and Theobroma form the genitive in atis. Folia is plural; genitive, follicum.

**Rule 2.** All nouns ending in us, um, or, on, form the genitive in i; as Conium, Conili. Exceptions: Rhus, gen. Rhoid; Flos, gen. floritis; Erigeron, gen. Erigeronatis. Fructus, Corus, Quercus, Spiritus do not change.

**Rule 3.** All other nouns of whatever termination make the genitive in s, or is. Elixir, gen. Elixiris.

Some lengthen the termination thus: 

| as, genitive | atis, as Acetas, | Acetas. |
| is, " | idis, as Anthemis, | Anthemidis. |
| " | ousis, as Pepo, | Peponis. |
| " | icles, as Cortex, | Corticis. |

There are a few exceptions. Asclepias, gen. Asclepiadis; Mas, gen. Maris; Phosphorus, Sulphur, etc., gen. Isis; Mucilago, gen. Mucilaginis; Solidago, gen. Solidaginis; Pulvis, gen. Pulveris, etc.

The following words do not change in their genitive: Azeredarch, Buchu, Cannabis, Catechu, Condurango, Corus, Curara, Cusso, Fructus, Digitalis, Hydrastis, Jaborandi, Kino, Matric, Quercus, Sassafras, Sago, Sinapis, Spiritus, Gambir, Sumbul.

The accusative is rarely employed. It is formed according to the following rules (Mann):

**Rule 1.** Nouns singular ending in a, are feminine, and make the accusative singular in um and the plural in as. Example: Drachmas, acc. sing. Drachmam, pl. Drachmas.

**Rule 2.** Those ending in um or us, make the accusative singular in um. The accusative plural of those in us is on, and of those in um is a. Those in as are masculine, those in um are neuter.

**Rule 3.** Those whose genitive ends in is, form the accusative in em, plural es.

Attention is also called to the fact that adjectives change their endings, a fact which the student is apt to forget.

The following prepositions are frequently used, and command the following cases:

| ad | to | accusative. |
| ana | of each | genitive. |
| cum | with | ablative. |
| in | into | accusative. |

1 From the Greek.
The following **Latin words and phrases** occur frequently in prescriptions (adapted from Mann):

- **ad**................................................. to, up to
- **ad libitum**.............................. at pleasure
- **adde**.............................................. add (thou)
- **ana** (α)................................................. of each
- **aqua bulliens**........................... boiling water
- "**fontana**"................................. spring water
- "**fervens**"................................. hot water
- **destillata**............................... distilled water
- **beneficio**................................. twice daily
- **bis** in **dies**............................ take, let him take
caepe, capiat.............................. a paper (medicated)
- **chartula**................................. a small paper for a powder
cibus............................................. food

- **cochlearis magnum**..................... a tablespoon
- "**parvum**"................................. a teaspoon
- **cola, colatus**............................ strain, strained
- **collyrium**................................. an eye wash
- **congus** (C.).............................. a gallon
- **cum**.............................................. with
- **dilute, dilutus**........................... dilute (thou), diluted
dimidius........................................ one-half
divide (Div.)................................. divide (thou)
dividendus...................................... to be divided
dividetur in partes aequales................ let it be divided into equal parts
dosis.............................................. a dose

- **extendetur supra**....................... spread upon
- **fac, fiat, fact (ft.)**.................. make, let be made, let them be made
- **fac tales doses**.......................... make such doses
- **filtrum**........................................... filter (thou)
- **gargarismo**............................... a gag
- **gutta, guttae** (gtt.).................. a drop, drops
- **haustus**........................................ a draught
- **hora**.............................................. an hour
- **hora soli**..................................... just before going to sleep
- **hora decumbitus**........................ at bed time
- **in diem**....................................... daily
- **initio**............................................ like (with genitive)
- **libra** (lb.)................................. a Troy pound
- **mene primo**............................... very early in the morning
- **magnus**........................................ large
- **mense** (M.)................................. as directed
- **non repetat**.............................. do not repeat
- **númerus, numero** (Num.).............. a number, in number
- **scutarius** (O.)........................... a pint
- **ovum**............................................ an egg
- **pen**.............................................. a part
- **partes aequales** (P. æ.).............. equal parts (governs genitive)
- **persus**........................................ small
- **pilus** (pil.)............................... a pill
- **po po nata** (p. r. n.)................ according to circumstances, occasionally
- **pulvis (gen., pulveris)**............... a powder
- **quantum sufficit** (q. s.)............ as much as is necessary
- **quaque hora**.............................. every hour
- **quattuor semissae** (sq.).............. a half
- **signa**.......................................... sign
- **sin**.............................................. without
- **squis sit**..................................... a half
- **solvit**........................................... dissolve, dissolved
- **solutus**....................................... a solution
- **solutio**....................................... a solution

**PREPARATIONS—RED COLORS**

Tr. Cocci, B.P.—10 per cent. Dose, 0.2 to 0.1 c.c., 5 to 15 minims, B.P.

Carmineum, Carmine.—A precipitate obtained from decoction of cochinella by alum or cream of tartar. Soluble in alkalies, brightened and precipitated by acids. Also soluble in alcohol. Contains carminic acid. Used in powders, etc. (s: g00).

Liquor Carminii (Liq. Carm.)—A glistening extract of carminii. Pink to deep red in alkaline solutions, precipitated by acids. Used in the proportion of about 1 per cent.

Tr. Cardamomi Co. (Tr. Card. Co.)—An aromatic alcoholic (50 per cent.) vehicle, colored with cochinelle. Used undiluted (see Index).

Tr. Persimons (Tr. Persimmon.) Tinct. of Cudbear (a lichen allied to ltmun).—Red in neutral or acid, purplish in alkaline solutions. Used in the proportion of about 1.5 per cent.

**PREPARATIONS—BROWN COLORS**

Caramel is a concentrated aqueous solution of carbonized sugar. Commercial caramel is generally made by heating glucose with a little alkali, until the sweet taste is destroyed and a uniform dark mass results. It is probably a complex mixture. Caramel from cane-sugar according to Stolle, 1892, is a single substance, C₁₂H₁₀O₁₁, formed by the elimination of two molecules of water from sucrose. Caramel is being tried in diabetes, being apparently well tolerated (Griff. 1914; Umbir, 1915).

* Fldct. Glycyr rhize and * E11i. Glycyrh. (see Index).

1 The preparations of each class are generally arranged alphabetically under the crude drugs. The important preparations, which the student is expected to study, are marked *. In addition to these, he should glance over the corresponding crude drugs.
FLAVORS

PREPARATIONS—YELLOW COLORS

*Crocus*, Saffron, has been used as abortifacient; but it apparently lacks this action and is practically non-toxic (Cevialdi, 1924).

*Tr. Curcumae* (Tr. Curcum.) (Turmeric) precipitates with water, but sufficient remains in solution to impart a yellow color. Used in ratio of 1 per cent. Curcuma changes to reddish brown in alkalies.

*Tr. Hydrastis* (Golden Seal) is used similarly (see Index).

FLAVORING

This subject, although often neglected, is quite important. It not only humors the patient and secures more conscientious compliance with the prescription, but also often aids absorption and digestion—just as condiments do in foods.

Patients often fail to take a disagreeable medicine, and the physician should always be on the lookout for such cases. He should approximately control the amount taken by judging as to the quantity left in the container, as he should also, in general, control the medicine dispensed by the druggist as to its appearance and taste.

Some patients carry the deceiver further and pour away the appropriate amount of the medicine, and if the physician does not obtain the anticipated results, it may be well to prescribe some test medicine, such as salt (0.5 gm.), or potassium iodide (0.5 gm.), which can be detected in the urine.

Improving the Taste of Liquid Medicines.—This may be done by dilution; sweetening; demulcents; aromatics; alcoholics; acids; bitters; and drugs which paralyze the taste-endings. Several of these means are often combined.

Simple Dilution.—This is often most effective for salts, alkalies, choral and other hypnotics; and in general, substances with disagreeable but not very marked taste. These should be taken in a half-glass or glass of water, milk, tea, or carbonated water.

The Most Important Flavors.—The following will be found to be generally sufficient:

To disguise bitter taste: Aromatics (Tr. Cardamomi Co.; Elixir Aromaticy, Syr. Aurantii); for children, Glycyr rhiza, Aq. Anisi, Syr. Tolitanaus.

To disguise acid taste: Aromatics as above; also syrups, acacia, acid flavors (Syr. Auranti.).

To disguise salty or alkaline taste: Dilution with simple or carbonated or aromatic water or milk.

To disguise oily taste: Aromatics (Oil or Spirit of Peppermint, lemon, orange, wintergreen or almond, according to personal preference).

*For insipid drugs: Aromatics and acids (Syr. Aurantii).*

PREPARATIONS—SUGARS AND HONESYS

*Saccharum* (Sacch.), U.S.P. | *Saccharum Purificatum* (Sacch. Pur.), B.P.; Sugar (Can or Beet), C_{12}H_{22}O_{11};—Very sol. in water (1:95); slightly in alk. (1:700). Used for sweetening powders; for the administration of volatile oils (eleoanacharr), and the preparation of syrups, elixirs, etc.

*Sugar Substitutes.*—In cases where sweetening is desired and sugar is excluded, particularly in cases of diabetes, the artificial synthetic product *saccharin* may be substituted. It is about 300 times as sweet as sugar, but the taste is not exactly the same.

The following abbreviations will be used in connection with solubilities. Alc. = alcohol; eth. = glycerin; eth. = ether; chlor. = chloroform. The figures refer to the parts of the solvent (water) to dissolve 1 part of drug (4:1 = 1 part of drug dissolved in 4 parts of solvent). The activities refer to 25°C. (room temperature), unless otherwise stated.
same. The dose for a cup of coffee or tea is about 1/2 to 1 gm. Glucosin is another sweetening substance which does not contain sugar, and is sometimes employed in place of saccharin. A principle of quite a different kind is the glucoside of glycyrrhiza. This acts only in alkaline liquids. It has no taste if the liquid is made acid.

Many other substances have a sweet taste. Attempts to connect this with the chemic structure (Haycraft, 1852; Sternberg, 1868) have not been very successful.

*Saccharum Lactic (Sacch. Lact.), U.S.P., B.P., Sugar of Milk (Lactose); CaH12O11.5H2O—White, hard, crystalline masses, or white powder, feeling gritty on the tongue; odorless; faintly sweet taste. Freely sol. in water (1: 4.0); almost insol. in alc.

Glucosum (Glucos.), U.S.P., B.P., Glucose (Syrupy)—The product obtained by the hydrolysis of starch, consisting chiefly of dextrose, maltose and dextrins. Colorless, or slightly colored, thick, syrupy liquid. Very sol. in water, sparingly sol. in alc.

It is used as a food and is apparently not deleterious. White rats have consumed commercial glucose in quantities equivalent to 200 grams per man, daily for six months, without bad effects (Carlson et al., 1916).

*Syrupus, B.P.—Glucose 1, syrup 2.

Dextrose, N.N.R.—Prepared artificially by the action of dilute acids on starch; is sometimes used as nutrient (to 180 Gm., 6 ounces daily); and as an addition to saline infusion liquids (0.1 per cent.).

Oxymel, B.P.—Honey with 1/4 acetic acid. Dose, 2 to 8 c.c., 1/2 to 2 drams.

Mel Rose, U.S.P.—Honey of Rose.—Fistula; 1, Honey, 7.

Fistula, R. U.S.P.—Dose, 2 c.c., 30 minims, U.S.P.

Syr. Rose (Syr. Ros.), B.P.—Dose, 2 to 4 c.c., 1/2 to 1 dram, B.P.

Rhamnus Petala, B.P.—Red Poppy Petals. Syr. Rham., B.P.—Dose, 2 to 4 c.c., 1/2 to 1 dram, B.P.

PREPARATIONS—FLAVORING SYRUPS

*Syrupus (Syr.), U.S.P., B.P.; Syrup—A strong aqueous solution of sugar containing 85 Gm. of sugar in 100 c.c. of syrup, U.S.P. (66.7 Gm. in 100 Gm. of syrup, B.P.). Miscible with water or alcohol. It is more commonly employed in the form of the flavored syrups. Their dose is ad libitum.

*Syrupus Acidis Cirtici (Syrac. Acid. Citr.), U.S.P.—A per cent. solution of citric acid, flavored with sugar and lemon peel.

Limonis Cories (Limon. Cory), U.S.P., B.P.—Lemon peel (fresh).

Ok. Limon., U.S.P., B.P.—A volatile oil obtained by expression from the fresh, ripe peel of Citrus medica var. Limonum. Dose, 0.2 c.c., 3 minims, U.S.P.; 0.03 to 0.18 c.c., 1/4 to 3 minims, B.P.

Syr. Limon, B.P.—About 50 per cent. of lemon juice, flavored with lemon peel.

Tr. Limon. Cort., U.S.P.—50 per cent.

Tr. Limon., B.P.—25 per cent. Dose, 2 to 4 c.c., 1/2 to 1 dram, B.P.

Inf. Aurantii, B.P.—1 per cent. Dose, 15 to 30 c.c., 1/4 to 1 ounce, B.P.

Inf. Aurantii Co., B.P.—25 per cent., with lemon and cloves. Dose, 15 to 30 c.c., 1/4 to 1 ounce, B.P.

Ok. Aur., U.S.P.—Dose, 0.2 c.c., 3 minims, U.S.P.

Dose, 2 to 4 c.c., 1/2 to 1 dram, B.P.

Tr. Aur. Amar., U.S.P., 20 per cent. Tr. Auranti, B.P., 25 per cent.—Dose, 4 c.c., 1 dram, U.S.P.; 2 to 4 c.c., 1/2 to 1 dram, B.P.

Vin. Aurantii, B.P.;

Aq. Aur. Flor. Fort., U.S.P.—The saturated aqueous distillate prepared by distilling the fresh flowers of Citrus Aurantium amara with water.

Syr. Aur. Flor., U.S.P.; Syr. Aurantii Flor., B.P.; Syrup of Orange Flowers.—Dose, 1 to 2 c.c., 1/2 to 1 dram.

*Elixir Aromaticum (Eliz. Arom.), U.S.P. (Simple Elixir).—Syrup containing about 12 per cent. of alcohol and flavored with aromatics (Comp. Spir. Orange).

Syr. Aromat., B.P.—Flavored with orange and cinnamon. Dose, 2 to 4 c.c., 1/2 to 1 dram, B.P.

Glycyrrhiza (Glycyrrhiza), U.S.P.; (Glycyrrh. Rad., B.P.—The dried rhizome and roots of Glycyrrhiza glabra typica, Spanish Licorice, or of Glycyrrhiza glabra glandulifera, Russian Licorice. Dose, 2 Gm., 30 gr., U.S.P.

Fluidextractum Glycyrrhize (Fidext. 1; Glycyrrh. Fr., B.P.; Ex. Glycyrrh. Liq., B.P.—An extract of Glycyrrhiza (licorice root), preserved with 25 per cent. of alcohol. The U.S.P. contains some ammonium to dissolve the sweet glucosid, Glycyrrhetin. This is precipitated by acids, which are therefore incompatible. It is miscible with water or alcohol. Mixed in the proportion of 1:7 with syrup or elixir, it is a good vehicle for quinin, etc. Dose, 2 c.c., 30 minims, U.S.P.; 2 to 4 c.c., 1/2 to 1 dram, B.P.

Glycyrrhizin belongs to the saponins, although it does not have the typical formula and does not hemolyze (Kohert, 1911; he also describes a new chemical test). The bark infusion contains resin. Composition: Houseman, 1916.

*Syryr. Glycyrrh.—Fidext. 1; Syrup 7.

Glycyrrhizinum Armonionum (Glycyrrhiz. Armonon.), U.S.P.—Dark brown or brownish-red scales, without odor, and having a very sweet taste. Freely sol. in water and sol. in alc. Dose, 0.25 Gm., U.S.P.

*Syr. Toluta (Syr. Tolut.), U.S.P.; Syr. Tolut, B.P.—Prepared from Tolut Balsam. Dose, 15 c.c., 4 dram, B.P.; 2 to 4 c.c., 1/2 to 1 dram, B.P.

Vanillinum, U.S.P.; Vanillin. Methylprotocatechuic aldehyde (C₆H₅-OH-OCH₃-COH)

—Fine, white, crystalline needle-shaped odor and taste of vanilla. Sol. in water (1:100), freely sol. in alc. glyc. or eth. Dose, 0.05 Gm., 1/2 gr., U.S.P.

AROMATIC WATERS, SPIRITS AND OILS

Aromatic Waters.—These are miscible with water or alcohol. Their dose is ad libitum.

Aromatic Spirits.—These are used in alcoholic and oily liquids, in the proportion of 2 per cent. They are immiscible with water.

Aromatic Oils.—These may be used for flavoring alcoholic or oily liquids, in the proportion of 0.2 per cent. However, the spirits are generally preferred.

Aromatic Tinctures.—These are used similarly to the Spirits. None of the simple tinctures are especially important.

Some flavors, such as Gaultheria, etc., have also more important actions, and will not be discussed here.

Anisum (Anis), U.S.P.; Anis. Fruct., B.P.—The dried ripe fruit of Pimpinella bulgarum. Dose, 0.5 Gm., 8 gr., U.S.P.

Sp. Anis., U.S.P., B.P.—10 per cent. Dose, 2 c.c., 30 minims, U.S.P.; 0.3 to 1.2 c.c., 5 to 10 minims, B.P.

Oli. Anis., U.S.P., B.P.—The volatile oil. Dose, 0.2 c.c., 3 minims, U.S.P.; 0.03 to 0.05 c.c., 5 to 10 minims, B.P.

Paniocum, U.S.P. (Fennel seed).—The dried ripe fruits of cultivated varieties of Foeniculum vulgare. Dose, 1 Gm., 15 gr., U.S.P.

Ol. Fumic, U.S.P.—The volatile oil. \textit{Dose}, 0.2 c.c., 3 minims, U.S.P.

\textit{Fenchon} is a constituent of fennel oil. It is isomeric with camphor, but is liquid. It is used as a counter-irritant, as such or diluted with alcohol; to 1 : 10 (Schlesinger, 1914).

\textbf{Anethi fructus}, B.P.—Dill Fruit. From Peucedanum graveolens.

\textit{Aneth, B.P.—Dill Water.}

\textit{Aneth, B.P.—Volatile oil. \textit{Dose}, 0.03 to 0.18 c.c., \frac{1}{4} to 3 minims, B.P.}

\textit{Ag. Carvi, B.P.—Caraway Water.}

\textit{Ol. Carvi, U.S.P.; Ol. Carvi, B.P.—Volatile oil. \textit{Dose}, 0.2 c.c., 3 minims, U.S.P.; 0.03 to 0.18 c.c., \frac{1}{4} to 3 minims, B.P.}

\textit{Ol. Ajowan, B.P.—Volatile oil of fruit of Carum copticum. \textit{Dose}, 0.03 to 0.18 c.c., \frac{1}{4} to 3 minims, B.P.}

\textit{Cinnamosum Zeylanicum, U.S.P.; Cinnam., B.P.; Ceylon Cinnamon.—The dried bark of cultivated trees of Cinnamosum zeylanicum. \textit{Dose}, 0.25 Gm., 4 gr., U.S.P.}

\textit{Ol. Cassia, U.S.P., Ol. Cinnamon, B.P.—A yellowish or brown volatile oil distilled from the bark of Cinnamosum Cassia, U.S.P.; zeylanicum, B.P. \textit{Dose}, 0.2 c.c., 3 minims, U.S.P.; 0.03 to 0.18 c.c., \frac{1}{4} to 3 minims, B.P.}

\textit{Pulv. Cinnamonum, B.C., B.P. (Pulvis Aromaticus)—Equal parts of Cinnamon, Cardamom and Ginger. \textit{Dose}, 0.6 to 4 Gm., 10 to 60 gr., B.P.}

\textit{Sp. Cinnamon., U.S.P., B.P.—10 per cent. of oil. \textit{Dose}, 2 c.c., 30 minims, U.S.P.; 0.3 to 1 c.c., 5 to 30 minims, B.P.}

\textit{Tr. Cinnamon, U.S.P., B.P.—20 per cent. of the bark. \textit{Dose}, 2.5 c.c., 30 minims, U.S.P.; 2 to 4 c.c., \frac{1}{4} to 1 dram, B.P.}

\textit{Cinnamonum Saigonicum, U.S.P.—The bark of an undetermined species of Cinnamon. \textit{Dose}, 0.25 Gm., 4 gr., U.S.P.}

\textit{Oliveri Cori, B.P.—The bark of Cinnamon. Oliveri.}

\textit{Tr. Oliveri Cori, B.P.—10 per cent. \textit{Dose}, 2 to 6 c.c., \frac{1}{4} to 1 dram, B.P.}

\textit{Oleum Sasafras (Ol. Sassafr.), U.S.P.—A yellow or reddish yellow volatile oil distilled from Sassafras root. \textit{Dose}, 0.2 c.c., 3 minims, U.S.P.}

\textit{Aqua Rose (Aq. Ros.), U.S.P., B.P.; Rose Water.—A 50 per cent. dilution (33 per cent, B.P.) of Stronger Rose Water.}

\textit{Aqua Rosa Fortis, U.S.P.—Prepared by distilling the fresh flowers of Rosa centifolia with water.}

\textit{Ol. Ros., B.P. (Otto of Rose).—The volatile oil of the fresh flowers of Rosa damascena.}

\textit{Ol. Granatini Citri, B.P.—Oil of Lemon Grass. \textit{Dose}, 0.03 to 0.18 c.c., \frac{1}{4} to 3 minims, B.P.}

\textit{Ol. Coriandri (Ol. Coriand.), U.S.P., B.P.—Volatile oil. \textit{Dose}, 0.2 c.c., 3 minims, U.S.P.; 0.03 to 0.18 c.c., \frac{1}{4} to 3 minims, B.P.}

\textit{Coriandrum, U.S.P.; Coriand. Fruct., B.P.; Coriander.—The dried ripe fruit of Coriandrum sativum. \textit{Dose}, 0.5 Gm., 8 gr., U.S.P.}

\textit{Pinctura Cardamomi Composita (Tr. Cardam. Co.), U.S.P., B.P.—1 per cent. of Cardamom, with Cinnamon, Caraway and Cochiniels, in 50 per cent. alcohol, U.S.P. \textit{Dose}, 4 c.c., 1 dram, U.S.P.; 2 to 4 c.c., \frac{1}{4} to 1 dram, B.P.}

\textit{Tr. Card., U.S.P.—15 per cent. in 50 per cent. alcohol. \textit{Dose}, 2 c.c., 30 minims, U.S.P.}

\textit{Cardamomi Semen, U.S.P., B.P.; Cardamom Seed.—The dried seeds of Elettaria Cardamomum. \textit{Dose}, 1 Gm., 15 gr., U.S.P.}

\textit{Tr. Lavand. Co., U.S.P., B.P. (Compound Spirit of Lavender).—Lavender, Rosemary, Cinnamon, Clove, Myristica, Red Saunders, in 72 per cent. Alcohol, U.S.P. \textit{Dose}, 2 c.c., 30 minims, U.S.P.; 2 to 4 c.c., \frac{1}{4} to 1 dram, B.P.}

\textit{Spir. Lavand., 5 per cent. of oil, U.S.P.; 10 per cent., B.P. \textit{Dose}, 2 c.c., 3 minims, U.S.P.; 0.3 to 1.2 c.c., 5 to 30 minims, B.P.}

\textit{Ol. Lavand., U.S.P., B.P.—A volatile oil distilled from the fresh flowering tops of Lavandula vera. \textit{Dose}, 0.2 c.c., 3 minims, U.S.P.; 0.03 to 0.18 c.c., \frac{1}{4} to 3 minims, B.P.}
TREATMENT OF DISEASES

ERIODICTYON (YERBA SANTA)

The leaves of this plant disguise bitter taste (not sweet, salt or acid taste). It is, however, therapeutically objectionable. It probably renders alkaloids insoluble, and as for ordinary bitters, it is extremely probable that the therapeutic action is connected with the bitter taste. One c.c. of the fluidextract covers the taste of 0.012 Gm. of quina sulphate or 1.5 Gm. of quassia.

Similar properties are found in the following plants: Gymnema sylvestre; Bulnesia dulcisca, and Phrynium Danielli. Gymnema contains gymnemic acid, which destroys bitter and sweet taste, not acid or salt.

PREPARATIONS

Eriodictyon, U.S.P. (Yerba Santa).—The dried leaves of Eriodictyon californicum (Composition, Tutin, 1910). Dose, 2 Gm.; 15 gr., U.S.P.

THE TREATMENT OF DISEASE

Development of Therapeutics.—A glance at the history of therapeutics, the treatment of disease, will serve to explain errors which have long adhered and which still adhere to the subject.

We may imagine one of our remotest ancestors brought face to face with disease. How mysterious must have seemed to him the phenomenon that to-day he is strong, active, and full of life, and to-morrow, without any cause apparent to him, he is weak, listless, and about to die! What strong hold it must have taken upon his untutored imagination! How earnestly he must have sought for means to remedy it! Here he happened at once upon two apparently very different methods: a spiritual and a material. On the one hand, overpowered by the mysteriousness of the process, he lost himself in superstition. He deemed the disease due to malevolent spirits which could be appeased by prayers and incantations. This formed the principal materia medica of prehistoric ages, as it does of the modern savage. It still survives in a modified form as a "Christian Science".

On the other hand, chance and the observation of animals revealed to him that certain material products were also efficient. As long as he limited himself to actual observation, the results were usually good. However, he soon began to search for more of these remedial agents. We must remember the total ignorance which then existed regarding the nature of the action—both of the disease and remedy. In this darkness he was only too glad to be guided by any ray of light, without having the means to examine whether the light came from a beacon or was only an ignis fatuus. With the fantastic, half logical incomprehension so characteristic of the untutored mind he assumed the most extraordinary relations.

It is interesting to observe a little closer the principles which guided the blind savage in his search for remedies. Having found that most active medicines had a bitter or disagreeable taste, he came to regard any such substance as beneficial. Thus arose a host of simples most of which might now be disregarded were it not that some zealot occasionally disturbs their repose and attempts to launch them as something new.

Nor did this love of the disgusting die out with the stone age. It was prolonged far into the middle ages. To it we can probably trace the employment of feaces and urine, of smoked snake, and of others still worse.

At a later period of the middle ages it was tried to combine the spiritual and the material treatment. It was thought that the Deity alone could cure disease, but that he had given man material remedies, and in His wisdom He had put a seal upon them by which man might know them. Thus arose in due time what is called the doctrine of "signatures." According to this, the use of a remedy was suggested by a fanciful resemblance in shape or color to some organ; e.g., the liverwort, the lungwort, bloodroot, etc. Even a name was sufficient. Silver was used in lunacy because it was dedicated to Luna.

On the other hand, alchemists had arisen with their pertinacious search for the philosopher's stone, which was to convert all metals into gold, and cure all diseases. In this search they gave their onstrue extensive trial on sick and well.

It would appear that the native Chinese materia medica is largely based on the doctrine of signatures.
The school of spagists was founded toward the end of the fourteenth century and reached its zenith with Paracelsus. They insisted upon the mystical virtues of salmmony, arsenic and silver and chemicals in general, and stood opposed to the old Galenists, who used only organic drugs. Notwithstanding their mysticism, which savors of quackery, we must thank them for the discovery of some valuable medicines.

Thus, a mass of materials, rubbish and otherwise, was added to the various simples, etc. Having so well-stocked an armory, the physician of that day did not feel that he was not doing his duty unless he gave his patient the benefit of it all, and the “shot-gun” prescription flourished at its best.

The Homeopathic Doctrine.—A natural reaction against this excessive drugging set in, and had for one of its first results the establishment of homeopathy by Hahnemann, near the end of the eighteenth century. The Hahnemann system was by no means new. For the most part it had its roots much further back. It was the natural result of the then existing theory of “vitalism.”

Hahnemann believed that disease depends upon a perversion of the purely spiritual vital powers and is entirely immaterial in its nature. Logically, a thing spiritual could not be combated by material remedies, and, hence, Hahnemann turned to a spiritual power which he believed to be bound up in plants and liberated by dilution. The activity would therefore increase with the dilution, and be the greater, the smaller the dose (doctrine of potency). This liberation of the principles exactly turned their action around, so that the action of his dilutions was, he stated, exactly the opposite of that of the concentrated drug, and could be used for the relief of such symptoms as the latter produced: Similia similibus curantur. This was the first tenet of Hahnemann. The second was that the nature of the disease being uneasiable, it was not subject to treatment, but that only its symptoms can be treated. Hence, homeopathy, in so far as it follows the principles of its founder, has no place for the medical sciences, such as physiology, anatomy, pathology, or chemistry. Any one with an indexed book of symptoms and their remedies would be able to practice it without an elaborate study or preparation.

In marked contrast to the above is the third dictum: that the medicinal treatment must be supported by dietetic and hygienic measures.

The claims of homeopathy as a rational system hinge on the proof of the similia similibus theory and of the doctrine of potentiation by dilution. Most of its advocates seem to deny altogether the relevance of scientific testimony, and to base themselves purely on the slippery ground of empirical experience. Others, however, while they carefully neglect the great body of scientific experience which disproves their theory, seem very glad to avail themselves of the few experimental facts, which, through a variety of logical contortions and sophistications, can be twisted into a specious support. Hahnemann himself seems to have started from the observation that large doses of drugs produce the opposite effects from moderate doses. The correctness of this principle may be granted, for many cases. But it is a very unwarranted feat of logic to assume that infinitesimal doses must again cause effects opposite to those of moderate doses.

The more recent discovery of the effect of dilution on electrolytic dissociation, on ionization, has also been seized upon as illustrating homeopathy—quite disregarding the fact that the action depends on the number of ions rather than on the degree of ionization; and the further fact, that the majority of the substances employed in homeopathy are not electrolytes at all! These few examples of inconsistencies may suffice.

Hahnemann’s system was the natural outgrowth of his time. At present it is an anachronism, as his pupils acknowledge in practice, if not in words. But in his time Hahnemann accomplished considerable for medical science. He called attention to the importance of diet, etc., when this was only too much neglected; but perhaps the principal use of homeopathy has been to show to rational medicine the fact that disease tends to recovery without any medical interference.

Therapeutic nihilism.—This was, indeed, the next step which medicine took—total emancipation from all drugs. This dates from the establishment of the Vienna school by van Swieten, in 1745. The strongest advocate of nihilism was Skoda (1805-1881), the founder of the methods of percussion and auscultation. Such nihilism was absolutely necessary at that time, just as periods of skepticism are necessary in philosophy, and mark steps in progress. The accumulated refuse was so great as to bury the good. The only way was to empty out the whole and begin anew. This was a necessity then, but now consistent nihilism is as obsolete as the “Shot-gun” prescription.

The rise of Rational Therapeutics.—The reestablishment of therapeutics, founded new upon reason, was thus aided by the very man who had attempted to destroy it. For he established physical methods of diagnosis, and demonstrated the effects of
TREATMENT OF DISEASE

disease as they had never been demonstrated before, making it possible also to demonstrate the effect of remedies.

Then followed the isolation of active principles (led by the discovery of morphin in 1817), thus substituting the definite for the indefinite drugs. Finally followed animal experimentation, by means of which modern pharmacology has developed.

Services of Pharmacology.—This has made possible a much more exact knowledge of the action of drugs, without which their employment would be a matter of mere chance. It also made available much more accurate methods of observation, and established standards by which therapeutic trials must be conducted. It led to the introduction of the great number of synthetic drugs, some of great usefulness, because they pointed out the directions in which new drugs could be sought with most success. It furnished the means of trying their actions and probable usefulness on animals, when their use on man would not be justified without these preliminary trials. It has also contributed to the development of experimental pathology, and thus laid the foundation of experimental therapeutics—the experimental investigation of the action of drugs.

Psychotherapy.—Rational therapeutics is now on a firm basis. But, at the same time, the mystic has also been further developed, not only in homeopathy, but also in the many forms of suggestion. The value of suggestive therapeutics proper cannot be denied. It is a strictly scientific method of treatment, and is employed in its milder forms by every physician as "the personal influence" and the "faith in doctor and medicine." It often constitutes all there is of merit in those medical fads which have accompanied medical science since the oldest time.

Vis Medicatrix Nature.—It is most important to the rational treatment of disease that the physician should understand that he cannot directly make a patient well. That is exclusively nature's task. Physiologic functions tend to run their normal course, or to return to it if they have been disturbed. "Nature," therefore, tends very strongly to bring the organism back to its normal conditions, or life would long since have disappeared from the globe. The task of the physician consists in directing his treatment in such a manner as to remove obstacles from nature's path.

Just as the surgeon can not cause the union of a broken bone, but can only put it in the most favorable condition for nature to perform this union—i.e., set it—so the physician cannot cure heart disease. He may either remove the condition which causes it, if still present, or remove by digitals, etc., the factors which retard the cure; but in any case he must rely upon nature to perform the last, the really important act: viz., the permanent return to normal.

That nature not only puts the final touch upon every reparative process, but that she may take every step as well—i.e., that a patient may get well without any medical interference—is too well known to require further discussion. The ways in which these processes of repair take place constitute one of the departments of pathology and medicine.

The Field of Therapeutics.—In the light of the above, it might well be asked: If nature is thus able to effect cures; if the greater number of diseases tend to spontaneous recovery, what is the function of the physician? Can he do anything but harm if he attempts to meddle with the processes of nature? If he undertakes to aid, does he not really meddle? We must, in examining this question, lay the emphasis in the right direction, as at the present, we are at fault quantitatively. Nature may do too much or too little. It is now conceded that fever, pain, inflammation, etc., are protective mechanisms; but when the fever becomes so high as to be itself dangerous to life; when the pain is intolerable and constant, and persists after it is no longer needed; when the inflammation spreads; then it is evident that the original salutary process is becoming the reverse. That the processes of nature are often insufficient is evident from the fact that they do not in all cases effect a cure. Nature may sometimes be absolutely wrong; e.g., the desire for solid food in typhoid.

It is then, the duty of the physician judiciously to modify the natural tendency, if he possesses the means of doing so. But he must do so wisely, or it were better not at all. He must understand the diseased condition; he must understand nature's way
of meeting the difficulty; he must judge in what ways nature may be supported; and, finally, he must thoroughly understand the means at his command for the purposes, i.e., pharmacology. As long as he is not clear in regard to these factors, he is merely groping in the dark, as likely at least to do harm as good. In this case expectant treatment is alone justifiable. 

Preventive or Prophylactic Treatment.—This aims to protect the body from disease. It comprises individual and community hygiene.

Etiologic, Causal or Curative Treatment.—The cure of disease is scarcely possible while the original cause persists. The physician must therefore always aim to discover and remove that cause. If this can be done, the conditions will generally return to the healthy normal unless anatomic lesions have already occurred. The chances for complete recovery are therefore the better, the earlier effective treatment is instituted. However, even considerable anatomic deficiencies can be compensated by the fact that the organism has large "factors of safety" (Meltzer).

Symptomatic, Functional or Alleviative Treatment.—When the cause of the diseased condition cannot be attacked, it is often possible to remove its functional manifestation or symptoms. This may be useful in some cases, objectionable in others.

In striking the symptoms one very often also strikes the disease. The symptoms in themselves may be so objectionable or lead to such secondary results as to make their removal desirable. Pain, cough, and fever are all purely symptoms, and yet no one would refuse to treat them simply because unable to remove the root of the disorder. The derangement of function may be immediately threatening to life, f.e., cardiac dilatation; or it may add to the tax on the diseased organs, f.e., the edemas of valvular disease. It may also be relieved by increasing other compensating functions, f.e., diaphoresis in renal disease.

On the other hand, the symptoms may be very deceptive—a chill will not require external heat; a referred pain will not be relieved by local application of lodin to the place where it is felt. In removing the symptoms the physician also deprives himself of the only index to the treatment of the underlying disorder. He must constantly be on his guard against believing himself successful when he has succeeded in removing one or several of the symptoms of the disease. In many cases the symptom may itself be salutary; in which case it would not do to remove it (e.g., cough when there is hypersecretion of mucus; a certain amount of pain when rest is indicated in fracture).

It need scarcely be added that it is not ethical to persuade a patient that he is being cured when he is in fact only being relieved of the symptoms.

Restorative or Rohorant (Strengthening or Tonic) Treatment.—Disease generally impairs the vitality and resistance of the organs directly involved, and of the body at large. This is corrected by rest and efficient nutrition of the diseased organs and of the entire patient; and by correcting any other abnormal conditions (digestive disturbances, suppurations, etc.) which may be present, and which are added drains on the vitality of the patient.

Expectant Treatment.—This is the absence of any real attempt at treatment beyond hygiene, rest, diet, and other similar general measures; with the object of leaving the powers of nature free play. This should be employed in all cases where no better treatment is known; but, as has been said, it is usually within the province and power of the physician to support nature in her endeavor.

The expectant treatment must also be used when it is desired to let the disease progress to a certain point, if this is necessary for diagnosis.

Empiric and Rational Therapeutics.—The treatment of disease has developed by two different methods, or perhaps more accurately, attitudes.

\[\text{In this connection see S. J. Meltzer's essay on the Therapeutics of Self-Repair; Am. J. Med. Sc., July, 1908.}\]
of mind. The Empiric method follows merely the dictates of experience, without concerning itself about the reasons of these.

It is typified by the patent medicine slogan; "it has cured others and will cure you."
While in the present state of our science it is still necessary to employ it only too often, it requires scarcely a thought to see how often it may be not only useless, but even injurious. Conditions which resemble each other very closely superficially may really be diametrically opposite, and may require very different treatment. The objection to the empiric method is not that it rests upon experience, which is the basis of all science, but that it does not endeavor sufficiently to distinguish whether the experience is real or deceptive. It is, of course, an equally grave error to go to the opposite extreme, and to base treatment on theories and deductions inadequately supported by observation.

Rational or scientific therapeutics should employ observation, experiment and scientific reasoning, checking each against the others.

A real science of therapeutics, by which it would be possible to foretell the exact results is still largely a vision. The numerous physiologic and pathologic variables render predictions uncertain. The personal factor plays a large role; and the due ascertainment of this—"the art of therapeutics"—is therefore very important. However, the best results can only be secured by the critical application of all the known scientific facts.

Pharmacal and Non-pharmacal Therapeutics.—A distinction is sometimes made between "drugs" and "physiological agents," including under the latter physical measures, such as heat or cold, bathing or climate, rest, exercise and massage, diet, etc. The distinction is convenient, but not fundamental. The use of drugs is no more "unphysiologic" than the use of abnormal heat or cold, or of special diets, etc. The mechanisms of their action are not essentially dissimilar. Each is intended to produce definite changes of functions. One or the other may be better adapted to secure this end; and the physician should not hesitate to employ whichever is best suited.

Physiologic Processes Normally Controlled by Pharmacologic Agents.—The body normally produces a variety of pharmacologically active substances, as direct or by-products of its metabolism, and uses them as aids in regulating its own activity. The control of the respiration and the various other hormones and internal secretions are familiar examples in mammalian physiology (Starling, 1908). The use of drugs is therefore not an unphysiologic proceeding.

THE CHEMICAL AND PHYSICAL BASIS OF PHARMACOLOGY

Scope of Pharmacology.—The term Pharmacology in a general sense covers all scientific knowledge pertaining to drugs, i.e., to substances which may be used in the treatment of disease. Materia Medica, Pharmacognosy, and Pharmacographia have the same meaning when they are used in a general sense.

More commonly, however, the term "pharmacology" is used in a more restricted sense, as a synonym for pharmacodynamics. It concerns itself with the actions of drugs on living structures; or with the reactions occurring between drugs and living structures. It is therefore a branch of physiology on the one hand, of chemistry on the other; and is essentially a division of biology. It has important practical relations with toxicology (the science of poisons); and with therapeutics (the treatment of disease).

The Nature of Pharmacologic Action.—The processes of life are essentially conditioned on chemical and physical changes in the constituents of the cells. Foreign chemical substances may enter into these reactions,
and thus modify them more or less profoundly, with corresponding changes of function. These are termed drugs or poisons, according to whether they are useful or harmful in a given case. Some of the reactions are comparatively simple, analogous to those produced on isolated proteins. Others, however, occur only in living substance. Our limited knowledge of the chemical details of the living cell does not permit any deep insight into the nature of the action of these substances, except in a few directions. They suffice to show that the mechanism of the action of different drugs is not uniform, but is sometimes along chemical, and sometimes along physical lines. No sharp division can be drawn.

Physicochemical Conditions of Life.—The living cell may be considered as a very complex laboratory, where chemic decompositions and syntheses, reductions and oxidations, etc., are constantly going on. These chemic changes lead to transformations of energy which find their final expression in the phenomena of life. The vital manifestations of the cell are, therefore, inseparably connected with physico-chemic transformations, which require for their occurrence the existence of certain chemic and ical conditions. The chemic essentials are: the presence of substances capable of liberating energy, and the conditions suitable for their reactions, such as a proper temperature, alkalinity, presence of ferments, etc. The physical conditions of life are: A viscous medium, containing colloidal proteins, salts, fats, and water.

Ordinary Chemic Reactions.—In the simplest cases the actions occur on dead tissues, and resemble those produced on substances of known composition; this is the case with strong acids, alkalies, metals, etc.

Obscure Chemic Reactions.—In many cases, particularly with alkaloids, glucosids and toxins, the action is confined to the living cells; for most of these, no adequate explanation can be offered. It is very probable that many of these produce chemic changes in the protoplasm; but the evidence is suggestive rather than conclusive.

From the complicated structure of the protein molecules we conclude that it must be capable of a very great number of reactions, a conclusion which is confirmed by the large number of substances which are utilized by the cell. We find an expression of these chemic changes in the final excretory products of the cell; but we are very ignorant of the reactions by which these final changes are produced. When we find, therefore, that a chemic substance possesses actions for which there is no adequate physical explanation, we presume that it enters into chemic reactions with the protoplasm. This has been expanded especially in the side-chain theory of Ehrlich. This assumes that the poisons combine with certain groups (receptors) of the cell which are essential for its metabolism.

Evidence of Chemic Actions.—The theory of chemic combination is confirmed by the fact that most of the poisons (not all) are altered in the body; although it does not follow that the action is due to this particular change. The toxicity is often parallel to the chemical reactivity or liability of the poison. Other indications of chemic reaction are, that these poisons often accumulate in the cells; and that the effects generally increase with the dose. This would be expected with chemic reactions, but could also occur on physical grounds. In any case, the combination is often very loose and unstable, for the poison can often be removed by simple solvent (fix., antipyretics and fuchsin stain by alcohol, P. Ethyl). Indeed, the organism recovers promptly from most poisons when these are washed out, unless secondary changes have occurred. In some cases, the action seems to be produced only whilst the poison is passing into or out of the cell (Straub; Kuyer and Wijnenbeck, 1923). The action is then probably on the plasma membrane. The relation between the action and chemic constitution of poisons also speaks for chemic reactions, but may in some cases be explained by corresponding alterations of the physical properties. Compounds between alkaloids and proteins have been described; but it is not certain whether these are real combinations, or merely adsorption products (Eddy and Gies, 1907).

Modifications of Ferments.—Catalytic reactions, which are so important to the cell, may be modified by chemic reagents, without as well as within the cell. This explains the asphyxiant action of cyanides. Changes in the Cell Membrane.—Since most cells are in contact with surrounding fluids, they must be protected against changes of composition by a limited permeability of their surface layer, the cell wall or plasma membrane. This apparently contains lipid and protein constituents. It may, therefore, be altered by fat-solvents, or by agents which either precipitate or liquefy proteins. This explains, at least partly, the
effects of lipotropic remedies; hemolysis by these, by alkalies and saponins; the actions of various ions, especially Ca, etc.

Osmotic Changes.—Cells are generally much more permeable to water than to dissolved substances. This leads to osmotic phenomena—the withdrawal or absorption of water—when the cells come into contact with solutions of higher or lower salt concentration. This explains the actions of many otherwise nearly indifferent salts, e.g., saline cathartics and diuretics.

Surface Forces.—The physical structure of protoplasm is such as to present large surface, and therefore gives peculiar opportunity for the development of the surface force, which are very important for various vital functions. These are greatly modified by a variety of substances, including the lipoid solvents, salts, etc.

Colloid Phenomena.—Many chemical and physical conditions depend on the colloid character of protoplasm. The state of aggregation of colloids, and hence their reactions, are easily modified, especially by salts, acting both by their chemical properties and electric charges. This is an important element in salt-action.

Dependence of the Pharmacologic Action on the Chemic Constitution.

As a general rule, drugs having a similar constitution, possess similar actions; and definite changes in the molecule—as in homologous series, or the introduction of new groups—often produce definite modifications in the pharmacologic effects. This should be expected, since the physical as well as chemical properties change with the constitution. This relation has a wide general application; but its application to details has been rather disappointing, because we have not sufficient knowledge of the chemic constitution and reactions to take account of the numerous variables.

It must be remembered, for instance, that the action is not so much determined by the elementary composition of the substance, but rather by the manner in which the elements are combined. Isomeric compounds have often very different actions. Apparent exceptions result also from the different penetrability of cells to substances which could be introduced into the cell, would cause similar effects. Other manifestations of selective action also come into play.

Attempts to construct a general theory of pharmacologic action on chemical lines have merely shown that this is as yet impossible. The data which we possess has therefore to be gathered empirically without much guidance.

The Importance of the Chemic Radicals or "Side-chains."—A substance, to produce chemical pharmacologic actions, must be capable of combining with protoplasm and then of altering its properties. These two functions—combination and action (analogous to amboceptor and complement, P. Ehrlich)—may be united in the same group; but they may be distinct ("haptochrome" and "toxophore" groups), so that one may be modified without the other. Often several groups are present which may enter different combinations under different conditions. It is evident that these may introduce great variations in the actions.

Morphin, f.d., produces its hypnotic action by "anchoring" or combining with its phenylhydroxyl. When this group is closed, f.d., by the methyl radical, as in codein, it anchors in a different way, to different cells; and the convulsant action becomes more prominent. The introduction of acid radicals into the amido-group renders this more liable and less toxic; but the same acid radicals when introduced in the OH group (e.g., in heroin) increases the toxicity, by providing a new combining group. In these cases, the new groups act only by altering the combining properties of the active group. In other cases, the new group may itself be active.

Several instances of the insufficiency of the narrow side-chain theory are furnished by the toxicity of diazo-dyes (Cecil and Weil, 1917).

The Construction of Synthetic Compounds.—The recognition of the general modifications produced by the different radicals is of practical importance. It permits the prediction, with considerable probability,
of the effects of new drugs; and it points the way to modifications which will emphasize desirable quantities and eliminate those which are undesirable. This has led to the introduction and improvement of many new remedies. Really new properties can not, of course, be predicted by known properties. Their discovery is generally accidental. Accordingly, synthetic chemistry has introduced relatively few new principles, but endless modifications; some useful in the ways indicated; many others needless and detrimental. It is easy to devise minor changes in composition which do not alter the actions of the original drug materially, but which are commercially profitable by evading the patent and trade mark laws. This needless multiplication is confusing and, therefore, undesirable.

**Distribution of Drugs Within the Body.**—Drugs are not distributed uniformly, but accumulate especially in certain cells, according to their permeability and physical and chemical affinities. This influences their action; either by bringing them in contact with reactive tissues, or by storing them in places where they may be inactive. The distribution has been studied in relatively few cases, especially for inorganic poisons; but the data are not sufficient to permit generalizations. The distribution appears to be altered by disease; e.g., degenerating tissue takes up more iodid, etc.

**Storage Places.**—The poisons disappear quite rapidly from the blood, the greater part within a few minutes. The chlorides, bromids, and related ions accumulate in all organs, but mainly in the skin and blood. The thyroid stores a relatively high percentage of iodin as iodoxyrin. The bones retain the earthy metals and florid. The heavy metals are deposited as loose organic compounds, especially in the liver and spleen; mercury as a loose globulin compound; arsenic as a more stable nuclei combination (Vanossy, 1903). The iron deposits serve as a reserve stock of this metal. Little is known about the distribution of organic poisons, mainly for want of suitable assay methods.

**Chemical Changes in Drugs.**—The majority of poisons are more or less altered in the body, and generally rendered less harmful. This is effected by the oxidation, reduction, hydration or dehydtration, or other decomposition of the poison, or by the storage of the poison in certain organs, or by its combination with other substances which render it harmless. This process of detoxication is of great practical importance. It makes it necessary to administer the drugs progressively in order to maintain their effect; it often requires the use of continuously increasing doses as the power of detoxication becomes more developed; and was it not for the power of the body to destroy or remove poisons, and thereby to recover from their action, all therapeutic use of drugs would be impossible.

**Decomposition by Digestion.**—The digestive juices destroy some organic poisons by hydrolytic cleavage; especially the proteins, toxins and antitoxins, and the glycosides. On the other hand, they are necessary to sapenify and liberate the active constituents of insoluble esters, e.g., phenyl salicylate. The acidity of the gastric juice is important for the solution of bases. It also often splits off acyl groups.

**Decomposition in Tissues.**—Strychnin and many other poisons are partly oxidized in the body. Morphin is largely destroyed, especially by those accustomed to its use. Reid Hunt (1905) has shown that feeding with thymol markedly diminished the toxicity of acenitritil, by preventing its conversion into cyanide. The resistance to morphin is also modified. It has been claimed that excision of the thyroid increases the toxicity of a number of other poisons; but Lerd and Dziez, 1905, obtained negat results with caffeine, strychnin, urin, and tetrox and diapherum toxins. Organic compounds of metals (cacoodyl, etc.,) only develop the metal action after oxidation. Me organic acids (citric, etc.), alcohol and formaldehyde, are oxidized, and thus disinteg-
MANIFESTATIONS OF PHARMACOLOGIC ACTIONS

Methylenamin is activated by the liberation of formaldehyde in acid urines. This ring is very resistant, most of the changes occurring in the side-chains. It is very toxic by destroying, but particularly by storing poisons, so that the same dose is effective (perhaps one-half) when given by the mouth, than by the injection. This has been demonstrated for curare, strychnin, morphin, cocaine, quinin, atropin, and the metals. Perfusion of alkaloids, glucosidas, toxins, etc., through excised liver, also decreases their toxicity (Woronow, 1912). Stomachs seem to be less active. They did not destroy strychnin, but attacked atrocton (1920). Experiments with Eck's fistula gave rather negative results (W and Winterberg, 1905).

Perfusion through excised muscle also produced disinhibition, but in the liver, with chloral atropin, physostigmin, curare and alcohol, not with and ricin (Woronow, 1912). Excision of the spleen is said to increase the most alkaloids, but not all. The phagocytes accumulate and thus disinhibit, especially colloids. The serum of atropin-resistant animals destroys

**Detoxification by Absorption.**—The detoxification is sometimes apparently an effect of the liver, as with curare, but may be recovered from this in fully active form by extraction with alcohol, or that it was not destroyed. The nature of the adsorbing substance is not clear. It is abundant in rabbit serum, less in that of cats or oxen, and is absent in the blood (v. Lezuwen, 1918).

**Detoxification by Combination.**—Phenols and other aromatic compounds are detoxified by combining with sulphates; many metals by the proteins; toxins by acids by alkalies; aldehyds, camphor, chloral and ethereal oils by glycerin; cyanids by sulphur; benzoic acid by glycocoll, etc. The extent of the detoxification depends upon the activity of the metabolic processes which are concerned in the neutralizing substance present in the body.

**Detoxification by Activity of Concentration and Action.**—The ratio is generally not in the same proportion. There is usually a "minimal threshold," all concentrations below which are ineffectual. At the other extreme, once the "maximal response" has been reached, further increase of concentration can produce no further effect. Between these points, every increase of concentration increases the action; the increment decreases the lower the original concentration. For instance, when the concentration of ouabain was doubled from 0.0025 to 0.005, the action was increased 4.6 times. The concentration was doubled from 0.005 to 0.01, the action increased only three times (Sollmann, Mendenhall and Stingel, 1915; the paper also discusses the reasons of the phenomenon).

**THE MANIFESTATIONS OF PHARMACOLOGIC ACTIONS**

**Detoxification of Functions.**—Since protoplasm is essentially identical, the action of pharmacologic agents must also be essentially the same. But just as quantitative differences exist in the cell, pharmacologic action show quantitative differences and selectivities. Of these we shall have more to say presently. As a rule, the most conspicuous changes occur in the most conspicuous of the cell—partly because these are the most readily appreciated, and also because specialized functions are the most complex and most sensitive. Pharmacologic agents do not create new functions in a cell or tissue; only modify existing functions, or at most make evident functions that were previously latent. The functions of a cell may be or may be abolished, resulting in *stimulation* or *depression*. Since also structures the stimulation of which would lead to an inhibitory structure, an actual increase of function is sometimes described as *augmentation*. A very violent stimulation passes usually by; such injurious stimulation is called *irritation*. Moderate, but if, stimulation also passes into depression, either by the disappearance of food substances (exhaustion), or by actual injury to the struc-

---

This text is a extract from "Medical Pharmacology and Therapeutics" by J. B. Hebert, published in 1922. The original document contains detailed discussions on the pharmacological actions of various substances and their effects on different biological systems.
ture (fatigue). If the depression is so great that the given function disappeared, the condition is called paralysis; if all the functions abolished, there is death.

The greater number of pharmacologic agents produce at first a stimulation, which is followed in larger doses by a depression. In this respect the differences between the different poisons are again mainly quantitative. The so-called "stimulants" produce a very strong and protracted stimulation, the depression being produced only by relatively large doses. The "depressants," on the other hand, cause only a slight stimulation which passes readily into depression. Indeed, with some depressants, stimulation whatever exists. It is very rare that a depression precedes a stimulation; when this occurs, the action is presumably on different structures.

Selective Action.—The actions of drugs are generally much greater on some tissues than on others; i.e., they are selective. The difference is almost or quite absolute, so that the drug acts specifically on one class of cells. This "monotropic" action is especially important in parasiticide and is the ideal of modern "chemotherapy," the treatment of infective disease by chemic agents. Antibodies also illustrate a strictly monotropic active action. With most drugs the differences are merely quantitative relative; a number of structures being affected with various degrees of predilection, which may sometimes shift with changing conditions. Actions on the central and peripheral nervous systems generally belong to this relative type.

Mechanisms of Selective Actions.—These may consist in difference in penetration; of the chemic affinities of the cell; or of sensitiveness of functions. The details are known only in a few cases.

Selective Absorption.—A drug may act upon a cell without acting penetrating into it; for instance, by exciting the nerves supplying the or more directly, by withdrawing water from the protoplasm; but generally, the poison must be absorbed into the cell or cell-membrane before it can produce any action. In order that this absorption may take place, the drug must be soluble in the cell contents, and particularly the cell envelope. The solubility of a substance in protoplasm is not necessarily the same as in water. Indeed, it varies for each kind of and consequently the penetrability of different cells for a given substance may vary greatly.

Whilst the renal cells, for instance, are very permeable for sulphates, the intestine cells are but slightly permeable. It is in virtue of this peculiarity that cells are capable of preserving their own composition, notwithstanding considerable changes in the chymolytic action. This fact also explains why a given substance acts more strongly upon one cell than another.

The differences are illustrated strikingly by the distribution of dyes in living dead tissues; or indeed, in unorganized materials. Their behavior has been extensively studied, but as yet without leading to secure general conclusions.

The differences in absorption may be due partly to the cell envelope, partly to cell contents. Lipoid solvents generally penetrate better than other agents, being of their affinity for the lipoid constituents of the cell membrane. Other agents pass through similarly, i.e., the basic stains by the acid character of the nuclear chromatin. Absorption and surface forces probably play an important part.

Selective Absorption into Pathologic Tissues.—The distribution is often more by conditions—reaction, oxygen, the presence of a second substance, etc. Important differences arise also in diseased conditions, e.g., iodides are taken up in higher concentration by degenerating tissues.
Tuberculous caseous tissue particularly has this property of condensing solids and dyes, especially those of the safranin and acridin groups (A. Lewis, 1917). Other inhaled tissues and inflammatory products also have a marked tendency to take up the dye (Cecil and Weil, 1917). This can be well demonstrated by the appearance of typano-cren in the aqueous humor, which occurs much more readily when the eye is inflamed, or when physostigmin is applied (P. A. Lewis, 1916).

The feeding of madder dye stains bone and pathological calcareous tissue in vivo; probably by forming calcium alizarin (Macklin, 1917).

**Effect of Concentration.**—The amount of a drug absorbed into a cell varies generally with the concentration of the drug in the surrounding fluid. This concentration is greatest at the place where the poison enters and leaves the body, i.e., in the alimentary canal, liver, and kidneys. Differences of blood supply also come into play. The influence of concentration is most readily seen with locally acting drugs.

**Chemic Differences.**—The various cells differ in their chemic properties, and therefore in their reactions. This is seen most definitely with the antibodies, precipitins, cytolysins, antitoxins, etc., which are supposed to fit especially into certain cells, “as a key is fitted to a special lock.” Something of the same kind doubtless applies at least to some of the ordinary poisons, which can unite only to certain side-chains or certain constituents; but little is known of the details. Similar combining properties may make a poison innocuous to certain cells, by leading to its destruction, or binding it into a harmless form. On the other hand, the decomposition may serve to liberate or form an active substance—f.i., formaldehyde from hexamethylenamin in acid urines.

**Functional Differences.**—The cause of selective action lies often in the cells themselves, the more delicate functions being damaged more readily, hence a poison which acts indifferently on all tissues produces always the most conspicuous effect on the central nervous system.

The sensory nerve fibers are uniformly more susceptible than the motor fibers. The inset of the king-crab lissus furnishes a good illustration. Its structures fall in the same order (ganglion, motor nerve-plexus, muscle) in respect to all kinds of injurious agencies, alkaloids, anesthetics and other drugs; heat and cold, etc. (Meek, 1908.)

Certain cells also accommodate themselves more readily to altered conditions.

**CLASSIFICATION OF DRUGS ACCORDING TO SELECTIVE ACTION**

Poisons which act on all tissues, and which therefore produce effects at the place where they are applied, are termed “locally-acting” drugs. They may produce similar chemic changes in dead tissues. These usually cause inflammation when applied to living tissues, and are then called irritants (including simple irritants, corrosives, and astringents). Others cause inflammation mechanically (emollients and demulcents).

Others act chemically on all living structures, without changing dead tissues; these are termed “proteolytic poisons.” Poisons which act selectively on a few structures are called “mucolysis poisons.” They may affect end-organs (sensory endings, gland cells, etc., wrapped, smooth or cardiac muscle); or the nerve-endings; or ganglia; or any part of the central nervous system.

Nerve trunks are so resistant that they are only affected when the poison is applied then directly. The access of drugs to them is restricted, in intact animals, by their limited blood supply. The nerve fibers are also protected by the slight permeability of their sheath.

**Pharmacologic Groups.**—Various systems of classifying nerve-poisons have been devised. None is really satisfactory, because most drugs pro-
duce several effects which, by their interaction, complicate the subject so that no simple system will apply. With some drugs, one pharmacologic chemic or physical feature predominates so greatly that they can be separated as fairly distinct groups. However, this is more or less arbitrary and artificial.

Variations in Symptoms.—The selective action of drugs is rarely absolute; even strychnin, a highly selective poison, acts as a general protoplasmic poison when it is directly applied in sufficient concentration. Often, however, some one action is so prominent that it may be considered as characteristic for the drug. Even in this case the poison as a rule acts selectively on several structures. This accounts for the great variability which is often noted in the action of the same drug under different conditions. Thus, atropin stimulates the vagus center, but paralyzes the endings: it may therefore cause either a quickening or a slowing of the pulse. Again, through the opposed action of small and large doses, strychnin, e.g., may cause either a stimulation or a paralysis of the vasomotor center. Another frequent cause of variable actions lies in the indirect actions of a drug. A drug which causes convulsions will thereby tend to stimulate the vasomotor center, although its direct action on this center may be depressant.

These variable actions and interactions make the effects of many poisons appear very complicated, although they prove quite simple on analysis. This analysis is important for a proper understanding of the action, but it is still more important to remember the complex effect which results, for it is with these that the practicing physician has to deal.

Often the pharmacologic action in this sense is not the therapeutic action. An important pharmacologic action of morphin, for instance, is a stimulation of the spinal cord; but no one would think of employing the drug therapeutically for this purpose, since this action is overshadowed by its other effects.

For this reason it would not be a good plan to classify the drugs strictly according to their pharmacologic actions. On the other hand, a therapeutie classification, although useful in some respects, is not favorable to a study of the underlying actions of the drugs, and tends to empiricism. The best principle of classification yet devised is that of Buchheim, according to which drugs are grouped according to their principal pharmacologic characters, taking account of all the important actions, as well as of their chemic properties, and in many cases also of the therapeutic uses of the drugs. This is the general plan adopted in this volume.

Definitions of Pharmacologic Terms.—Some rather loosely use pharmacologic terms may be defined in this place, in the sense in which they are generally employed in this volume:

**Local actions**: produced at the place where the drug is applied; **Remote actions**: occurring in distant parts of the body (may be either systemic or reflex); **Systemic effects** (sometimes called general action): produced after the absorption of the drug into the circulation; **Direct effects** (sometimes called primary): produced by the direct action of the drug on the tissue concerned; **Indirect effects** (sometimes called secondary), are not produced by the action of the drug on the tissue concerned, but by the intervention of some other structures on which the drug acts (e.g., asphyxia convulsions are an indirect effect of asphyxiant poisons); **Reflex effects** are indirect actions arising from local irritation; **Immediate effects** (also some times called primary) are the effects resulting at once; **Late effects** are those occurring later; if they are preceded by other (immediate) actions, they are properly called secondary actions. Side actions are actions which are not desired in the therapeutic use of the drug.

Buchheim may be considered the founder of modern pharmacology, by the establishment of the first pharmacologic laboratory, at Dorpat in 1896. Pharmacologic actions. On this account, as the pharmacologic character often appear to have identical actions. Thus the action of strychnin resembles that of tetanus toxin, arsenic that of cholera, barium that of digitalis. In some cases the action may be supposed to be really identical, but in others the resemblance is merely superficial.
LOCALIZATION OF ACTION

Localization of Action.—The effects of drugs on patients, or in cases of poisoning, are by far too complex to furnish any real insight into the actions which are involved. To attain the object of pharmacology—the explanation of the action of drugs—it is indispensable to simplify the conditions as much as possible, and to make the functions, which are to be studied, accessible to measurement, and if feasible, to graphic representation. The methods of experimental physiology are employed for this purpose.

The Study of Isolated Structures.—To eliminate the complications which arise from simultaneous actions on several structures or from indirect actions, the tissues to be studied are generally isolated. The most certain method is the actual anatomic isolation of the structure. Drugs of known antagonistic actions may also be utilized, but they are apt to lead to erroneous conclusions.

The anatomic isolation may be accomplished by employing unicellular organisms if the action on undifferentiated protoplasm is to be investigated; or by excising the tissue (as muscle, etc.) from the body; or by applying the drug to the exposed tissue (e.g., to a sympathetic ganglion); or by severing the connection with other tissues which might be affected (as by section of a nerve); or by restricting the action of a drug to a given part, by cutting off the circulation.

One or the other method of isolation may be employed, according to circumstances; that giving reliable results with the least difficulty of technical being naturally preferred. Complete isolation is in many cases superfluous. If the question is, for instance, whether an observed stimulation is of a central or of a peripheral structure, it suffices to divide the nerve: on an efferent chain, this will abolish the effects of a central stimulation, whilst those of a peripheral stimulation will persist. With an afferent chain the conditions would be reversed. By making sections at various levels of the chain, the location of the action may be accurately determined. When the structures to be investigated are inaccessible to the scalpel, one may substitute drugs which are known to paralyze these structures selectively (curare for the endings in striped muscle; strychnine for ganglia; atropine for endings of the vagi or parasympathetic, etc.). The site of a paralysis is similarly located by successive stimulation. The stimulation is accomplished by electricity or by appropriate drugs (e.g., for sympathetic endings: muscarin for vagus endings: pilocarpine for glands; barium for smooth muscle, etc.).

A few examples will make this general method clear:

1. Strychnine.—It is noted that strychnine produces a tetanus. This implies a motor stimulation somewhere. The sciatic nerve is cut; it is found that the convulsions disappear in the leg but persist in the rest of the body. The action must therefore be central. The cerebrum and medulla are successively excited; the convulsions persist, and must, by exclusion, be located in the cord. This is confirmed by destroying the cord, which causes the complete disappearance of the tetanus.

2. Curare.—This produces a complete muscular paralysis. Stimulation of the sciatic elicits no response. The paralysis must therefore be peripheral. Direct stimulation of the muscle is effective. This excludes all the possible structures except the nerve trunk and endings. The nerve of another preparation is laid into the curare solution, and after a time, is stimulated; a contraction results, so that the nerve trunk is not paralyzed. The action must therefore be on the endings.

If a peripheral structure is stimulated or paralyzed, it is impossible to decide by this method whether there is not also a central action, for the peripheral effects would obscure the central. A stimulation of the cord, for instance, could cause no effect if the drug had paralyzed
the motor endings. In these instances, it is necessary to confine the action of the drugs to the centers, which requires a more complicated technic.

The Study of the Effects of Drugs on Intact Normal Animals. — A complete conception of the actions of a drug can be obtained only by supplementing the study of its effects on isolated structures, by careful observation and analysis of the symptoms which it produces in intact mammals. The effects on metabolism, and the histologic lesions, etc., can only be studied in this manner. Indeed, these experiments are often undertaken before the more difficult investigations on isolated structures; for they furnish valuable hints of the direction which the latter should take. When circumstances permit, it is advisable to proceed from the lower to the higher classes of animals, and finally to man. Opportunities for observing the effects of drugs on man occur in cases of poisoning, and should not be neglected; but intentional experiments with drugs on man are to be undertaken only with the greatest caution, with doses which do not exceed the therapeutic maxima; and, as a rule, only after the effects have been thoroughly studied on animals.

The Effect of Drugs in Disease. — The action of drugs is not always the same in disease as in health. The differences are, however, as a rule quantitative rather than qualitative. Since the drugs are in practice employed most extensively in disease, their action in these conditions is of the greatest importance. As a general rule, it is possible to explain, and even to predict, the action of drugs in disease from their action on normal tissues. However, the actual test must always be made.

Animal experiments are as yet of limited value in this connection, and we are forced to rely mainly on observations on patients. To make these of value it is necessary that the observations be made accurately and that psychic factors be excluded; it is further necessary that the existing pathological condition be correctly known. These requirements are unfortunately not fulfilled in many cases, which accounts in part for the differences which are occasionally noted between the clinical and the experimental data. These exceptions will be discussed in the text.

In the case of the older drugs, clinical tests have been made so abundantly that further observations might seem superfluous. This is by no means the case. Accurate observations in the light of our advancing knowledge, and employing the improved methods of diagnosis and observation, are always needed.

It is also highly desirable that every physician should obtain his knowledge of the therapeutic action of drugs at first hand. He should utilize every case under his care for this purpose, and conduct his treatment as if it were a critical experiment, the interests of the patient being, of course, paramount. The conclusions will be greatly simplified if but one drug is used at a time.

Chemical Investigations. — Since the action of drugs depends so largely upon their chemical constitution, the latter is a legitimate subject of pharmacologic inquiry. The study of the fate of the drug in the body, of the mechanism of its absorption, excretion, and storage, is also indispensable. These involve the methods of quantitative chemical analysis.

Transfer of Results of Animal Experimentation to Man. — The utilitarian aim of pharmacology is to supply the science of medicine with a rational and scientific basis for the practice of therapeutics and for the study of toxicology. It was shown in the preceding section that these objects can be attained only by experimentation on lower animals. This brings up the fundamental question: To what extent can results observed on animals be transferred to man? The same question applies to all other fields of experimental medical research, and has been abundantly answered by their results. A similar physiology implies a similar pathology and pharmacology. In the vast majority of cases, similar structures are affected in the same way by a given drug, no matter in what animal they are studied. Where differences exist, they can usually be explained by differences of physiologic function, as will be discussed under "Racial Idiosyncrasy." Those which are not yet explained must be referred to our ignorance. The differences in animals, physiologic and unexplained, are now generally recognized so that suitable species can be chosen for experimentation. They can furthermore be eliminated by using the drug on several species: If a given poison affects all species alike, it may be concluded that its action on man is also the same. If it produces different
ADMINISTRATION OF DRUGS

effects, but if these can be explained by differences in physiology, the effects on man will be similar to those produced on the species the physiology of which resembles most closely that of man.

Value and Limitations of Experimental Pharmacology.—It will be seen that great care must be used in applying the results of experimental pharmacology to man. The neglect of this precaution, the drawing of far-reaching conclusions from a few limited experiments, threw discredit on pharmacology in its earlier days, and is still seen all too frequently. Pharmacology can not be held responsible for this misapplication of its data by half-trained enthusiasts. Its scope is limited primarily to its own results and not to their application, although it may legitimately suggest the latter. It should not be made to replace the science of therapeutics, but should only aim to place well-studied tools in the hands of the latter. If this limitation is realized, if the therapist will carefully study the results of pharmacology and will utilize and interpret them in the light of bedside experience, then pharmacology will be of very great value to medicine.

One very important service is rendered by pharmacology through the examination of new remedies. The development of synthetic chemistry especially has resulted in the discovery of a very large number of new substances of some therapeutic value. The number is indeed so large, that all could not be given a thorough trial on patients. Most of these substances possess some value, but many differ from each other by very insignificant details. In this case, pharmacology can select the most promising drugs of a type, and by their thorough study, indicate those which are worthy of trial by the clinician.

THE ADMINISTRATION OF DRUGS

The effects of a given drug or poison are not always uniform, but vary with conditions; such as the dose; the absorption and elimination; the method and time of administration; the simultaneous presence of other substances; the age, sex and race of the patient; the existence of disease, etc. A knowledge of these variations is very important.

Methods of Administering Drugs.—The channel by which a drug is introduced into the body, or the place to which it is applied, must vary with the object to be secured—whether the action is to be local or systemic; the desired rapidity of absorption; the necessity of avoiding irritation of certain organs, etc.

Local Application.—Drugs may be used locally either to protect a surface, or for reflex effect, or as antiseptics, or as stimulants. They may be applied to the skin in various vehicles: If it is desired to secure the absorption of the remedy or its deep penetration the drug should be presented in a vehicle in which it is relatively insoluble. The influence of the ointment base varies for different substances (Sauerland, 1912). The remedy may also be applied in aqueous solutions (washes), especially if intended for an antiseptic; or it can be used in powder form. Caustics may be used either as solids or liquids. Counterirritants are used as liniments, i.e., dissolved in oil, turpentine, or alcohol.

Oil or Moisture on Skin.—These modify the penetration of fat-soluble substances, such as phenol, dichloretethylsulphid or mustard oil (Sollmann, 1910); namely in the sense that the good solvents (oil) tend to retain the drug on the surface, whilst poor solvents (water) tend to drive it into the skin. This is analogous to the partition of a substance between good and poor solvents, in a test-tube.

Absorption from Skin.—Local application to the skin can be used for producing general effects, but it is only employed in those cases (mercury with some patients) where the stomach has to be avoided and subcutaneous administration is not practical. The principal objection to the administration of drugs by the surface of the skin consists in the uncertain absorption, exact dosage being in consequence impossible. The absorption is greatest where the skin is most delicate; in the axilla, loins, and
the inner surfaces of the extremities. Absorption is aided by friction and cleanliness.

*Watery solutions* are not readily absorbed from the skin, unless the drug is caustic. The reason for this non-absorption lies in the fact that the stratum corneum of the epidermis is practically non-permeable to solutions. Absorption must take place through the glandular structures of the skin, and these are filled with fatty matter, which prevents the penetration of watery solutions, but not, of course, of other fats. However, when the skin has been macerated for several hours it may absorb some salt. It also absorbs H₂S and other gases.

It must be borne in mind that the application of solutions to open wounds or abraded surfaces is practically the same as subcutaneous injection, and absorption occurs in this case very readily.

Local medication may be used also on other surfaces than the skin, if they are accessible; e.g., mucous membranes. The drugs are usually applied as aqueous solutions (injections, washes, and gargles).

*Cathaphoresis.*—This process has been employed in dentistry to facilitate the penetration of cocaine, but it has not as yet found very extensive adoption in medicine and surgery. It is a process by which the molecules are carried from the + to the − pole. The solution to be introduced must possess a higher conductivity than the liquid of the tissues.

*Sprays.*—Vapors and finely “atomized” sprays are inhaled for their local action on the respiratory mucous membranes. They must not be too irritating.

To reach the lower air passages, they should be inhaled deeply with the nostrils closed, the mouth wide open, and the tongue protruded. Even so, the numerous branching surfaces prevent the spray from reaching any but the larger bronchi (Semmole).

*Inhalation.*—This method is used only for gaseous medicines, such as anesthetics or oxygen.

When giving drugs by inhalation, it must be borne in mind that the effect does not depend upon the quantity given, but the concentration of the gas and the time during which it is administered. The rich capillary area of the alveoli is one of the best absorbing surfaces, so that the action is very rapid. The lungs also absorb fluids and dissolved substances rapidly; if these are introduced through the trachea.

*Oral Administration.*—This, the most ancient method, is still the standard one. Its advantage lies in its great convenience and in the relative freedom from local irritation. Nevertheless, certain drugs do give rise to disturbances of digestion. This can be minimized by giving them in such a form that they will not be dissolved in the stomach (pills), or by giving them at a time when the stomach is filled with food. Absorption is, of course, also delayed by these means. *Pills* should never be employed for insoluble powders or for corrosive drugs which require dilution.

*Absorption from Alimentary Canal.*—The absorbing power of the stomach is relatively low, even for water and soluble substances (Hirsch, 1852); so that the main absorption does not occur until the drug has reached the small intestines. The effects, with gastric administration, are therefore relatively slow. The passage is quickest if the drug is taken fasting in water; somewhat slower with milk, soup or wine; slowest after eating, especially when administered dry (Moritz, 1898).
The conditions in the small intestine are very favorable for absorption, which is aided by the long sojourn, the extensive surface, the folds and villi, the segmental movements, etc.

The relative roles of the stomach and intestine in absorption vary for different drugs and animals. Strychnine, e.g., is absorbed from the stomach with dogs and cats, but not with rabbits and guinea pigs; whereas sodium salicylate and iodide give just the opposite result. Isoye and Kashiwado (1905) have shown that atropin and rhubarb are not absorbed from the dog's stomach, whilst salol is absorbed. The data as to man are insufficient.

Certain drugs are more or less destroyed in the alimentary tract, e.g., toxins and antitoxins, so that oral administration is relatively inefficient. Glucosides are also partly destroyed, so that the oral dose must be larger. On the other hand, drugs which require the action of the digestive juices for their solution (resins, oils, etc.) are more efficient by mouth than by other channels. The oral route is of course the only one for drugs intended to act locally on the upper parts of the digestive tract.

Rectal Administration.—The stomach and small intestine may be avoided by giving the drugs per rectum, either in the form of enema or suppositories. The rectum is a fairly good absorbing surface for many soluble substances; so that the effects are often greater or more prompt than with oral administration (e.g., for salts, narcotics etc.). The absorbed drug also avoids the passage through the liver, and the consequent destruction.

Enemata, when introduced for the absorption of the medicine, should be as small as possible, but not so strong as to produce local irritant effects. One or 2 ounces is usually the proper quantity, the rectum being first cleansed with warm water. When enemata are employed for their mechanical effects, the amount must, of course, be much greater—several pints. These should be raised to the body temperature.

Conjunctiva.—This absorbs easily, so that systemic effects often follow the application of drugs, for instance, atropin, to the eyes. A few milligrams of apomorphin applied to the conjunctiva of a dog suffices to produce vomiting (Macht, 1917).

Vagina.—This absorbs freely, and clinical poisoning by this channel is frequent, especially in connection with the improper use of mercuric chloride douches (Macht, 1918, references).

Urinary Bladder.—This absorbs very poorly. Strychnin, apomorphin and morphin are almost harmless when injected into the bladder, if the urethra has been tied (cf. Macht, 1918). Even salts and water are absorbed poorly.

Urethra.—This absorbs very readily, so that poisoning has frequently occurred from the excessive application of local anesthetics.

The laws of the absorption of local anesthetics have been studied by Seilmann, 1918 (cf. Local anesthetics). The rapidity of absorption is illustrated by the injection of 1 per cent apomorphin into the urethra of a male dog; vomiting occurs in 3 to 5 minutes (Macht, 1918).

Urethral and Renal Points.—These absorb fairly well. This enjoins caution in the use of silver salts etc., for x-ray work (Macht, 1918).

Perineal Cavities.—This is also an absorbing surface (iodin, Hisachi, 1908).

Other Mucous Surfaces.—Macht, 1917, has demonstrated absorption from the nasal duct, prepuce, etc.

Subcutaneous or Hypodermic Administration.—The injection of solutions through a hollow needle into the loose subcutaneous tissue has
the advantage of securing quicker and more certain effects, and more exact dosage.

Hypodermic injections are generally made into the forearm, arm, thigh, or nates. For very bulky injections, e.g., for antitoxin or for saline solution, the loose areolar tissue of the subscapular or mammary region is chosen. The subcutaneous dose may often be made somewhat smaller than the oral dose. The *rapidity of absorption* from hypodermic injections may be hastened by massage, by distributing the injection over several places, and by dissolving the drug in a small amount of fluid. The concentration in salts should not exceed that of the blood, or the injection will be painful. Normal saline solution is the least irritant solvent for alka- loids. Subcutaneous injection is naturally inadmissible, if local effects in other parts of the body are desired (e.g., for stomachics, cathartics, locally acting emetics, etc.).

The hypodermic injection of drugs that are not local irritants produce little discomfort and no after-effects, provided that reasonable asepsis is preserved. Irritant drugs, however, cause severe pain, and may be followed by induration, sloughing and abscess.

Hypodermic injection was probably first practiced by E. Rynd, 1844, but was introduced practically by Alex. W. Wood, in 1853. Pravas invented his syringe in 1853, for the injection of aneurisms (Macht, 1916).

**Intracutaneous Injections.**—Injections made into the tissue of the skin proper (instead of under the skin) are used for provoking local reactions, for instance diagnostic skin reactions (lueatin, diphertheria toxin, hay fever, etc.); also for local "infiltration anesthesia." They are not suited for systemic administration; for the paucity of the blood-vessels makes the absorption much slower than with hypodermic injections. However, even solid elements are gradually absorbed (Kasahara, 1916).

**Intramuscular Injections.**—These are made by thrusting the needle through the skin deep into the substance of the gluteal or lumbar muscles. The absorption is more rapid than with subcutaneous administration (Meltzer and Auer, 1904), and the irritation and tendency to abscess formation are less. Auer and Meltzer, 1911, advise the sacro-spinous muscles in preference to the gluteal, as giving better absorption with less pain and other complications.

**Precautions in Intramuscular Injections.**—A careful technic is necessary for injections near any nerve; for instance, *sciatic neuritis* has followed arsphenamin injection (A. Kissmeyer, 1916).

**Subcutaneous Injection.**—Injection under the mucous membrane of the nasal septum gives extremely rapid absorption, the efficiency approaching intravenous injection (Pilcher, 1914, 1915).

**Intrapерitoneal and intrathoracic injections** are used in experimental technic, and resemble subcutaneous injections, the drug being absorbed more rapidly. Intra-peritoneal injections in man have been made by Schmidt and Meyer (1905), but are not recommended. The pleura absorbs through the parietal and pulmonary surface; but the absorption is less than from the peritoneum (Naegeli, 1913). In both membranes, it occurs by the blood rather than lymph. Gravity plays a part, the absorption being rather better with pelvis down position (Dandy and Rowntree, 1914).

**Intrapерicardial Injections.**—Solutions are quite rapidly absorbed from the pericardial sac into the heart-muscle. Gunn and Martin, 1915, suggest that this could be utilized in epinephrin-resuscitation.

**Injections into the Trachea.**—Massive injections are very rapidly absorbed through the alveolar capillaries, and act more like intravenous
injections. They may cause asphyxia, and are not used intentionally. Tracheal sprays are used for local effects. Oily solutions of menthol, etc. may be injected into the trachea for local action (J. A. Thompson, 1897).

**Intracerebral Injections** (i.e., into the substance of the brain) have been used experimentally. The injections are at once conveyed to the ventricles and produce local and mechanical effects often different from the systemic action of the drug.

**Subdural Injections.**—These are used if the drug is to act directly on the spinal cord or nerve roots, especially for spinal anesthesia. The technique is that if lumbar puncture, some cerebro-spinal fluid being withdrawn before the injection is made. The procedure may be dangerous; especially if the poison produces local effects or is conveyed directly to the medulla.

Drugs intended to act on the central nervous system are generally more active if administered in this way. For instance, Lewandowsky, 1900, found that strychnin is six times as efficient when injected intraspinally than when injected intravenously. The efficiency of the absorption of drugs from subdural injections into the general circulation is in dispute. Bacht, 1920, found no systemic effects after subdural injection of epinephrin, niestin and secretin, so that their absorption must be very poor. He attributes the contrary results of Meltzer and others to direct entrance into veins.

**Irrigation on Permeability of the Meninges.**—The observations appear discordant. Selman and Swift, 1915, found no change in the absorption of salvarsan. Carrier, 1916, claims that the inflamed meninges are very permeable to phlorhizin. Mehetenus and West, 1917, state that they are less permeable to phenolulophonephethaline.

**Subarachnoid Irrigation.**—This has been tried experimentally (Weed and Weigelforth, 1919). Normal saline produced toxic effects, but Kinger’s solutions appeared harmless and prolonged the life of animals with meningeal infection.

**Intravenous Administration.**—This is often used in pharmacologic experiments and has become perhaps somewhat too popular clinically. Its dangers restrict its application mainly to emergencies when an immediate action is necessary (strophanthin), or where other methods are not applicable (salvarsan).

Intravenous injection was tried rather extensively in the seventeenth century, but its modern application dates from Landerer, 1883, and F. Mendel, 1908 (history, Epstein, 1915; Macht, 1916; Eggleston, 1917).

While it is the quickest way of securing the action of the substance, it presents some serious dangers. Air may be introduced into the vein, and while the presence of a small bubble of air in the circulation of a man is not as dangerous as in that of a rat, it may lead to very serious results. The action of drug injected intravenously may be quite different than when taken by other channels. They act upon the heart more directly and with less dilution. Many substances also have the property of clotting the blood, and unless the administration be very skillfully done, the result might be disastrous.

With guinea pigs, collapse and asphyxia follow frequently on the injection of substances that are ordinarily considered indifferent, for instance, acacia (Hanlik and Kanner, 1920). These are rare in men, but they do occur occasionally and are then so serious as to militate strongly against indiscriminate intravenous injections.

**CONDITIONS INFLUENCING ABSORPTION**

The time required for absorption into the body and into the cells varies from a few seconds (e.g., hydrocyanic acid), to several weeks (e.g., lead). The rapidity of absorption depends upon the nature of the drug, the place of administration, and a number of accessory factors.

**Place of Administration.**—Absorption of drugs may occur from the alimentary canal or from other mucous surfaces; from subcutaneous tissue or serous cavities; from
the alveoli of the lungs (gases and volatile substances); a limited number of substances may also be absorbed from the intact skin. The influence of the place of administration has been discussed.

**Solubility.**—Only soluble drugs can be absorbed (except the small quantities taken up by phagocytosis); but the solubility in the protein containing fluids of the body is not necessarily the same as the solubility in water. The solubility may also be modified by chemic changes in the digestive canal.

**Solid Substances.**—These are practically unabsorbable from the alimentary tract, although Koelliker and many others, on feeding rabbits with carbon, found particles in the prevertebral and mesenteric ganglia. There is always considerable uncertainty in the absorption of solid substances, even when they are soluble. They should therefore be avoided unless a very slow action is desired. Free dilution is favorable to absorption.

**Influence of Colloids, Etc.**—Oil, gums, extractives, kaolin and other colloids hinder absorption, partly by adsorption of the drug, partly by hindering its access to the absorbing surface. The presence of food in the alimentary canal has a similar action. The isolated active constituents (alkaloids, etc.) are preferred if a quick systemic action is desired, whilst the galenic preparations (extracts, tinctures, pills, etc.) are used for local effect. In case a crude drug contains several active ingredients, the employment of the isolated constituents will give more definite results.

**Fuller's Earth on Alkaloids.**—Fuller's earth (hydrates aluminum silicate) has a high adsorbing power, especially for alkaloids—varying, however, in degree with different samples (Lloyd, 1910; Fantus, 1915; Seidel, 1928). A specially effective preparation is known as "Lloyd's Reagent" or "Alkresta."

McGuigan, 1914, found that this mixture with strychnin is insoluble in acid fluids, and develops the bitter taste quite slowly; and that it delays and diminishes the tetanic action in frogs. Fantus, 1915, finds that the combination is not dissolved in the stomach, but dissociates gradually in the intestines. He also investigated the suitability of the earth as an alkoldal antidote, and found it very limited. It is somewhat improved by the addition of tartaric acid or acid sodium phosphate; it is highest against morphin, coain, nicotin and ipecac; and least efficient against strychnin, aconitin and colchicin. The effects of Kaolin and related substances were also investigated by Friedberger and Tsuneoka, 1915.

**Clowes and Walters, 1920, claim that the fuller's earth adsorbate is not broken by sodium bicarbonate as assumed by the other authors; but that this requires the presence of soap or other unnamed constituents of protoplasm. Sollmann had found that bile salts, whose general properties resemble those of soaps, do not liberate demonstrable quantities of emerin.

Sabatani, 1913, found considerable antagonism between strychnin and colloidal carbon (caramel) when mixed in vitro. The intravenous injection of the carbon also furnished some protection against the oral administration of strychnin; but this was too uncertain for practical application.

**v. Paulucci, 1915, showed that fatty substances (including petrolatum) diminish the toxicity of strychnia, both hypodermically and with direct application to the nerve centers.**

**Concentration.**—The absorption varies generally in the same direction as the concentration, especially for hypodermic injections; but the relation is not a simple one. Absorption tends also to increase with the extent of absorbing surface (e.g., by making multiple hypodermic injections). This seems to be less important in the intestines (Sollmann and Hanulik, 1911-1913).

**Changes of the Absorbing Cell.**—In the alimentary canal, injury to the absorbing cell may either facilitate or hinder absorption; astringents tend to have the latter effect, corrosives and simple irritants the former.
Absorption of Drugs

Sollmann and Hanslik found that phenol, alcohol, iodid, and probably other substances are absorbed by their own absorption; so that the absorption, at first very rapid, is promptly slowed.

Circulation.—The rapidity of absorption is proportional to the rapidity with which the drug is removed; just as a burning lamp-wick absorbs the oil more quickly (Mialhe). It therefore increases with the rapidity of the circulation and of the lymph flow. Active hyperemia (hot air; Klap, 1901) and hemorrhage hasten absorption; while it is delayed by venous stasis, passive congestion, deficient heat action, vasoconstriction, catarrh, etc. Increase of lymph flow, by moderate distension and massage also quickens absorption. Excessive distention diminishes absorption by slowing the local lymph flow (Hamburger, 1907).

Absorption in Absence of Circulation.—Considerable absorption occurs when the circulation has stopped. Thus, strychnin and morphin are absorbed by frogs with ligated hearts, producing interesting modifications in their actions (Meltzer, 1911–1912). Abel, 1912, and Abel and Turner, 1914, believed that the solutions in cardecomised frogs are circulated by the lymph hearts; but Meltzer, 1914, Joseph, 1914 and Guthens and Meltzer, 1917, affirm that general effects from the local injection of strychnin, fuchsin or epinefrnin may occur even when all the lymph hearts are definitely excluded, the absorption occurring through the lymph spaces.

The absorption in frogs is delayed by destruction of the spinal cord (Filippi, 1912). Considerable absorption occurs also in dead animals (Sollmann and Hanslik, 1913), probably by diffusion.

Absorption by Blood and Lymph.—Most soluble substances are absorbed from the alimentary canal by the blood, rather than the lymph. This also holds for the serious exudates; methylene blue injected into the peritoneum or pleura, for instance, appears in the blood before it is seen in the thoracic duct (Starling and Tulby). A few drugs, however, take the lymphatic path. Tetanus and diptheria toxin, and perhaps other toxins, are absorbed from the local injections by the nerve sheaths, and reach the central nervous system along these (Meyer and Ransom, 1903; Meyer, 1917; C. W. Field, 1907). These toxins are more active on homodynamic or intramuscular than on intravenous injection, since apparently they reach the nerve centers in more concentrated form by the lymph than by the blood.

Sojourn in Blood.—This is generally very short.

It must not be forgotten that a drug, after it has been absorbed into the circulation, seems still to penetrate into the cells. This intracellular absorption depends upon the nature of the poison (selective absorption), and to some degree on its concentration. As a rule, it is a very rapid process: Masson (1903) found the time which elapses before just toxic doses disappear practically completely from the blood, after intravenous injection, to be for Arsenic, nine-tenths to thirty seconds; Tetania, twenty seconds; Cysails, two to six minutes; Diphtheria toxin, four minutes; Antitoxin, several hours.

Sojourn of Dyes in Blood-stream.—This has been investigated in the development of methods for measuring the blood volume. One group remains in the plasma for long periods; another group is excreted rapidly by the urine; and a third group disappears from the plasma, but is not excreted by the kidneys. These groups have no apparent relation to the chemical structure (Dawson et al, 1920).

The Excretion of Drugs

Channels of Excretion.—This occurs mainly through the urine and feces, and with volatile drugs through the lungs. The sweat and, indeed, all the secretions play a minor part. The relative importance of the different channels varies for each drug, the reasons being but little understood. The rapidity is proportional to the circulation and to the functional activity of the excretory organs, and may be increased by the factors which stimulate these.
The excretion of certain drugs appears to be limited by their existing in the body in the form of combinations. The elimination of these is favored by substances which displace them from the compounds. This is probably the explanation of the increased excretion of iodides on the administration of chlorides, and possibly of the favorable effect of iodides in chronic poisoning by metals.

Excretion by Sweat.—A considerable number of drugs are thus excreted (iodides, bromides, borates, phenol, salicylates, antipyrin, methylblue, As, Hg). The quantities are too small to make them significant for elimination, but they may help to explain exanthemata.

Excretion by Saliva.—This is rather limited, and is only important for the haloids (iodides) sulphocyanates, K and NH3, Hg and Pb, menthol and guaiacol, hexamethyl- enamin, and some alkaloids (morphin and quinin). The excretion generally begins within twenty minutes and may last over nine hours (Howe, 1912).

Passage into Cerebro-spinal Fluid.—Inorganic substances are excreted into this only in a slight degree; iodides and bromides are generally present. Many organic substances pass into it much more freely; Alcohol, chloroform, acetone and hexamethyl- enamin occur constantly in about one-third the concentration of serum (Hald, 1911).

Anilin Dyes are not generally found in the cerebro-spinal fluid or in the grey matter after intravenous injection. Those that are liposoluble are found in the gray matter. The passage into the cerebro-spinal fluid varies also with the species. Picric acid penetrates in dogs, cats and guinea pigs, but not in rabbits (L. Stern and Gautier, 1918).

Passage to Fetus.—The more important drugs which have been demonstrated are: ferrocyanid (Mayer, 1871); chloroform, ether, CO, ethyl bromid, atropin, morphin, scopolamin, chloral, salicyl, quinin, benzoic acid, chlorhiazin, alcohol, nitrate, uren, methylblue, As, Hg, Kf, KBr (Kehrer, 1907).

**DOSAGE (POSLOGY)**

Definition.—Drugs are administered to produce a desired effect, and the dose must be sufficient for this purpose, and neither too small, nor too large. Since the effect is influenced by numerous conditions, it is impossible to state exact doses for any drug; experience is the only safe guide. However, the doses vary under ordinary conditions only within narrow limits, so that it is feasible to state the customary or average dose, as is done in the U.S.P. and in this book. This is convenient as a starting point.

The "maximum dose" signifies the largest dose which can be safely used in ordinary cases; the "minimum dose" is the smallest dose which produces therapeutic effects; a "toxic dose" is one which produces dangerous effects; the "just fatal dose" is that which is just sufficient to cause death; the "physiologic dose" (a rather indefinite term), is used in physiologic experiments on animals.

Variations According to Administration.—The different methods of administration, by altering the rapidity of absorption, produce quantitative differences in the effects, and therefore in the dosage. Since these vary with each drug, they must be determined by observation. General ratios of oral, rectal and hypodermic doses, supposed to apply more or less to all drugs, are dangerous (Hatcher, 1910; Hatcher and Eggleston, 1914).

The same dose acts the more profoundly, the more rapidly it is introduced; mainly because there is less excretion and destruction before the full dose has entered; also because it reaches the heart and other centers before being distributed through the body. This must be taken into account in fixing the minimal fatal dose. Extremely rapid intravenous injection may simulate a higher fatal dose, if death occurs during the injection; because in this case really more poison may have been administered than was necessary for death (I. Simon, 1905).

Action and Dose.—With some drugs, the fatal and active dose are far apart (atropin); with others, they are close together (strychnin). The distance varies with the delicacy of observing the active dose, and for different actions of the same drug.
Daily Dose.—The single doses are usually calculated on the assumption that sufficient time is allowed to elapse between the doses for the greater part of the drug to be excreted. This constitutes a periodic medication. The exact time varies of course with the nature of the drug, but in most cases the drug is administered three or four times a day; so that the daily dose is about three or four times the single dose. If a continuous action is desired, correspondingly smaller doses are given at shorter intervals.

Repetition of Dose.—Cash, 1908, found that doses of indaconitin, repeated at sufficiently long intervals, gave imperfect summation of the temperature action; but if the interval exceeded two hours, with doses less than one-half fatal, the later doses produced actually less effect.

Variation of Dosage.—The doses ordinarily stated in textbooks apply only to adults of average size, and to oral administration.

Effect of Weight.—Other things being equal, the effect of a given dose is inversely proportional to the weight of the individual (exclusive of the adipose tissue). It is rarely necessary to make allowance for the weight in adults (twenty to sixty years), but it may be used for calculating the doses for children.

Body Surface.—This is regarded by some as a more accurate although less convenient index of the dose (Moore, 1900; Dryer & Walker, 1914); but the subject is in dispute (Kislikait, 1912).

Calculation of Doses for Children.—In most cases, the adult dose is reduced in simple proportion to the weight of the child—either by direct calculation, or by the use of empirical rules based on averages, as described below. The dosage so obtained is generally sufficiently exact. It is inadmissible only with extremely young children; and with drugs the action of which is influenced specifically by age.

Clark’s Rule.—Multiply the adult dose with the weight of the child (in pounds) and divide by 150 (the weight of the average adult). This rule gives the most exact results.

Cowling’s Rule.—Multiply the adult dose with the age of the child at the next birthday, and divide by the adult age, taken as twenty-four. E.g., the dose for a child of three years would be $\frac{3}{24} \times \frac{1}{2}$ of the adult dose. This rule is simple, easily remembered, and gives data agreeing sufficiently well with the average weight curve; more accurately than Young’s Rule. The results are rather too low, below four years and above fifteen years, but the error is on the safe side.

Young’s Rule.—Multiply the adult dose with the age of the child (in years), and divide by the age plus 12. E.g., the dose for a child of three years would be $\frac{3}{15} = \frac{1}{5}$. As compared with Cowling’s Rule, it gives somewhat higher doses below twelve years, and somewhat lower above this age.

Fried’s Rule for Infants.—Divide the age in months by 150 and multiply it by the adult dose; e.g., for a baby of five months, the dose would be $\frac{5}{150} = \frac{1}{30}$.

The dose for aged people is generally taken as somewhat less than that for adults. Above sixty years, the adult dose is reduced to fourths or two-thirds; and in extreme senility, to one-half.

Specific Influence of Age on Drug-action.—These (i.e., apart from the difference due to weight) are known definitely only for a few drugs. Children are comparatively tolerant to cathartics, strychnin, iodids, iron, belladonna, calomel, digitalis and spartein (A. Jacobi, 1907). Old age is
generally less resistant to drugs; purgatives and emetics are especially debilitating. The frequent existence of atheroma makes it dangerous to use drugs which raise the blood pressure, directly or indirectly.

**Influence of Sex.**—Women usually require somewhat smaller doses than men (one-half to four-fifths). The greater susceptibility is in large part due to the lesser weight, but in part also to the anatomic and functional peculiarities. The influences of sex are of course most pronounced with drugs which act on the generative organs. Pregnancy also modifies the action of drugs, and contraindicates the use of irritant cathartics (because of the danger of inducing abortion) and of irritant diuretics (on account of the tendency to nephritis), etc.

**CONDITIONS INFLUENCING DRUG ACTIONS**

The time of administration also influences the action of drugs. Hypnotics and Cathartics, for instance, are most effective when their action coincides with the natural time of sleep and defecation, and if the external conditions are favorable. Stomachics are best given shortly before meals. Drugs which are to be absorbed rapidly are given on an empty stomach, whereas irritants are administered just after meals, when the stomach is protected by food; etc.

**Idiosyncrasy.**—This term (from ἰδιός, one's own, and ἴδεωμα, a blending) is applied to peculiar, exceptional reactions to the effects of drugs. The differences are generally quantitative, and may concern the main action, or the side actions, especially skin eruptions. They may be inherent in the remedy, or may be due to extraneous causes, or they may be referred to the constitution of the patient. In the latter case, they may be due to anatomic or to functional peculiarities. They may be congenital or acquired, temporary or permanent. Neurotic patients are especially liable to show unusual effects. Some apparent instances of idiosyncrasy are due to differences in the strength or constituents of drugs.

**Impurities in Drugs.**—Qualitative abnormalities in the effects of drugs are usually due to the exaggeration of a side action, but in some cases they may be referred to the presence of impurities. It is rather doubtful, however, whether these impurities have the importance which is often assigned to them. Whilst it is desirable that drugs should be as pure as it is practical to make them, minimal amounts of foreign substances can not be said to be very objectionable, unless they are particularly poisonous. The pharmacopoeias have taken a wise stand in this matter by permitting the presence of small amounts of such innocuous impurities which it would be very difficult and costly to remove.

**Increased Susceptibility.**—This may be due to very rapid absorption, or slow elimination; to the presence of synergistic agents in the body; or to increased functional susceptibility.

**Anaphylaxis.**—This is a striking type of highly increased susceptibility; but it seems to be confined to proteins. It has been suggested that the peculiar irritative reactions to iodides, volatile oils, etc., are also anaphylactic; but this is not the case (H. N. Cole; Zehner, 1912; Gluck, 1914). One striking difference is that the hypersusceptibility to ordinary drugs can not be transferred passively.

**Cumulative Action.**—This is said to exist when the continuation of a given dose of a drug produces greater effects than the first doses. It may be due to an actual accumulation of the drug, absorption being greater than the capacity for excretion; or it may be due to the sum-
mation of effects, when the changes brought about by the first doses persist; the drug may use up some substance required for it disintoxication (phenol); or there may be general decrease of resistance.

Inconstant absorption is a frequent cause of apparent cumulative action. Successive doses of the drug may be unabsorbed in the alimentary canal, to be finally taken into the system in toto when the conditions are favorable to absorption. This explains that the greatest individual variability to toxic doses exists precisely for those drugs which are absorbed with the greatest difficulty. Irregularities of Excretion (nephritics, etc.) are also favorable to the development of cumulative effects.

"Education."—It is sometimes noted that effects are more easily reproduced after they have once been induced. This is seen particularly in drugs acting upon the central nervous system. It is explained, e.g., that the susceptibility to stimuli is increased in administration, and it would seem that this is caused by the central nervous system becoming educated to the stimulating actions and responding to them more readily.

Tolerance.—This may be due to non-absorption, to rapid elimination, to the neutralization or destruction of the poison, or to anatomic peculiarities. Many cases can not be explained in this manner, and must be assumed to be functional (the "histogenetic" immunity of Behring). The tolerance is rarely absolute, so that it is scarcely correct to speak of "immunity." (Critical review of the literature of tolerance, Heger and Ann., 1914.)

Habituation.—Tolerance may be congenital, or it may be developed by the repeated administration of the poison. This habituation may be functional (alcohol, caffeine, nicotine); or it may be due to diminished absorption (arsenic) or increased elimination (atropin in cats); or to increased destruction of the poison (morphin); or to the production of antibodies (toxins). The tolerance is usually limited, not absolute. With some poisons, it develops a craving and serious abstinence symptoms, if the drug is suddenly withheld.

It is interesting that functional habituation, when acquired for a particular drug, may hold also for other drugs having a similar action. A habitual drunkard, e.g., is resistant to the general anesthetics; morphinists are said to be more tolerant to cocaine (Chouppet, 1889); etc.

Beusmann, 1907, and Santesson, 1912, give reviews of the data on habituation.

Anaphylaxis formation is a conspicuous instance of acquired tolerance. It was supposed to be confined to proteins, but seems to exist also toward certain glucosids (toadstool, and poison ivy, Ford, 1905; snake venom, Faust, 1911). It does not occur with alkaloids or any of the simpler poisons.

Acquired Immunity in Protozoa.—This has a practical as well as theoretic bearing on chemotherapy, and has been investigated by Ehrlich, 1909, and Neubaut, 1910. These organisms acquire immunity for several groups of poisons—metals and dyes—their tolerance induced by one drug applying to other chemically related drugs, but not to the other groups. The immunity, when once induced, is transmitted unlimited from generation to generation. It is probably due to diminished affinity of the proteplasm for the poison. With alkaloids, Prowazek, 1910, found that different individuals, even in the progeny of a single parent, show varying resistance to the same alkaloid. He also found that lecithin protects against the alkaloids.

Racial Idiosyncrasy in Animals.—Different species of animals often vary in their response to a poison. This can usually be explained by differences in the physiologic functions. For instance, the cerebral actions are usually the more pronounced, the more highly the central nervous system is developed; whereas spinal actions predominate in the lower vertebrates. Rodents are incapable of vomiting and therefore do not respond to emetics. Atropin quickens the heart of the dog, but not that of the rabbit, because it acts by paralyzing the vagus, which is not tonically active in the rabbit. The dog-fish, which is more or less resistant to nephrotic poisons, normally excretes urea and probably other metabolic products mainly by the intestines and bile (Denis, 1913).

Natural resistance is often due to the destruction of the poison, i.e., that of atropin
by the serum of rabbits, etc. The destructive mechanism may be greatly increased by habituation; f.s. with morphin. Differences of absorption and excretion also come into play.

There are still a number of differences which can not yet be explained on a physiologic basis. These must be referred to our ignorance of the physiologic differences which are involved. The *hedgehog* has a high unexplained resistance to many poisons; morphin, atropin, nicotin, cyanid, cantharides, arsenite, diphtheria and tetanus toxins; not for strychnin (Strubel, 1905; Wilberg, 1912).

Even the same organs in different classes of animals may show unexplained differences. Thus, Gunn, 1909, claims that apocodein, quinin, and yohimbine, which cause vasodilation in mammals constrict the blood vessels in frogs—both peripherally. Characteristic differences in epinephrin are well known; but the mechanism of these is explained by differences in innervation. Individual Idiosyncrasy in Animals.—In animals, as well as in man, peculiarities exist in different individuals of the same species. Qualitative differences are seen particularly in the action of Cannabis on dogs.

Instances of quantitative differences are very numerous:

In a large series of experiments with toxic doses of drugs on animals the author has found that there is a fair degree of uniformity in the proportion of animals which die with a given dose. Thus, certain limits can be found inside of which, out of five animals three will always die. These limits vary from 0.5 per cent. (strychnin) to 25 per cent. (ergot), but are usually comprised within from 5 per cent. to 10 per cent.

On the other hand, the susceptibility of any one animal is subject to greater possible variations; e.g., with a given preparation of digitalis, 0.6 mg. per gram will always kill three guinea pigs out of five. But in a large series of experiments, a number of animals will be found which will die of doses as small as 0.4 mg., while others will die only when 0.9 mg. is reached. Whether these comparatively immune animals always enjoy this immunity, or whether the condition is only temporary, as well as the influence of age, sex, etc., has not been determined.

These individual differences are still more striking if, instead of observing the toxic doses—i.e., the sum total of the effects—we direct our attention upon some one particular action, e.g., the amount of slowing of the heart or the variation of blood pressure. The differences in this respect are so great qualitatively that it is unsafe to draw conclusions from a single experiment, and it is difficult in these cases to establish any quantitative standard.

Seasonal Variations.—The susceptibility of animals to a number of poisons varies considerably with the season. With cold-blooded animals, this would be referred mainly to differences of temperature; but considerable variations exist also in mammals. Guinea pigs, f.s., are more resistant to ouabain, and less resistant to acetanilide and diphtheria toxin during November to January than in the spring and summer months (Haskell, 1912).

Temperature.—This has a marked effect in cold-blooded animals; digitalis, veratrin, nicotine, strychnin, tetanus toxin, chloral, and alcohol, for instance, are rendered more active, morphin and curare, less active, by raising the temperature. The temperature quotient of strychnin was investigated by Schlimovits and Chase, 1916.

The influence is especially marked with poisons that have to undergo a transformation in the body. At 37°C, the susceptibility of frogs to atoxyl is increased 13 times, that for colchicol 50 times, above ordinary room temperature. With muscles, the activity of drugs increases in a mathematical ratio with the temperature within certain limits (Veley and Waller, 1910).

The temperature relations of digitaloids are fully discussed by Sollmann, Mendelssohn and Sipinel, 1915.

In mammals, cooling generally increases toxicity by adding its direct depressant action.

Temperature on Spinal Reflexes.—In decapitated cats, reflexes are optimal at 38°C; but the changes are very slight between 35 and 37°C. In frogs, the optimal temperature for reflexes is 5° for winter-frogs, 6.8° for summer-frogs. A second optimum is reached between 19° and 21°; but this is much less efficient than the first optimum (van Leeuwen and van der Mades, 1916).

Diet.—This has a marked effect on the resistance of animals to many poisons (Hunt, 1910; Opi and Allford, 1914); but little is known of this in man.

The people of the undernourished war-countries were said to show greater susceptibility to the toxic manifestations of mercury and arsphenamine; to the narcotic action of morphin, and to cutaneous reactions for various drugs (Zernick; 1919, Rumpel, 1919).

The calcium content is important in influencing cutaneous irritation (Lutfbrue, 1911, 1912). Barium is better absorbed from a Ca-poor diet (Alsborg and Black, 1912).
The acid-base content of the food is also an important factor, especially in relation to renal irritations (Salant and Bengis, 1917; Salant and Swanson, 1917).

Influence of Pathologic States.—The effects of drugs in disease may differ materially from those on healthy animals. The pathologic conditions may diminish absorption (diarrhea) or increase it (corrosion); they may hasten the destruction of the poison (alcohol produces less intoxication in fever); or they may alter the effects entirely. Some of these modifications are readily explained by the functional or anatomic changes of disease; others are obscure.

The antipyretics reduce the temperature in hyperpyrexia, but do not affect it when it is normal; digitalis is an efficient diuretic in cardiac disease, but not in health; it affects the normal cardiac muscle, but has little action on a fatty heart, etc.; the antiseptics and antitoxins are active only in infections, etc. Numerous other instances may be found in the papers of Salant, 1911, and Wallace, 1912.

Pathologic conditions which modify absorption and excretion are of particular practical importance: Suppression of urine, as by nephritis, may lead to toxic symptoms from drugs or doses which are ordinarily harmless. The general reduction of vitality, the "insured resisting power," which is so common in many diseases is similarly important. As an instance of such modifications, the investigations of Lusini and Sebastiani, 1906, may be quoted. They found the absorptions of poisons hastened immediately after hemorrhage but not later. The toxic symptoms were not modified. The resistance was found lowered to a varying degree for different poisons: Most for strychnine, less for veratrum, and not at all for physostigmine.

Inflamed Vessels.—These react abnormally. Eskin, 1914, found constrictor drugs generally less and dilator drugs more effective. Equine print often produced dilatation, while caffein, which normally dilates, constricted the inflamed vessels of rabbit's ear.

Diseased intestine allow a much more rapid diffusion of proteins, toxins and fermenters that healthy intestine (Mayerhofer and Pribram, 1900).

The distribution of the drugs in the body may be different in disease and health. This is best illustrated by fluorescein (see Index).

Iodid and many dyes tend to accumulate in the necrotic areas of tuberculosis, tumors, etc. (Well, 1910; Cecil and Well, 1917).

The Combined Action of Drugs.—The effects of drugs are also influenced by the unusual conditions induced by the simultaneous administration or presence of other drugs. A quantitative change may occur either in the sense of increasing the efficiency (synergism), or of diminishing it (antagonism). There may also be qualitative changes. In other cases, new actions are developed by the reaction of the drugs on each other, with the production of new compounds. For instance, the presence of acids renders the basic salts of bismuth soluble and toxic; oxidizing substances may liberate lodin from iodids; the iodids also decompose calomel and render it irritating.

Antagonism of action is employed in the treatment of poisoning; or sometimes to remove undesired side effects. When it interferes with desired effects, it constitutes "therapeutic incompatibility."

Combination Therapy.—Synergism is utilized to secure the summation of the desirable effects of several drugs, whilst the side actions are not increased or may even be neutralized. The efficiency itself may be increased, especially when the drugs attack a given cell or function simultaneously by several different mechanisms. Chemo-therapy has furnished some illustrations of this (Ehrlich, 1909). Formerly, combinations of drugs were very popular, but on the empirical principle of the shot-gun mixture—that of many ingredients, some at least might fit the disease. Such indiscriminate mixtures are not scientific. It is better to employ the fewest possible drugs, until it has actually been shown that
combinations give superior results in the particular condition. In giving several drugs of similar actions, the dosage of each must be correspondingly reduced.

Variations of Combined Action.—When several drugs are administered together, each may act independently, as if it were present alone. The result would then be a simple algebraic summation of the effects, either synergistic or antagonistic. In many cases, however, the combined action is greater or smaller than would be calculated (potentiated and deficient summation). The relations may differ entirely according to dosage.

F.1. stimulants are antagonistic to depressants only in small doses. Large doses often become synergistic, the depression being greater than if the depressant were used alone. Instances of this are atropin and pilocarpin on embryonal growth, Soliman, 1904; caffeine and alcohol toxicity, Pilcher, 1912; atropin and physostigmin toxicity, Fraser; Fothergill gives other interesting examples of antagonism.

Sometimes, an action develops only in the presence of another drug; f.1., pilocarpin provokes the action of minute doses of atropin on the intestine; or the point of attack may be shifted by the second drug. Instances will be found in the chapter on “Autonomic Poisons.” The ratio of loss in the medium surrounding the cell influences the effects of drugs very materially.

Instances of Synergism.—The best-studied examples are from the group of narcotics. The simple lipolytic narcotics (alcohol, ether, chloroform, etc.) show practically only simple summation; but the addition of the alkaloidal narcotics (morphin and scopolamin) gives considerable potentiation (Knell, 1907; Fuechner, 1911; Kochmann and pupils, 1913). Bromide gives simple summation with lipolytic and alkaloidal narcotics (Klammer, 1913). The different opium alkaloids potentiate each other in interesting ways (Straub, 1913; Macht). The organic local anesthetics do not usually potentiate (Schmid, 1913). Fuechner, 1912, has worked out the summation of hemolytic agents.

Mechanisms of Potentiation.—There are several possible explanations, but few definite data. One drug could modify the penetration of another. Fuechner, 1913, showed that this is true of the solubility coefficient of the narcotics; or it might alter the chemic affinity, either by acting as an amboceptor, or by closing the combining groups of the cell or of the drug (antitoxins); or it might attack the cell from a different point.

Mansfield and Hamburger, 1915, believe that magnesium potentiates urethane; and that ether potentiates chloral or morphia, by favoring the distribution of these agents in the nervous system; for they find that the augmented action of the combinations persists after the magnesium is neutralized by calcium; or after the ether has been eliminated.

Those interested in summation and antagonism should read Chapter VIII of Versborn’s “Erregung und Lachmung.”

Buerger’s Law.—Buerger, 1910-1912, proposed a universal explanation of synergism but his generalization is double quantitatively speaking. He announced that potentiation occurs, always and only, when two drugs have different points of attack in the cell; because two different receptors could take up more poison in a given time than could a single receptor from the double quantity of a single drug. Fuechner, 1913; Iskutov, 1913; Zorn, 1913, and others have pointed out numerous important exceptions to this “law.” It is certainly not universally applicable.

FERMENTS AND NUTRIENTS

DIGESTIVE FERMENTS

Nature of Ferments.—The digestion of food in the alimentary canal is accomplished mainly by the secretion of organic ferments or enzymes; colloid substances of unknown composition, whose presence accelerates chemical changes. Commercial ferments are more or less purified extracts, rich in protein, and dried or preserved by glycerin.
Our knowledge of the nature of ferments is very incomplete. Like colloids, they possess electric charges (Michaelis, 1900). Emil Fischer found their action on sugars to depend on their optic activity. Several workers have shown that the cleavage ferments may, under proper conditions, produce synthetases (Taylor, 1904). The term "fermentation" is derived from fermentum, leaven, and this probably from fervere, to boil. It was originally applied to all effervescence.

Conditions of Action and Deterioration.—The digestive ferments are specifically adapted to the hydrolytic cleavage of the various food products (amylolytic, proteolytic, lipolytic, etc.). Their activity is greatly influenced by various conditions, especially by temperature (40° to 45° C. being optimal for mammalian ferments); by acid or alkaline reaction; by salts, etc. Solutions are quite unstable. They are destroyed rapidly about 95°C., immediately by boiling and more gradually by any excessive conditions, and by putrefaction. Pepsin is much more resistant to destruction than trypsin, but both deteriorate even in neutral solutions, trypsin often in a few days. Dilute watery solutions deteriorate quickly even at ordinary temperature; and even dry "pancreatin" is unstable (Long and Muhlmann, 1914). Pepsin can be completely destroyed by shaking (Shaklee and Meltzer, 1909).

Incompatibilities.—Solutions of ferments are therefore incompatible with excess of acid and alkali (Long and Muhlmann, 1914) or salts; with many antiseptics; with excess of alcohol; and with all protein-precipitants. Pepsin in neutral or alkaline solution is destroyed by sodium chlorid (W. H. Hamburger, 1915).

Mixtures of ferments digest each other more or less rapidly according to their reaction. Pepsin, in the presence of weak acids, destroys trypsin and amylase completely; but trypsin has little effect on pepsin under ordinary conditions (Long and Muhlmann). "Compound Digestive Elixirs," supposed to contain pepsin with pancreatin, etc., are practically worthless (J. A. M. A., 1907, v. 48, p. 434).

Administration of Ferments in Digestive Disorders.—This has not realized the early expectations, one reason being that digestive disturbances are rarely due to deficiency of ferments. It is also difficult to administer ferments so that they could develop their actions. Apparently favorable results may often be explained by the other treatment with which they are usually combined.

Persistence of Ferments in the Stomach.—The reaction of the stomach is best suited to pepsin, and is more or less inimical to diastase and trypsin. However, when these ferments are thoroughly mixed with food, they may act in the fundus of the stomach for an hour or so (Cannon), before the mass becomes acid (Gruenter, 1907); and since the acid is largely bound by the proteins, some of the trypsin may pass the stomach unchanged (Long and Hull, 1917). The actual quantity is generally too small for any practical use. However, there are some data which suggest that the administration of fresh pancreas by mouth improves the absorption of fat and proteins in dogs deprived of natural pancreatic secretion (Sandmeyer, 1895; Pratt, 1905). The action of pepsin is too feeble at body temperature to deserve consideration.

Other Uses.—A more rational field for ferments is in the preparation of predigested foods, especially for rectal alimentation. Kennin and Pepsin are used for curdling milk. Pepsin has been employed to dissolve diphtheritic membranes.

Pancreas Preparations in Diabetes.—The important relation of the pancreas to carbohydrate metabolism encouraged the hope that its administration would be beneficial in diabetes mellitus. The results, however, have been essentially negative, both
in human diabetes and experimental glycosurias, however much the experiments, preparations, channels of administration, etc., have been modified (Murkin and Kramer, 1913). The exceptional positive results may be fairly attributed to the natural variations in the clinical course; whilst the experimental results (such as those of Zuelzer, 1908) fall within the limits of ordinary variation (Jacoby, Exp. Ther., p. 155). The hypothetical internal secretion of the pancreas can not therefore be utilized therapeutically.

Somewhat positive results are reported on depancreatized dogs by Kleiner and Meltzer, 1915 and Kleiner, 1919. If dextrose is injected intravenously, the restoration of the normal level of blood-sugar requires twice as long as normal in an animal whose pancreas has been removed. They claim that this delay is prevented by pancreas-emulsion, and that this also diminishes the spontaneous hyperglycemia of pancreatectomy.

It produces toxic symptoms resembling those of albumoses (Hildebrandt, 1890). Smaller doses give rise to the formation of specific antibodies. Normal serum and other native proteins are also markedly resistant to proteolytic ferments (Levene and Stookey, 1909). This resistance is destroyed by heating to 70°C, and is connected especially with the albumen fraction (O. Thart, 1904).

Trypsin Injections against Cancer.—These were advocated by J. Beard, 1905; and Shaw-Mackenzie, 1906, but proved disappointing. They produce local lesions and toxic effects resembling peptone-poisoning (Kirschheim, 1911). Papain and taekildase act similarly (Kirschheim, 1913).

PREPARATIONS—FERMENTS

* Pepsinum (Pepsin), U.S.P., B.P.—A proteolytic extract obtained from the mucous membrane of the stomach of the pig (or sheep or calf, B.P.). Capable of digesting not less than 3,000 parts of coagulated egg-albumen (U.S.P.), (2,500 parts, B.P.), when the test is made according to the official directions. Various processes are used in its manufacture. White or yellowish scales or powder, slight odor and taste; acid reaction. Sol. in water (1:50); nearly insol. in alc. Solutions are incompatible with alkalies, salts, metals, and tannin.

All acid solutions deteriorate gradually in proportion to their acidity (C. F. Ramsay, 1917).

To: Optimal reaction for pepsin is H = 4, X 10^-2; but there is practically little difference between 3.8 and 1.7 X 10^-2 (Okada).

Dose, 0.5 Gm., 8 gr., U.S.P.; 0.3 to 0.6 Gm., 5 to 10 gr., B.P. Numberless proprietary preparations are advertised, but without material advantage.

Glycer. Pepsinum, B.P.—10 per cent. of pepsin; 1.15 per cent. of hydrochloric acid.

Dose, 4 to 8 c.c., 1 to 2 drams, B.P.

Pepsin. Succus.—1:10 of milk-sugar.

Liq. Seriarius, N.F., B.P.C.; Liquid Rennt.—Extracts of the fourth stomach of calves; used to coagulate unbeaded milk (1:100 to 300, 38°C, 100°F.) for the preparation of junket and whey.

* Pancreatinum (Pancreas.), U.S.P.; Pancreatin.—A mixture containing enzymes, consisting principally of amylase, trypsin and trypsin itself, obtained from the fresh pancreas of the hog of the beef. It converts not less than 25 times its own weight of starch into sugars. However, commercial pancreatic generally contain little or no proteolytic ferment, and very uncertain amounts of diastase. The U.S.P. test does not insure pancreatic activity. The amylase acts best in a faintly alkaline (0.015 per cent. NaHCO3) or neutral medium, and is destroyed by very weak acidity (0.006 per cent. HCI) (Long and Muhlman, 1914). Trypsin also acts best when alkaline (0.2 to 1 per cent. Na2CO3) but is somewhat active with very weak acidity.

The optimal reaction varies for different proteins (Long and Hull, 1917).

Excess in either direction is detrimental. It acts best on fibrin or casein, feebly on cooked albumen, and scarcely at all on raw albumen (Long and Muhlman; Sugimoto, 1911). Pancreatin occurs as a cream-colored, amorphous powder, having a faint, peculiar odor. Slowly sol. in water; insol. in alc. Dose, 0.5 Gm., 8 gr., U.S.P., B.P.

Liq. Pancreas., B.P.—An alcohol-glycerin extract. Dose, 4 to 8 c.c., 1 to 2 drams.

This, Pancreatin (in N.F. of B.P.), however, is a more concentrated with 4 parts of sodium bicarbonate; is used for the artificial digestion of milk (1.5 to 500, 38°C, 100°F., for half an hour).

Pepsin.—The dried milk-juice of the unripe fruit of Carica Papaya. Extracts are marketed under proprietary names. It is supposed to digest proteins in acid, alkaline and neutral media; its activity, however, is variable, and always much less than pepsin.
The digestion is more rapid at 80° to 90° C. (Potter, 1899; some of its peculiarities were shown by Mendel and Blood, 1910). *Extrait Malt* (Ext. Malt), U.S.P.—A watery, extract of malt, prepared at 53°C, and evaporated at this temperature to the consistence of a thick honey. Contains diastase, and therefore digests starch; but the diastatic power of the commercial extract is very weak. It is more properly nutrient, being rich in carbohydrates.* Dec. 15 C.C., ½ ounce. Many *fluid malt extract* are practically strong beer.

*Maltum*, U.S.P.; *Maltum*.—The grain of barley. Hordeum sativum, partially germinated artificially, and then dried at a temperature not exceeding 35°C. It is capable of converting not less than five times its weight of starch into sugars.

*Diastaseum*, U.S.P.; *Diastase*.—A mixture containing amylolytic enzymes obtained from an infusion of malt. It converts not less than fifty times its weight of potato starch into sugars. A yellowish-white, amorphous powder or in translucent scales; odorless and tasteless. Diastase gradually loses its amylolytic power on keeping, is diminished by the presence of acids or alkalies. Sol. in water; almost insol. in alc. Dec. 0.5; Gmcl. 4 gr, U.S.P.

Diastatic ferment are also obtained from other sources, animal and vegetable; this diastase, for instance, from a Japanese mould. Their diastatic action is also weak and unreliable.

**Lactic Acid Producing Organisms**

These were introduced by Metchnikoff, with the idea of acidifying the intestines, and thereby preventing intestinal putrefaction, which he held responsible for premature senility. They had only a brief popularity.

This theory of old age was without scientific support; nor does the administration of these organisms, or of milk soured by them, check intestinal putrefaction. On the contrary, they succumb promptly to the ordinary putrefactive bacteria of the intestines.

On the other hand, sour milk is sometimes distinctly beneficial, especially in pediatrics, against vomiting, acute and chronic diarrhea, etc. (see N.N.R.), and there are advantages in souring the milk by known organisms. *Bacillus Bulgaricus* is used, alone or in combination with *Streptococcus lactis*. The reliable commercial preparations are listed in N.N.R.

**Medicinal Foods**

Limitations.—The administration of food in the guise of medicine is sometimes advantageous; but medicinal foods are subject to the ordinary law of dietetics, and therefore can not accomplish the wonders which are often claimed for them. The proprietary foods have been enormously overestimated, and therefore have probably done more harm than good.

The value of any food depends mainly on the amount of calories which it can yield, and on its supplying at least a minimum of proteins. In these respects, the medicinal foods are all inferior, for they can not be administered practically in sufficient quantity to supply the needs of the body. They have a place as adjuvants to other foods, permitting the introduction of more food than the patient could otherwise be induced to take. This may be needed for superalimentation; when digestion is low, as in fevers or convalescence; or to tide the patient over some temporary crisis. Aside from the special diabetes foods and cod liver oil, their value is largely psychic. The better medicinal foods, it is true, are free from indigestible portions, and are pleasantly flavored; those which contain meat extracts would stimulate the flow of gastric juice; but all these properties are possessed by milk, eggs, cereals and soups. A few are more concentrated; but this has no advantage in feeding the sick, since water must be supplied in one form or another.

**Predigested Foods.**—The value of these is doubtful, even if they are well utilized; for digestive disturbances involve the motor functions and

---

absorption more commonly than the chemical functions. The continued use of predigested foods often produces irritation.

Utilization of the Products of Artificial Digestion. — It has been questioned whether this is as effective as that of the products of natural digestion. However, the work of Aberghalden and others has shown that nitrogen equilibrium can be maintained in animals on a diet of the products of acid-hydrolysis of proteins, if these are sufficiently varied to secure a proper balance of the various amino-acids, etc. (Rep. C.P.C., 1912.) Animals with their digestive canal excised can be kept alive by intravenous injection of amino-acid mixtures, but not by peptones, proteoses, ammonium or urea (Herrizquez and Anderson, 1914).

Dry "Peptones."—The dried product of the artificial digestion of meats, usually consisting mainly of albumoses. Their taste is disagreeable and they often cause irritation. Intravenously they are toxic, lowering the blood pressure and rendering the blood non-coagulable (see Index).

Liquid Predigested Foods. — As found on the market, these are flavored solutions containing small amounts of predigested proteins (3/4 to 6 per cent.) and of sugars and other carbohydrates (1/2 to 1/2 per cent.), with 12 to 19 per cent. of alcohol, and often with large quantities (up to 50 per cent.) of glycerin (details in Rep. C.P.C., J.A.M.A., May 11, 1927). Their protein content averages less than that of milk (5-6 per cent.) and in energy value, on the basis of calories, they are vastly inferior. Their daily dose (50 to 150 c.c.) yields but 55 to 400 calories, including their alcohol; and this is only one-thirtieth to one-fifth of the minimum daily requirement, even of resting patients (1,500 calories, yielded by two quarts of milk). To increase their dose to that required to maintain nutrition would mean the ingestion of an amount of alcohol equivalent to about a pint of whisky per day.

No liquid food should be given consideration unless it contains, exclusive of alcohol and glycerin, at least as much food value as milk; and at least one-fourth of this should be in the form of nitrogenous constituents. Even these can only be considered as adjuvants and vehicles.

Meat and Beef Juices. — When prepared extemporaneously by expression of fresh or slightly boiled meat, these contain from 2.3 to 9 per cent. of coagulable proteins, and 2 to 4 per cent. of other proteins and nitrogenous extractives. They have therefore a moderate value as sources of nitrogen. The commercial preparations are supposed to be concentrated; in fact, however, they are very inferior, containing but 0.2 to 0.7 per cent. of coagulable proteins; others are reinforced by the addition of defibrinated blood, sugar, glycerin, etc., which are of doubtful utility (Rep. C.P.C., J.A.M.A., Nov. 20, 1920).

Bouillon and Meat Extracts. — Bouillon (beef-tea) is prepared by boiling meat with water; the extracts by evaporating the solution to a semisolid consistency. The coagulable proteins are removed by this process, the extract containing the salts of the meat, the flavoring substances and meat bases (santhin and creatin products) and a certain amount of non-coagulable protein, in the form of gelatin, albumoses, etc. In the small amounts in which they are used, these preparations contain a very insignificant quantity of nutrition. They are, however, valuable as stimulants. They owe their action largely to the odorous principles which they contain, and which are excellent stomachics (Woff, 1912). The potassium salts have also been invoked to explain the action, it being claimed that they stimulate the heart in moderate doses and paralyze it in large doses. But the dose required to produce the former effect is very much larger than would be administered in beef-tea.

Composition of Meat-extract. — American brands of the Liebig-type (pasty consistence) contain, on the average: Beef-bases, 26.4 per cent.; gelatin and albumose, 16.5 per cent.; N-free extractives, 14.0 per cent.; inorganic salts, 22.5 per cent.; water, 20 per cent. (N.N.R., 1920).

Insoluble Meat Powders. — Tropen, etc., they are employed to thicken soups.

Their usefulness is very limited.

Casein Powders. — Include "Surise," N.N.R. (sodium caseinate); and some advertised to the public with most extravagant claims (Sanatogen, J.A.M.A., May 6, 1911, etc.). They have no serious advantage over ordinary cottage-cheese.

Foods for Diabetics. — These are intended to reduce the intake of sugar-forming carbohydrates. They fall into two groups: sugars and carbohydrates that do not yield dextrose; and foods for diabetics. Non-Destructive Sugars: — Lactose (N.N.R.), inulin and lactate are sometimes tolerated better than other sugars. (v. Noorden, 1910; Goudberg, 1913) but the difference is
usually not important. In pancreatic diabetes and phosphorus glycosuria the levulose is deposited as glycogen, whilst destrose is not (E. Neubauer 1900). H. B. Lewis and Frankel, 1914, conclude that insulin is quite useless. It is not digested, although some is burned by the intestinal bacteria. None is converted into utilizable carbohydrate, even in phlorhizin animals.

**Rapidly of Oxidation of Sugars.**—In man, the respiratory quotient shows that sucrose, lactose, levulose and lactate begin to be oxidized within five or ten minutes after their ingestion. With glucose and maltose, oxidation begins only after 20 or 35 minutes (Higgins, 1916).

**Inulin.**—This carbohydrate, C_{12}H_{22}O_{11}, occurs in several plants and in muscle.

Kalt, 1874, found that on feeding, only insignificant amounts appear in the urine; and that diabetic glycosuria is not increased. From this he thought it might serve as a sugar substitute in diabetes. However, it soon appeared that it is not burned. (R. J. Anderson, 1916); the greater part being eliminated unchanged by the feces.

However, Greenwald and Weiss, 1917, claim that it is slowly, but completely converted into sugar in phlorhizin-diabetic animals (Greenwald and Weiss, 1917). In man, daily doses of 0.5 Gm. per Kg. cause diarrhea (J. A. M. A., 1916, 67:900).

**Grape, 1914, finds promising results with caramelize[d sugar. It is all absorbed and completely tolerated even in severe diabetes. It does not increase the blood-sugar, and the respiratory quotient shows that it is utilized in the diabetic as well as normal organism.

**Mannit** is also employed as sweetener, being assimilated without causing glycosuria; doses above 20 to 30 Gm. are laxative. (For normal assimilation limits of various carbohydrates, see Macklot, 1913 and 1914; Jacobson, 1914.)

**Benedict, N. N. R.—An artificial sugar, the lacton of a glucoheptonic acid; was introduced by Rosenfeld, 1914, as sweetening agent and food, but has failed to realize the original expectation. When administered by mouth, 21 to 85 per cent. is excreted unchanged by the urine and feces. The fate of the remainder has not been established. Large doses produce diarrhea and other digestive disturbances. Its excretion is diminished in nephritis, resulting in retention (Koshti, 1912; Kramer, 1912; Lenz, 1914).

**Fruit for Diabetics.**—These are intended to form a substitute for bread, as a vehicle for butter, etc. High food value is not desirable. Gluten flours should not contain more than 10 per cent. of carbohydrates. Many do not comply with this requirement.

**Jambul.**—The fruit, leaf, or bark of Syzygium Jambulana, Eastern Asia. It contains an essential oil, tannin, and probably a glucosid. (The constituents are discussed by Illie and Boyl, 1917). It has been recommended in diabetes mellitus in doses of 0.3 to 0.5 Gm. of the fruit (5 to 8 grains). Efficiency doubtful.

**COD LIVER OIL.**

This is employed as a nutrient “tonic,” especially in rickets, tuberculosis and other wasting diseases. In rickets it is used both as a remedy and for prophylaxis (Hess, 1917). It seems effective when it is tolerated. Its efficiency is due partly to its high yield of calories. Its principal value, however, is probably its richness in growth vitamin (“fat-soluble A”) although this is not unique; for butterfat probably contains as much. “Fat-free” extracts of cod liver oil, which have been widely advertised, contain neither the fat nor the vitamin (Street, 1915) and are apparently without value.

The oil may cause distaste, eructations and diarrhea. These are often avoided by starting with small doses, gradually increased. It is generally administered two hours after meals. Indigestion and fever contraindicate its use.

**Superiority over Other Fats.**—Cod liver oil was adopted into medicine in the early decades of last century from the Norwegian fishermen, who prepared it by very crude means, without putrefaction. These oils, therefore, contained free fatty acids (Borchard, 1874), bile constituents (Naumann, 1865), cholesterol, putrefactive alka-loids (adolin, mornthin, etc.; Gautier and Mourgés), traces of iodin (about as much as...
oysters, and other impurities. All of these have been credited with the effects; but these substances are eliminated in the modern sanitary processes, without decreasing the usefulness of the oil; whilst "oil-free," "tasteless" extracts, wines, etc., are useless (B. C. C., J. A. M. A., Oct. 9, 1909).

The easier emulsification of the oil is probably a peculiarity of its characteristic fats, which are largely glycerides of oleic and theriacic acids. Lipasin was a mixture of olive oil with 6 per cent. of oleic acid, based on Buchheim's suggestion that free acids aid emulsification. It has not established itself clinically. The digestibility of different animal fats is discussed by Langworthy and Holmes, 1915. Mottram, 1915, attributes the superiority to the high percentage of unsaturated fatty acids, which approaches more closely the form in which fat is supposed to be utilized in metabolism.

Sodium Morrhuate.—This has been tried hypodermically, similarly to sodium gyno- cardiate, against tuberculosis and leprosy. B. Rogers, 1918, claims good results; but these would require strict and extensive confirmation.

PREPARATIONS—COD LIVER OIL

* Oleum Morrhuae (Ol. Morrh.), U.S.P.; B.P.; Cod Liver Oil (Ol. Iecoris Aselli).—* A fixed oil from the fresh livers of Gadus Morrhua and other species. Occurs as a pale yellow thin oil, having a peculiar fishy, but not rancid odor, and a bland fishy taste. It thickens on exposure to air. Dose, 10 c.c., 25 drops, U.S.P.; 4 to 15 c.c., 1 to 4 drams, B.P.

VITAMINS

Importance of Special Food-factors.—It has long been recognized that the diet must not only represent a certain amount of calories, but that it must include certain foodstuffs. The special importance of proteins was naturally the first to be recognized. It also became known quite early that one-sided diets are likely to result in general malnutrition, and in special diseases, such as scurvy. The general advance of knowledge has shown that the subject of special food factors has a wider application than was formerly suspected; and it has also thrown considerable light on the nature of the factors that are concerned.

So far, two distinct types of deficiency factors may be recognized, viz.:

1. Deficiency in constituents that are used directly as food, notably the various amino-acids.

2. Deficiency of substances that are needed only in minute quantities, and which therefore presumably do not act as foods directly.

Deficiency of Amino-acids.—Osborne and Mendel, 1912 et seq., found that the animal organism is apparently unable to synthesize certain amino-acids that are essential to the animal proteins, and that these must therefore be supplied in the food. For instance animals placed on diets that do not contain the lysin or tryptophan groups cease to grow. When foodstuffs containing these are added to the food, growth may be resumed.

This phase of food-deficiency probably does not occur easily under the practical conditions of civilized life.

Vitamins.—The existence and importance of these was definitely established by the observation that the oriental disease "beri-beri" is caused by an exclusive diet of polished rice; that an analogous condition of polyneuritis can be produced in pigeons and fowls after about 3 weeks of a similar diet; and that this can be relieved at once by the administration of extracts of rice-hulls, yeast, etc. (Eykmann, 1897). The cure requires only very small quantities of the active substances, which were named viamins by Casimir Funk (1911 to 1913). An extensive bibliog-
rapy is given by A. Bruce Macallum, 1919; Trans. Royal Canad. Inst., page 175.

Other Diseases Probably Referable to Dietary Deficiencies. — These include scurvy and infantile scurvy; and possibly pellagra, rickets, and tetany.

Specific Growth Substances. — Rats kept on artificial diets that contain all the essential amino acids and energy units, nevertheless soon cease to grow, unless substances are added that contain small quantities of some special ingredients, that may be isolated in more or less purified form (Osborne and Mendel, 1913 and 1914; McCollum and Davis, 1913, Mendel, 1915).

There are two groups of these substances, one being fat-soluble (A) and the other water-soluble (B). McCollum, 1917, believes that there are only these two substances (A and B) concerned in the dietary protection. Some investigators assume a larger number of specific "vitamins." 

Importance in Diet. — Vitamins in general are present in most natural food, both animal and vegetable; particularly in glandular organs and products, including milk and eggs, and in green vegetables (spinach, cabbage, lettuce) and in the embryo and hulls of cereals. They may also be prepared from yeast.

They are relatively deficient in meats, potatoes, flour, most oils and sugar products (Osborne and Mendel, 1918).

Mechanism of Action. — This is practically unknown. Vitamin deficiency is always associated with loss of appetite; and the "cure" or resumption of growth on vitamin administration is accompanied by increase of appetite. The increased food-consumption is undoubtedly an essential factor in the growth but it is not known whether it is merely a result of the growth needs.

Macallum (A. B.) believes that the action is directly on tissue metabolism; and on the whole this seems the most probable view; because sometimes changes of growth may occur without change in food-consumption.

McCarrison, 1919 (Brit. Med. H. 1:177) believes that deficiency of polyneuritic vitamin causes "nervous starvation" of all cells, and that the neuritis is merely incidental.

Intestinal Change. — McCarrison also found, in pigeons and guinea pigs suffering from experimental vitamin deficiencies, that the intestines showed marked changes, i.e., atrophy of the coats, lesions of the nervous-muscular system, and impaired digestion and absorption. There is commonly persistent constipation, and the administration of the vitamin is usually followed by diarrhea. The rice-ball extract stimulates the contraction even in excised intestine.

These observations suggest that a direct action of the vitamin may possibly be that of regulating the peristalsis, and thus the intestinal bacteria; and that this may at least have a part in the result.

Parasympathetic Stimulation. — Uhmann, 1918, claims that antineuritic vitamins when injected intravenously, produces a typical pilocarpin action, i.e., stimulation of the parasympathetic junction in glands and unstriped muscle; the stimulation being removable by atropin. He attributes the digestive effect to stimulation of the digestive glands.

Secretin-effect. — Voegtlin and Myers find that intravenous injection of yeast extract increases the flow of pancreatic juice and of bile. They also find that secretin relieves experimental polyneuritis. There is a similarity in the chemical and physical properties of the two substances; but as they have not been isolated, their identity can not be affirmed.

Sugar Metabolism. — Pigeons on a vitamin-free diet develop hyperglycemia and decrease of liver glycogen. These are restored to normal by treatment (quoted from Macallum).

A " A " Substance; Fat Soluble or Growth Vitamin. — This is concerned mainly in growth, its deficiency causing suspended growth; or in advanced cases, a type of xerophthalmia. These are curable by the administration of the substance (McCollum, 1918).

Occurrence. — It is most abundant in the intracellular fat of glandular organs, and therefore in butter fat, beef-fat, egg-yolk, and cod-liver oil; whilst it is absent from
lard, or olive or almond oils. It is also widely distributed in plants, especially the leaves (McCollum, Simmonds and Pita, 1916). The ether extract of dried spinach or clover evaporated on starch, is a very effective growth substance (Osborne and Mendel, 1912).

Properties.—The "A" substance is soluble in oil and fat-solvent, and also fairly soluble in water.

The growth-promoting action of butter fat is not due to contamination with nitrogen or phosphorus compounds (Osborne and Wakeham, 1915). It is confined to the portion of the fat with low melting point; is not destroyed by steam (Osborne and Mendel, 1915) and as it exists in butter, is very stable under ordinary conditions of storage (Mendel and Osborne, 1916). In the more concentrated butter oil, it deteriorates almost completely within a year (Osborne and Mendel, 1916).

Macallum, by similar experiments, arrived at different conclusions as to the fat-vitamin:

He found that butter fat purified according to Osborne and Mendel still contains of N. C. components. He also claims that the growth-vitamin of butter fat is unalne alone to bring about normal growth increment in young animals. In short experiments it is not superior to hard and only quantitatively superior in long experiments.

Xerophthalmia.—This occurs in rats and also in rabbits, along with the loss of body weight (V. E. Nelson and Lamb, 1920). It is probably due to infection of the eye, consequent on lowered resistance from malnutrition (Mallanby and Fox, 1919).

"B" Substance, Water Soluble or Antineuritic Vitamins.—Deficiency of this results in beri-beri in human subjects, and in experimental polyneuritis in birds. The vitamin also promotes growth (Funk and Macallum, 1911).

Relation of Antineuritic and "B" growth-vitamin.—Although these occur together they do not appear to be identical. Excessive heat destroys the antineuritic value of whole rice for fowls; but does not destroy the growth factor for rats (Emmet, A. D. and Luors, 1910). Conversely, yeast-filler's earth adsorbate (L. Seidell) contains the antineuritic, but not the growth properties (Emmet and McKim, 1917). Beri-beri in Mammals.—Typical beri-beri polyneurides has been produced in cats and dogs by an exclusive diet of lean meat, heated for 3 hours at 120°C. with sodium carbonate solution. Different animals required different periods to develop the disease. The pathology and the response to treatment are the same as for beri-beri (Voegtlin and Lake, 1919).

Occurrence.—The "B" substance is also of wide occurrence in animals and especially vegetable food, particularly in green vegetables (McCollum et al, 1910). It is present in milk, eggs, liver and pancreas, but deficient in meat (muscle); (Osborne and Mendel, 1912). Traces have been isolated from ox-bile and from human urine (Muckenfuss, 1910). Fruit and fruit-juices protect against B-deficiency although rather large quantities must be taken (Osborne and Mendel).

Yeast as Source of Vitamin.—See next section.

Chemical Structure of Antineuritic Vitamins.—Funk, 1911 and 1912, succeeded in isolating from defatted rice-hulls a crystalline substance, of which 4 mg. effect the cure of a polyneuritic blind. (The process of isolation is described in Macallum.) Similar substances have been isolated from yeast and from ox-brain. The chemical structure, however, is still unknown. It is not an amino-acid. It is probably a rather simple derivative, perhaps of pyrimidin, puridin or purin. R. R. Williams, 1917, considers that the betain-zing is essential, betain itself being weakly protective. The antineuritic vitamin prepared from egg-yolk is not adenin (Steenbock, 1917) and adenin is not anti-aneuritic (Voegtlin and White, 1916).

Solubility Characters of Antineuritic Vitamin.—This is water-soluble and dialysable (Eykman, 1897). Fraser and Stanton, 1909 and 1911 showed that it is soluble in alcohol. When extracted from various sources by alcohol, it becomes soluble in organic solvents especially benzol (McCollum and Simmonds, 1918). This may have led to confusion with the "A" substance.

Resistance to Reagents.—The vitamin is highly resistant toward acids, remaining unaltered on boiling for 24 hours with 20 per cent. mineral acids (Funk and Cooper, 1914). Alkalies do not destroy it at room temperature; but they sometimes destroy it during its isolation.
Yeast

105

Yeast Stability of B. Vitamins.—It tolerates heating to 100° C. for several hours, in neutral or acid solution, and therefore persists in canned vegetables. However, it is quickly destroyed in neutral solution at 120° C., and in alkaline solutions also at lower temperatures (Goidl and Hume, 1917). Proc. Roy. Soc. 93 B: 160; McGillicu, 1918, Am. J. Publ. Health, 2: 171.

It remains active when yeast is autolyzed at 35° C. for 24 hours (Cooper, 1914).

Yeast (Faex Medicinalis)

Yeast as Source of Vitamins.—Ordinary baking or brewer’s yeast contains considerable water soluble vitamin (McCollum et al, 1910) similar to and perhaps identical with that of rice hulks. Fresh or autolyzed yeast is much more effective than dried yeast.

The active principle adheres to fuller’s earth, and can be concentrated by treating autoclaved yeast with this absorbent. Its extraction from yeast is further described by T. B. Osborne and Wakeman, 1915. Yeast has given good results clinically in huan beri-beri, although it is not as active as extracts of rice hulls (Saleebey 1919). It has been used with good results against experimental rice polyneuritis; but it has no effect on infantile scurvy (Hess, 1916). It was also tried against other forms of malnutrition, but with doubtful results; for American and European diets do not seem to be deficient in vitamin B.

Yeast as Nitrogenous Food.—Yeast has been proposed as a nitrogenous food; but its protein value is not high, a large part escaping by the feces. Its high purin content tends to raise the uric acid of the blood (Punk, Lyle and McCasky, 1910).

Degeneration of Yeast.—Caution should be observed in administering yeast continuously for Osborne and Mendel, 1910, observed that the testes of rats on a yeast containing diet often undergo degeneration, with consequent sterility.

Infections.—Yeast has been recommended as a bactericide, etc., against furunculosis (by mouth and locally); in gastroenteritis (1 to 3 gm. p. day); tonsillitis (10 to 20 gm. p. day); gonorheal vaginitis (Abraham, 1910); in skin diseases, burns, etc. More extended observations are needed to establish its value. Tsuiru, 1909, maintains that the bactericidal effects depend upon the products of fermentation, acids, alcohol, etc. Abraham, 1913, has given an explanation.

Laxative Action.—The ordinary doses of fresh or boiled yeast are somewhat laxative. This may partly explain their other effects.

Nucleoproteins, Nucleins, and Nuclear Acids

Chemistry.—These terms are often applied so loosely and incorrectly to the commercial products, that it may not be amiss to review briefly their meaning. Nucleoproteins.—Rich occur mainly in nuclear material—are natural compounds of nucleic acids and proteins. By peptic digestion or dilute acids, a fraction of the protein may be split off, resulting in modified nucleo-proteins, correspondingly richer in nucleic acid. These are termed nucleins. They contain about 30 per cent. of organic phosphorus. The remainder of the organic nitrogen component can be removed by tryptic digestion or alkalies, yielding the true nucleic acids. These are definite chemical substances, their composition varying according to the tissues from which they have been obtained (as does also the protein constituent; so that the different products are not identical). Their composition approximate: Cα, Hα, Nα, Oα, Pα; the atomic ratio of P : N lying between 4:14 to 7. Commercial nucleic acids are often contaminated with more or less nuclein, as may be readily shown by the bluer or Millon’s reactions. They are usually prepared from yeast, but also from thymus, pancreas, spleen, the sperm of certain fishes, and the embryos of grain. Nucleins and nucleic acids have fairly strongly acid characters. They are insoluble in water, but form soluble salts with dilute alkalies.

Actions and Uses.—On hypodermic injection, they increase the number of all varieties of circulating leucocytes; and it is claimed that they also raise the opsonic index.

In dogs, the injection produces a primary leucopenia followed in 24 hours by a marked increase, often to double; the changes involving mainly the polymorphous cells (Fox and Lynch, 1917).

Because of the leucocytosis, they have been used in tuberculosis and other infectious diseases (Chantemesse, 1907), but their value is very doubtful. The leucocytosis is of short duration, requires increasing doses, and causes other disturbances (Neymann, 1917).

Favorable results have even been reported for oral administration. The absurdity of these claims may be appreciated from the fact that 100 gm. of ordinary moist meat contains about 0.25 gm. of phosphorus (Kossel, 1882) corresponding to 0.2 gm. of pure
nucleic acid; the same quantity of moist liver, spleen, or pancreas corresponds to about 2 gm. of the pure acid; whilst the oral dose of the impure nucleins is stated at only 0.06 to 0.3 gm. (Bibliography, Merck's Rep., 1914, 27:1).

Fate.—Nucleic acid passes the stomach unchanged. It is partly split in the intestines, with the liberation of phosphoric acid, but not of purins. A further part is presumably split during absorption (bibliography, Forbes and Keith, 1914).

The nucleins are excreted as purin bases and uric acid; so that they are contraindicated in gouty and rheumatic conditions, etc. The phosphate elimination is also increased.

RECTAL FEEDING

This would be desirable when food by mouth is inadmissible. Its practical possibilities are, however, limited mainly to dextrose and water. It therefore suffices only for short periods, depending on the previous condition of the patient, especially the adipose tissue.

The rectum and large intestine have practically no digestive power, except to a limited extent for carbohydrates. Water, dextrose and sodium chloride are absorbed effectively from nutrient ememas. Dextrin is easily digested and then absorbed. Amino-acids are absorbable, but proteins are not; not even peptones unless they are first broken down by bacterial putrefaction. Fats are practically unabsorbed (a good discussion of the subject is given by van Noorden, 1920).

Water.—Its absorption is a normal function of the colon, for this resorbs $3/4$ to $3/4$ of the water of the colon-contents. The entire water-needs of the organism can be supplied by this channel; provided that the injections do not contain irritant substances, and are not too strongly anisotonic.

Salts.—Many are absorbed perfectly, including NaCl. The colon expels hypo and especially hypertonic solutions. 0.8 to 0.9 per cent. NaCl is osmotically indifferent, but may cause thirst. 0.6 to 0.75 per cent. is the best concentration.

Alcohol.—This is readily absorbed. 3 per cent. solutions are non-irritant; higher concentrations may be expelled.

Carbohydrates.—The most useful are dextrose (Bergmark, 1915) and dextrin, which are both absorbable. Dextrose.—May be used as 6 to 7 per cent. for single injection, or 5 per cent. for continuous irrigation. If salt is added, the dextrose must be reduced (for instance 2.5 per cent. of dextrose and 0.45 per cent. NaCl).

Dextrin.—This is non-irritant in any concentrations, and is easily digested. It may be used as 10 to 15 per cent. for continuous irrigation; or 25 to 25 per cent. for single enemas. This higher concentration makes it possible to introduce more calories than with dextrose.

Lemulce and Malsuse.—Excite peristalsis. Lactose is not easily absorbable, and Galactose is poorly utilized. Succharose is absorbed poorly. Starch, boiled or raw, is non-irritant, and is somewhat digested, but only in limited quantity.

Proteins.—These must be broken down to amino-acids and polypeptide acids before they can be utilized. The colon readily absorbs these cleavage products, but its peptolytic power is insignificant. However, bacterial putrefactive processes are active, and through them a fair amount of protein becomes absorbable. One of the most accessible sources is White's peptone. This may be given as 15 to 20 per cent. in single enemas, or 5 to 10 per cent. for continuous irrigation. About 75 per cent. of its nitrogen is absorbed.

Amino-acid mixtures (erepton, etc.), would theoretically be preferable, but have no apparent advantage.

Absorbable protein cleavage products can also be secured by pancreatin-digestion of milk carried on for 24 hours (Reach, 1901). This may be used as the vehicle for the dextrose (Bywaters and Short, 1913). Practically no protein is absorbed from milk or eggs, unless they are predigested to the amino-acid state (Bergmark, 1915; Adler, 1915).

The value of the proteins to an enema-nourished patient requires investigation. They increase the energy metabolism to such a degree that their caloric value is probably negative.

Fats.—Only small quantities are absorbable from the colon; (Makashima, 1914; Ornstein, 1918); at most 10 grams per day. Ordinary oils, for instance olive oil, are
least absorbable: milk and cream are somewhat better. Egg-yolk is absorbed most efficiently and is equally available to putrefaction.

**Technic of Nutrient Enemas.**—These may be given as “single enemas,” or as “continuous drop enemas.”

**Single Enema.**—Two of these should be administered daily, each of 300 c.c. They are warmed and injected very slowly through a funnel and soft rectal tube, inserted about 3 inches. The patient remains recumbent for at least 2 hours, and the anus may be compressed with a warm towel for 10 minutes. Tr. opii, 1/2 c.c., may be added to the injection or better be injected 20 or 30 minutes in advance. Small enemas are carried by antiperistalsis to the cecum, but not into the ileum; with larger injections, some of the material passes into the small intestine (Cannon).

With nutrient enemas containing albumen, peptone or fat, two cleansing enemas should be given daily; if only carbohydrate and albumen are used, one cleansing enema suffices.

**Continuous Drop-Irrigation is Preferable.**—The usual daily dosage is 1,000 to 1,500 c.c. and not over 4 liters.

Nitrogenous and carbohydrate injections are best given separately.

---

**PARENTERAL ALIMENTATION**

**Subcutaneous Feeding.**—The hypodermic injection of nutrient solutions has been tried with limited success. Dextrose has given the most promising results. Even large doses are well utilized and have no detrimental effects on nitrogen metabolism (Underhill and Closson, 1909; Berendes, 1912); but are capable of diminishing acetocetasia (Bergmark, 1915). Only a small proportion is excreted into the alimentary tract (Kleiner, 1911). A 5 per cent. solution may be given under the skin, or 10 per cent. intravenously, up to 1,500 c.c. per day (Kausch, 1912).

Sucrose is partly utilized (Mendel and Mitchell, 1905; about one-third, Sapelli and D’Errico); but mainly excreted unchanged (Mendel and Kleiner, 1910; Heilner, 1911). It is not available for feeding (Mendel, 1914). Roehmann, 1912, claims that it is excreted without alteration in the urine of over 90 percent of the patients he treated. He states: “The presence in the blood stream of sucrose is followed by a rise in the blood sugar level.”

**Abderhalden and Brahm** suggest that the utilization may be explained by partial excretion into the alimentary canal, where it is converted, and reabsorbed in usable form.

Kariyama, 1917, with rapid intravenous injection of sucrose into dogs, found about 20 to 30 per cent. destroyed. The remainder is rapidly eliminated by the kidneys, and a minute amount also by the liver and intestinal mucosa. Lactose, dextrin and glycogen are also not available. In normal animals, lactose injected into the blood disappear rapidly into the tissues and urine; after nephritis or in nephrectomized animals, it is retained in the blood (O. Schwarz and Pahy, 1912).

Oil can be utilized hypodermically; 10 to 100 Gm. per day of olive oil being slowly injected with the same technic as is used for the injection of antibiotic serums. The absorption, however, is so slow that these injections are almost worthless (Winteritz, 1903; Henderson and Crockett, 1905).

**Intravenous Alimentation.**—Dextrose has been used in this manner clinically, for instance in pneumonia (250 c.c. of 8 per cent., 3 or 4 times daily).

Animals have been successfully nourished exclusively by intravenous injections of a mixture of protein-cleansing products, dextrose, sodium acetate and salts (Hendriques and Anderson, 1911). Serum protein is well utilized (Austin and Eisenrey, 1912), but the dangers (anaphylaxis, etc.) preclude its clinical use as nutrient.

Fats introduced in emulsion intravenously is also burned (Marlin and Riche, 1913).

---

**EMOLLIENTS**

**Definition of Emollients and Demulcents.**—These are drugs which soften, "relax," protect, and "soothe" the parts to which they are applied; in other words, drugs which lessen irritation. The term emollient is restricted more to those used on the skin, demulcent to those applied to mucous membranes. No very sharp distinction can be drawn between these, and many belong to both classes; but, as a rule, the fats are used as emollients, the gums as demulcents.
These substances lessen the action of chemic, mechanical or bacterial irritants; diminishing pain, reflexes, catarrh, and other manifestations of irritation. They also delay and diminish absorption, particularly from the stomach, but also from the intestine, subcutaneous tissue, etc. In this way they diminish the systemic effects of absorbable poisons, whilst they prolong their local actions.

**Mechanism of Action.**—Colloids and fats are practically indifferental and inabsorbable for cells, so that they do not produce any direct effects on them; but through their adhesive character, they form an extra covering to the surfaces to which they are applied, and thus hinder the access of irritant agents. Their action consists, therefore, in mechanical protection, and is strictly local. Fine insoluble adhesive powders (talcum, bismuth) act similarly.

**Explanation.**—The oils prevent the penetration of water-soluble substances, the gums that of fats and resins. Gums also lessen the effects of crystalloids, although they do not impede their diffusion. They produce this effect by increasing the viscosity of the solution, thereby interfering with its transportation (von Tappeiner, 1902). Adsorption probably also plays a part, for dissolved substances are condensed on the surfaces of fine powders and thus removed from the solution.

One sees a beautiful illustration of these facts in the natural lubricants of body-coverings. Whilst the skin is normally covered with a thin layer of emollient oil, the membranes of the interior of the body are moistened with mucus, which is a typical gummy demulcent.

**Emollient Drugs.**—These comprise the true fats and oils (glycerides of fatty acids), woolfat, petrolatum, and glycerin. They are employed mainly on external surfaces, to soften and protect the skin, ulcers, burns, and other superficial wounds; as vehicles (salves) for the application of medicaments to the skin or, more rarely, for systemic effects (mercurial inunctions). Internally, the true fats serve as nutrients. Larger amounts than can be digested stimulate peristalsis and act as intestinal lubricants and laxatives. For external use, the liquid or semifluid fats (oils, lard, woolfat, glycerin) should be chosen if a deep effect is desired for softening the skin or for inunction. The effects of petrolatum and of the harder "cerales" and plasters are more superficial and prolonged.

**Penetration of the Skin.**—Oils penetrate the epidermis much more readily than watery solutions. Rubbed into the skin, they enter the sebaceous glands and eventually can be demonstrated microscopically in the lymph channels. True fats are gradually oxidized and disappear; but the mineral fats remain for a long time in the subcutaneous tissue, and thus produce chronic irritation and fibrosis. The animal and vegetable fats therefore deserve preference when penetration is desired (Sobieranski; Juckaff; Meyer; see "Ointments" in Index).

**Protection of the Skin.**—The emollients and glycerin soften the stratum corneum, and render the skin more pliable and resistant to injurious agencies. They reinforce in this manner the natural fat of the skin and prevent roughness and "cracks" from wind, cold weather, sunburn, skin diseases, etc.

**Fats on Penetration.**—Fats and oils protect the skin against the penetration of fat-soluble irritants, such as phenol, mustard oil, or "mustard gas" (Solmann, 1918, 1919).

**Rancidity.**—Fats turn "rancid" on keeping, especially if they are exposed to air, light, and heat, and if they contain protein impurities. The change consists in oxidation with the development of free volatile fatty
FATTY OILS

Acids. Rancid fats are disagreeable and irritating, and therefore unfit for medicinal use. Lanolin and the petroleum products are free from this objection.

OLIVE OIL AND OTHER BLAND FATTY OILS (OLEA PUNGUA)

Uses.—The expressed oils of olive, cottonseed, almond, sesame, etc., are essentially similar. For internal use, olive oil is preferred because of its more agreeable flavor. These oils are employed externally to soften the skin and crusts in eczema and psoriasis; as dressing for burns; as vehicles for liniments, etc.; and by rectal injection, to soften fecal concretions (2 to 500 c.c., 5 to 20 ounces, of the cheaper cottonseed oil, warmed. Hertz claims that oil is less effective than water for this purpose). Internally, olive oil is used as nutrient, laxative, and in hyperchlorhydria (15 to 50 c.c., 1/2 to 2 ounces before meals). Kennedy and others have claimed beneficial results in biliary colic, using large doses (150 to 500 c.c. in four to eight portions within three hours). Its effects, if any, have not been explained; it does not increase the flow of bile, and the concretions found in the feces when olive oil and epsom salt are given, are not gallstones, but simply soap (magnesium oleate).

These oils are insoluble in water or glycerin, very sparingly in alcohol, freely in chloroform, ether, volatile oils, or fats.

Fats are useful antidotes in corrosive poisoning.

Influence on Digestion.—Neutral fats alloy gastric peristalsis, diminish gastric secretion and acidity (Pawlow; Cowie and Munson, 1908; Chiarl, 1915), and lessen the pyloric tone. They leave the stomach slowly and in small portions; a fatty meal requiring seven hours for complete passage into the duodenum. The digestibility of animal fats is discussed by Langworthy and Holmes, 1915. The length of gastric digestion increases with the melting-point of the fat, Feyer, 1913. In the duodenum, fat checks the gastric discharge and stimulates the flow of pancreatic juice and the evacuation of the gall-bladder (Klee and Kniepel, 1914).

Subcutaneous injections of fats as nutrients were proposed by Leube, 1895. They can be administered indifferently without irritation or other disturbance, and are gradually absorbed by the lymph. However, the absorption of plain fats is too slow to be of practical value (Wintersteins, 1903; Y. Henderson and Crockett, 1905). Somewhat better results were obtained with fats emulsified by lecithin (Mills and Cogdell, 1912).

The injection of free fatty acids would be toxic. Fats are also oxidized when emulsions are injected into a vein (Murlin and Riche, 1915).

Oleic Acid Anemia.—The continued administration of large doses of oleic acid, by mouth or subcutaneously, to animals, produces hemolysis and severe anemia (Faust, 1906 and 1908; Polano, 1909; Adler, 1911). Similar effects produced by the injection of extracts of tapeworm (bothriocephalus) are also attributed to oleic acid-cholesterol esters (Faust).

However, Koita and Soencer, 1917, did not observe any changes in the number or structure of the blood corpuscles, after two weeks of intravenous injection of suspensions of cholesterol in sodium oleate.

The saturated higher fatty acids are also hemolytic (Shimazono, 1911). The hemolysis of bacterium putridum is oxyzimethyl thiol-erucic acid, a typical unsaturated fatty acid (Burckhardt, 1910).

Sepsis.—Salant and Bengis, 1917, claim that oral administration of fatty oils causes small disturbances in rabbits on an oats diet; but not when they are fed on carrots. The effect does not occur when the oil is injected hypodermically; it is perhaps due to some secondary product arising from the presence of the oil in the intestines.

PREPARATIONS—FATTY OILS

*Oleum Oleae (Ol. Oliv.). U.S.P., B.P.; Olive oil (Sweet Oil).—A pale yellow or greenish-yellow fixed oil, expressed from the ripe fruit of Olea europea. Slightly sol. in cli. Dose, 30 c.c., 1 ounce, U.S.P.
Oleum Gossypii Seminis (O. Gossyp. Sem.), U.S.P.; Cottonseed Oil.—Fixed oil, expressed from seeds of cultivated varieties of Gossypium. Slightly sol. in aq. On account of its cheapness, it is especially adapted for external use. It is inferior for internal administration; it can not be readily emulsified or saponified, since the free fatty acids have been removed in the process of purification.

Gossypol.—Feeding with "cottonseed meal" (not the oil) sometimes produces toxic effects. These are commonly attributed to the gossypol, a glucoside, not isolated by Marchlewski, 1869. It is soluble in gasoline. It may be rendered harmless by steaming and various methods of oxidation, precipitation or extraction (Withers and Carruth, 1915).

Gossypol is tasteless, and insoluble in water; but when injected in oily or alkaline solution, it produces local irritation and edema; for instance peritonitis. Intravenous injection kills acutely by circulatory depression. Cardiac irregularity is prominent. Chronic poisoning by oral administration to rats shows inanition and cachexia (Albers and Schmeltzer, 1940).

Oil, Sesami, U.S.P., B.P.; Oil of Sesame (Teel Oil, Benne Oil).—Expressed from seeds of Sesamum indicum.

Oil, Triticis, B.P. (Peanut Oil).

Oil, Amygdale Expressum (Ol. Amygd. Exp.); Ol. Amygd., B.P. (Oil of Sweet Almond).—Fixed oil from bitter or sweet almond.

Oil, Linum, U.S.P., B.P.; Linseed Oil.—Expressed from Linseed. Disgustable odor. Employed mainly in veterinary practice and in liniments. "Boiled" oil must not be used.

Dose, 30 c.c., 1 ounce, U.S.P.

Acid, Oleic, U.S.P., B.P.—Mixture of fat acids consisting chiefly of C16H32COOH.

Yellowish or brownish-yellow, oily liquid; peculiar lard-like odor and taste. Practically insoluble in water; completely miscible with about 85 per cent. alcohol; soluble in chloroform and in fixed and volatile oils. Used as solvent for metallic oxides and alkalis, intended to be absorbed from the skin.

Acidum Stericarum (Acid. Stere). U.S.P.—Mixture of fat acids consisting chiefly of C16H32COOH obtained from tallow or other fats. Hard, white, or yellowish-white, somewhat glossy, solid, odorless, or having a slight, tallow-like odor, tasteless. Melts above 65° C. Sol. in aq. (1:21); almost insol. in water. Used in glycerin supposi- tions.

* Oil, Theobromatis (Ol. Theobrom.). U.S.P., B.P.; Oil of Theobroma (Cacao Butter). A yellowish-white solid fat from the roasted seeds of Theobroma Cacao. It melts at the temperature of the body. It is used chiefly for making and as a lubricant in massage. Not to be confused with:

Oleum Cocos; cocoa-oil.—The expressed oil of the cocomunt, the fruit of the palm, Carica nucifera. It is a whitish fat, soluble in alcohol, used especially in soap-making.

Oil, Chaulmoogae, B.P.; Chaulmoogra Oil (Gynocardia Oil).—A fatty oil expressed from seeds of Tanaktogenos Kurtzii.

The oil is buttery, of greenish color, and peculiar odor and taste. Power, 1915; finds that the genuine (Tanaktogenos) oil consists largely of the glycerol of a new type of fatty acids, mainly chaulmoogric acid, C17H30O3, and the related hydrocric acid. Un. Chaulmoogae, B.P.—10 per cent.

Efficiency Against Leprosy.—The oral administration of chaulmoogra oil produces reaction in the leprosy lesions with subsequent amelioration in the majority of patients and sometimes an apparent cure. It is doubtful whether it produces a real cure. The same effects are produced by the subcutaneous or intravenous injection of soaps of chaulmoogric or hydrocric acids (sodium gynocardiate A; Roger, 1916); or of less irritant ethyl esters (Hollman and Dean, 1919). Equally good results have been reported with cod-liver oil soap (sodium morrhuate; Rogers, 1915; E. Muir, 1919).

E. L. Walker and Sweeney, 1920, claim that chaulmoogric acid has a specifically high bactericidal power for acid-fast organisms (leprosy and tuberculosis), and incline to attribute the therapeutic results to this. However, it is significant that they do not find this action for the cod-liver oil acids, which are said to produce the same effects.

Gurjun oil and cashew nut (anacardium) oil are also used against leprosy.

Administration.—Chaulmoogra oil is used by mouth in doses of 0.3 to 0.6 c.c., 5 to 10 minims; gradually increased to 2 to 4 c.c., 1/2 to 1 dram (B.P.). It tends to become very nauseating and to produce intestinal disturbance. These may be avoided by hypodermic injection of the oil, 0.3 to 0.8 Gm., to 10 drops.

Heiser, 1914, and Bercovitz, 1917, advise a mixture of 60 parts, each, of chaulmoogra and camphorated oil, with 4 parts of resorcin. Injections are made weekly, beginning with 1 c.c. and increasing gradually.

The original papers should be consulted for the dosage of the soaps and esters.
LARD AND SIMILAR ANIMAL FATS

These are employed as soft ointment bases. They have the inconvenience of rapidly turning rancid. This is delayed by antiseptics, as is Benzoated Lard.

PREPARATIONS—FATS

\* Adeps Benzoatus (Adeps Bezoa.), U.S.P., B.P.; Benzoated Lard.—Lard digested with Benzoil. In this process it takes up a certain amount of the latter, and acquires the antiseptic and stimulant properties of balsams, besides increasing its own keeping qualities.

Adeps, U.S.P.; Adeps Prepar., B.P.; Lard.—The purified internal fat of the abdomen of the hog. Insol. in water; very slightly sol. in alc.; melts between 36° and 42°C.

Adeps Prepar. (Sev. Prepar.), U.S.P., B.P.; Suet.—The internal fat of the abdomen of the sheep, purified by melting and straining.

So. Benzoa., B.P.; Budrum, Butter, is sometimes used as an ointment base. Since it can not be salted for this purpose, it keeps very poorly.

\* Other Animal Fats.—Other animals also yield fats which are popularly supposed to have special advantages—dog fat, goose grease, etc. There appears to be no established reason for preferring them to the more easily obtainable lard.

WOOLFAT—LANOLIN

This differs chemically from ordinary fats in that the fatty acids are not united to glycerin but to cholesterol and isoocholesterin and smaller quantities of other alcohols.

Crude woolfat or suint was used by the ancients, but was too disagreeable, until a purified product was introduced by Liebreich as "lanolin." Even this has a rather unpleasant odor and disagreeable sticky consistence, but it does not readily turn rancid. Since its composition resembles that of the natural skin-fat, it was believed that it would be more readily absorbed; but this does not seem to be the case. Its chief advantage lies in the property of forming salve-like emulsions with up to two or three times its volume of water, so that watery solutions may be incorporated with it. It also emulsifies other fats and petrolatum. Anhydrous woolfat is too sticky for use. It is employed after the admixture of 30 per cent. of water (Hydrous Woolfat), or better with the further addition of an equal weight of petrolatum or other fat. It is not absorbed from the intestines (Bloor, 1913).

Composition.—Woolfat consists of a mixture of cholesterol esters and of alcohols of the fatty series, including ceryl alcohol. Its fatty acids are largely those of ordinary fats (E. Rohmann, 1910).

Liebscher and Unna (E. Unna, 1912) attributed the emulsifying action to traces of the isoocholesterin and oxycholesterin; but Rohmann failed to confirm the presence of isoocholesterin (also of carnaubic acid or alcohol).

PREPARATIONS—WOOLFATS

**Adeps Lanos Hydrosus (Adeps Lan. Hyd.), U.S.P., B.P.; Hydrous Woolfat (Lanolina).—Contains from 25 to 50 per cent. of water. A yellowish-white, or nearly white, emulsion-like mass, having not more than a slight odor. Miscible with about twice its weight of water.**

\* Adeps Lan., U.S.P., B.P.; Woolfat.—The purified fat of the wool of sheep, freed from water. A light-yellow, tenacious, unctuous mass, not more than a slight odor. Miscible with about twice its weight of water. Sparingly sol. in alc., readily in chloroform, eth., acetone, etc. Melts between 36° and 42°C.
PETROLATUM AND OTHER PETROLEUM PRODUCTS

Properties.—These were introduced under the name of Vaselin by Chesborough, 1871. They are obtained from petroleum by distilling off the more volatile products, chilling, purification by filtration through bone-black, etc. They consist of hydrocarbons of the methane and related aliphatic series. According to the process of preparation, they occur of various consistencies, from the waxy “paraffin” (employed for hardening ointments, through the buttery “petrolatum” (a typical emollient), to the “liquid paraffin” (used especially for laxative and sprays). The color, from deep yellow to almost pure white, does not affect the action.

Notwithstanding the chemical difference, they resemble the fats in physical character and therapeutic application. They have the advantage that they are chemically indiffrent, do not undergo deterioration, can not become rancid or irritant, and do not react with drugs, such as oxidizing or reducing agents. They are not so well adapted for inunction.

Liquid Petrolatum as Laxative.—Mineral oils are not absorbed (except perhaps doubtful traces; Bradley and Gasser, 1912); but are eliminated unchanged by the feces (Randolph, 1885; Hutchison, 1890; Bloor, 1913). They can not, therefore, act as nutrients. By softening the feces, they are mildly laxative, and are used as such in intestinal stasis (A. D. Schmidt, 1905; Lane, 1913). Sometimes they do not mix well with the feces, the oil leaking from the anus. Occasionally they are followed by nausea and regurgitation (Bastedo, 1914). Any of the “liquid paraffins” (Petrolatum Liquidum Album) may be employed—there being no therapeutic difference between the light or heavy Russian or American oils (Bastedo, 1915). Their composition is perhaps also similar. The usual dosage is from 10 to 30 c.c., one-half hour before meals; or a single dose of 30 to 60 c.c. before retiring. The “light” oil is preferred for sprays (Wilbert, 1914); the more viscous oils for laxatives.

Irritation.—N. Burns, 1917, claimed that crysipeloid skin eruptions have followed the use as wound dressing of liquid petrolatum, when insufficiently purified. This needs confirmation.

Composition of Liquid Petrolatums.—All crude petroleum oils are complex mixtures of hydrocarbons, the composition varying quantitatively according to their origin. These differences are eliminated in refining, so that the composition of the thoroughly refined, colorless products is probably similar, whether the product is derived from Russian or from American oils. The liquid petrolatums consist mainly of napthenes (C_{20}H_{22}) and polynapthenes (C_{18}H_{20} and C_{20}H_{20}). They do not contain true paraffins (C_{10}H_{22}); so that the term “Paraffin Oil” is a misnomer. The irritant olefin hydrocarbons and the benzenes of the crude oils are absent from the refined. Certain ingredients, which give the fluorescence and rancid taste, are more difficult to eliminate from some oils than from others (Brooks, 1910).

The history and composition are discussed in the J.A.M.A., 1914, 62 : 1740; and by Hilton, 1914.

Criteria of Availability.—Brooks considers the physical qualities, the color, odor, taste and viscosity or specific gravity as much superior to all other tests.

Paraffin Treatment of Burns.—Paraffin of proper plasticity forms an excellent dressing for burns. A thin film of melted or liquid paraffin is painted on the clean burn; this is covered by a thin layer of cotton, and this again by a heavier coat of melted paraffin; then cotton, bandages, etc. The treatment obtained notoriety in the form of a secret preparation
Melted paraffin may also be used as a protective surface coating for ordinary dressings (Sollmann, 1917). Fisher, 1916, suggested the impregnation of bandages with paraffin mixtures to avoid adherence to wounds. Gauze impregnated with liquid petrolatum is not easily clogged by secretion, and therefore facilitates absorption by the dressings (Sollmann, 1917).

Sterilization.—H. Lyman, 1917, suggests paraffin for sterilization of instruments; 10 minutes at 150°C. kills even anthrax spores.

The persistence of the residual fats in the subcutaneous tissue has been utilized for the correction of deformities (e.g., of the nose), by injecting subcutaneously a mixture of paraffins melting at about 40°C. There is some danger of embolism, since the nascent fats are not permanent, the paraffin being gradually replaced by scar-tissue (Heldingfeld, 1910), which may be a starting point for neoplasms.

PREPARATIONS—MINERAL FATS

PETROLATUM (Petrolat.), U.S.P.; PARAFFINUM MOLLE (Paraff. Molli.), B.P.; Petrolatum, Soft Paraffin (Petroleum Jelly, Vaseline).—A purified mixture of semisolid hydrocarbons obtained from petroleum. An unctuous mass, varying in color from yellowish to light amber, having not more than a slight fluorescence; without odor or taste. Insol. in water; scarcely sol. in cold or hot alc.; freely sol. in fats and fat solvents. Melting-point, 38° to 54°C., U.S.P.; 40° to 46°C.; B.P. The color may be specified by adding “Albunum” for white, “Flavum” for yellow.

* PETROLATUM LIQUIDUM (Petrolat. Liqu.), U.S.P.; Paraff. Liqu., B.P.; Liquid Petroleum, Liquid Paraffin.—A mixture of liquid hydrocarbons. A colorless, transparent, oily liquid free from fluorescence, odorless, and tasteless when cold; insol. in water or alc. Diss. 1:5 c.c. 4, drams, U.S.P.; 4 to 16 c.c. 1 to 4 drams, B.P. Heavy Liquid Petroleum (Heavy Liquid Paraffin, Heavy Mineral Oil) is a very viscous liquid. Light Liquid Petroleum (Light Liquid Paraffin, Light Mineral Oil) is almost free from viscosity. Paraffinum (Paraff.), U.S.P.; Paraff. Dur., B.P., Paraffin, Hard Paraffin.—A purified mixture of solid hydrocarbons. Colorless, or white, more or less translucent mass, without odor or taste; insol. in water or alc. Melts at 50° to 57°C., U.S.P.; 50° to 60°C., B.P.

Toxic Effects of Petroleum Products.—GASOLIN (Petroleum benzoin).—The inhalation of the vapors causes headache, nausea, dizziness, inebriation, unconsciousness, muscular tremors, convulsions, dyspnea, cyanosis, and death (Buegi and Burgi; Wolf, 1911). Chronic poisoning results in dulness, pain in limbs, trembling, muscular weakness and other nervous disturbances (Rambousek), and pulmonary hemorrhages (Jaffe, 1914). The symptoms of acute and chronic poisoning, as they occur in the rubber industry, are described by Alice Hamilton, 1915.

Concentrated vapors cause purely paralytic symptoms in frogs, but in mammals they seem to have only a weak anesthetic action. If they are inhaled to the exclusion of air, they will cause an aphylactic anesthesia. Before this sets in there are very characteristic convulsions (Sollmann, 1904). The animal struggles violently, then falls on its side and convulses with all its limbs, as if running. The pupils are widely dilated. Respiration absent. The spasms are intermittent, and between them the dog is perfectly limp, except that the toes, tail and eyelids continue to twitch. The respiration is first stimulated, then weakened. There is paralysis of the vagus, then a depression of the medullar motor. Either heart or respiration may stop first.

Gasolin is, therefore, unsuitable as an anesthetic even for animals; although it has been tried on man (Felix, 1888). It is said to be used as an intoxicant. Its oral administration does not produce gastroenteritis. It is absorbed slowly from the alimentary tract, and excreted mainly by the lungs (Jaffe, 1914).

PETROLEUM (Coal oil).—When petroleum is swallowed, it produces narcotic effects similar to those of alcohol, with strong gastroenteritis. It is toxic in proportion to its content of the more volatile products. No fatal case has thus far been reported, although as much as a liter has been swallowed. Coal oil applied to the skin is a moderate irritant. Continuous handling of unpurified paraffin may lead to dermatitis (Joseph, 1890), acne and other eruptions, and papillomas (see “Tar”).
WAXES

These are used in pharmacy mainly to stiffen ointments (as in cerates).

PREPARATIONS

Cera Flava (Cer. Flav.), U.S.P., B.P.; Yellow Wax, Beeswax.—The purified product of the hive bee, Apis mellifera. Melts between 62° and 65°C. Sparingly sol. in alc.; sol. in eth., chlorof., and oils.

Cera Alba (Cer. Alb), U.S.P., B.P.; White Wax.—Bleached beeswax.

Colostrum (Cetac.), U.S.P., B.P.; Spermaceti.—A fatty substance, obtained from the head of the sperm whale, Physeter macrocephalus. Consists mainly of ester of cetyl alcohol and palmitic acid.

Rosin (Resin), U.S.P., B.P.; Rosin (Colophony).—The residue left after distilling off the volatile oil from turpentine, the concrete oleoresin obtained from species of Pine.

COMPOUND OINTMENT BASES

These are survivals of older formulas, generally without serious advantage over the simpler bases. Typical ointments melt at the temperature of the body.

PREPARATIONS—COMPONY OINTMENT BASES

Unguentum (Ung.), U.S.P.; Ointment (Simple Ointment).—3 parts White Wax, 8 parts Benz. Lard.

Ung. Paraff., B.P.—Hard Paraff., 27 per cent.; Soft Paraff., 70 per cent.; Beeswax, 3 per cent.

Ung. Ag. Ros., U.S.P., B.P. (Cold Cream).—Expressed Almond Oil, thickened with Spermaceti and White Wax, flavored with Rose Water, and containing 3 per cent. of Sodium Borate, U.S.P.

Ung. Cete., B.P.—Spermaceti, 20 per cent.; White Beeswax, 8 per cent.; Liq. Paraff., 72 per cent.

Ung. Lanca Co., B.P.—Lard, 40 per cent.; Woolfat, 40 per cent.; Paraff. Oint., 20 per cent.

Ung. Ros., B.P.—Resin, 26 per cent.; Yellow Beeswax, 26 per cent.; Olive Oil, 26 per cent.; Lard, 22 per cent.

CERATES

These are stiffer ointments, containing sufficient wax so that they do not melt at body temperature. They are also superfluous survivals.

PREPARATIONS—CERATES

Ceratum (Cerat.), U.S.P.; (Simple) Cerate.—Three parts of White Wax and 7 parts of Benz. Lard.

Cerat. Res., U.S.P.; Rosin Cerate (Basilicon Ointment).—Rosin, 35 per cent.; Yellow Wax, 15 per cent.; Lard, 50 per cent.

GLYCERIN

Therapeutic Uses.—This acts both as an emollient and demulcent. It is used to soften the skin, to prevent chapping, internally in coughs, etc. Concentrated glycerin abstracts water, so that the soothing action is preceded by smarting. It should therefore be diluted with two or three volumes of water (rose water for lotions). Roth has shown (with Cataplasma Kaolinii), that glycerin does not abstract water from the intact skin, because of the impermeability of the stratum corneum.

Undiluted glycerin injected into the rectum causes evacuation in a few minutes, without pain if there are no abrasions (5 to 10 c.c., 1 to 2 3; of the official suppository). Similarly, it provokes uterine contractions if introduced into the cervical canal. Large doses (100 to 150-
GLYCERIN

Gm. per day, in divided portions) have been employed to kill intestinal trichine.

Pharmaceutical Uses.—Glycerin has many uses in pharmacy, as a vehicle and solvent for salts; sweetening agent; to preserve ferments and vaccines; to keep pill masses or extracts moist, etc. As a sweetening agent in diabetes it has been displaced by saccharin.

Nutrient Value.—Glycerin has been tried as a substitute for cod liver oil. It is transformable into glycogen and sugar; but its nutrient value is rather doubtful, since larger quantities lessen gastric secretion (L. Kaat, 1910) and provoke diarrhea. Like other intestinal irritants, it produces increased elimination of uric acid (Abl, 1913).

Toxic Effects.—None have been reported in man, but they occur in animals when large doses are given, by any channel. The symptoms are convulsant and paralytic, probably through a direct action of glycerin on the central nervous system. The blood corpuscles are laked, especially if the glycerin is injected hypodermically. This is probably an osmotic effect, the glycerin remaining for a time unabsorbed, and in high concentration at the place of injection; and the corpuscles being laked during their passage through this area (Filemon). On muscle-nerve preparations, glycerin acts similarly to veratrin.

Germicidal Action.—Concentrations of 3% per cent. and higher are distinctly disinfectant, the efficiency increasing with the concentration. Undiluted glycerin destroys 99% of the bacteria in 3 hours (Wlasow and Holland, 1910).

On the other hand, glycerin hinders the antiseptic efficiency of substances for which it is a better solvent than is protoplasm; for instance thymol, phenol, mercuric chloride, or boric acid.

PREPARATIONS—GLYCERIN

Glycerinum (Glycerin), U.S.P.; (Glycer.), B.P. Glycerin, C₃H₅(OH)₃.—A liquid obtained by the hydrolysis of vegetable or animal fats, purified by distillation. Clear, colorless liquid, of a thick, syrupy consistence, sweet to the taste. Miscible with water or alcohol; insol. in eth., chloroform or oils. Dose, 4 c.c.; 1 dram, U.S.P.; 4 to 8 c.c.; 1 to 2 drams, B.P.

Glycerine are solutions of medicinal substances in glycerin.

DEMULCENTS OR MUCILAGINOUS SUBSTANCES

These comprise gums and other colloidal substances, which form viscid solutions with water, and are insoluble in alcohol. They are used to emulsify oils; to suspend insoluble powders; to mitigate the taste and local effects and to delay the absorption of other drugs; and to allay inflammatory actions of mucous membranes, especially in bronchitis, gastritis, enteritis and diarrheas. The effects are strictly local, but in the respiratory passages they are said to extend into the bronchi. Gums and proteins (raw eggs, milk, flour) are employed for their protective action against irritant poisons. They are also precipitant, chemic antidotes for metals. Acacia or gelatine are added to saline transfusions, to prolong their efflux in the circulation.

Mucilages and similar drugs (salep, Irish and Iceland moss) were formerly considered efficient carbohydrate nutrients; but it has been shown that they are very imperfectly digested, and for the most part eliminated unchanged by the feces (Muller, 1903; Swartz, 1911).

Demulcents as Flavors.—Gums and similar substances markedly diminish the characteristic taste of all substances, acid, salt, and sweet, as well as bitter. They act by
enveloping the substance and forming a protective layer over the mucous membrane, and in this way preventing the access of the substance to the taste organs. This, of course, diminishes absorption as well as taste. One can readily convince himself of this "corrective" action by mixing a per cent. solution of citric acid with water and with a sliced sweet almond. The latter will taste--much less bitter. Collodion substances of this kind are present in fruits as pectin bodies, and have a marked influence upon their taste. The raspberry, for instance, actually contains more acid than the currant and but little more sugar, its less sour taste being due to the greater amount of these pectin substances present in it.

Anaphylactic Phenomena on Intravenous Injection.—These are described under Anaphylaxis—see index.

PREPARATIONS—GUMS

* Acacia (Acac.). U.S.P.; Acacia Gumm (Acac. Gum.), B.P.; (Gum) Acacia (Gum Arabic, Gum Senegal).—The dried, gummy exudation of Acacia Senegal, and of other African species of Acacia. More or less spheroidal tears, or angular fragments; whitish to light amber colored; translucent; very brittle; nearly inodorous; taste insipid, mucilage-laginous. Insoluble in alc.; slowly soluble in twice its weight of water, forming a mucilaginous liquid, which is acid to litmus. Incompatible with alc., borax or metallic salts. 

* Mucilage Acacia (Muscil. Acac.). U.S.P., B.P.; Mucilage of Acacia. 15 per cent., U.S.P., 40 per cent., B.P., dissolved in cold water. Dose, 0.5 c.c., 4 drams, U.S.P.

* Tragacantha (Ttrag.). U.S.P., B.P.; Tragacanth.—The spontaneously dried gummy exudation from the stems of Astragalus species. Swells in water to a gelatinous mass, without dissolving. Used in pills excipients, emulsions, etc. 

Musil. Gum. Ind., B.P.—A gummy exudation from the stem of Anogeissus latifolia. 

PREPARATIONS—DEMULCENTS

Drugs containing mucilages are used as decoctions, ad libitum, mainly in folk medicine.

PREPARATIONS—DEMULCENTS

Althea U.S.P.; Marsh Mallow Root.—The root of Althea officinalis deprived of the brown, corky layer and small roots. 

Ampyrgus Dulcis (Ampyg. Dulc.). U.S.P., B.P.; Sweet Almond.—The ripe seeds of Prunus Amygdalus dulcis. 

Emul. Amyg., U.S.P.; (Milk of Almond).—An emulsion made by rubbing 6 parts of mashed sweet almonds with 1 part of acacia, 3 parts of sugar, and enough water to make 100 parts. 

Misl. Amyg., B.P.—12.5 per cent. Dose, 15 to 30 c.c., 1/4 to 1 ounce, B.P. 

Pass. Amyg., B.P.—Sweet Almond, Sugar and Gum Acacia. 

Cetraria; Iceland Moss, a Lichen.—A gelatinous decoction (1:20) is prepared after previous extraction with cold water; to remove a bitter principle. 

Chondrus, U.S.P. (Irish Moss, Carrageen).—The dried plant of the seaweeds Chondrus crispus and Gigartina mamillosa. Yields a demulcent jelly with boiling water. 

Cydonium—Quince Seed. 

Ipaghala, B.P.—Dried seeds of Plantago ovata. Dose, 6 to 10 Gm., 45 to 150 grains. B.P. 

Dec. Ipagh., B.P.—1:5 per cent. Dose, 15 to 60 c.c., 1/4 to 2 ounces, B.P. 

Salep.—The tubers of an orchid. 

Sassafras Medulla.—Sassafras Pith.
Triticum (Trit), U.S.P.; Agropyron (Agropyrt), B.P.; Triticum, Couch Grass.—The dried rhizome and roots of Agropyron repens. Dose, 8 Gm., 2 drams, U.S.P.

Ficus. Tri, U.S.P.; Ext. Agropyrt. Liq., B.P.—Dose, 10 c.c. 1/2 Drams, U.S.P.; 4 to 8 c.c., 1 to 2 drams, B.P.

Dcc. Agropyrt, B.P.—5 per cent. Dose, 15 to 60 c.c., 5/6 to 2 ounces, B.P.

Ulmus, U.S.P.; Elm (Slippery Elm) —The bark of Ulmus fulva.

GELATIN

Uses.—This is employed in pharmacy as a coating for pills, for making gelatin capsules, etc., and in the form of glycerinated gelatin as a base for suppositories. In the form of soups and jellies it is used as a nutrient, being easily digested and capable of replacing from one-fourth to two-thirds of the protein of an ordinary diet, especially if the carbohydrates are ample (Murlin, 1907). Subcutaneous injections of gelatin have been given to increase the coagulability of the blood, especially in aneurism. Their efficiency is doubtful. They have the serious objections of severe pain and danger of infection, since ordinary gelatin solutions are often not sterile, and may even carry tetanus.

Gelatin as Sypptic.—The efficiency of gelatin is affirmed by some and denied by others. Burton-Opitz, 1906, found that it increased the viscosity of the blood on intravenous injection. Count, 1912, claims the same effect hypodermically. Dastre and Flesco, 1897, and Grau, 1910, describe increased coagulability of the blood, lasting for several days. Zbell, 1901, and others are inclined to attribute the action to Ca, of which gelatin contains about 0.6 per cent. The contradictory data do not permit any definite conclusions. The gelatin was originally used subcutaneously (100 to 200 c.c. of sterile 1 to 5 per cent. solution) injected slowly into the thigh, not near the aneurism, every ten to fifteen days, until 10 to 20 injections have been given). The treatment is quite painful, and may raise the temperature to 105°F. Wood (1900) claims that the phialin is just as effective, only somewhat slower, when given by mouth, and recommends eating 3 or 4 ounces of flavored 10 per cent. jelly, three times a day.

PREPARATIONS—GELATIN

*Gelatinum* (Gelat.), U.S.P.; B.P.; Gelatin.—The purified, air-dried product obtained by the hydrolysis of animal tissues, as skin, ligaments, and bones, by treatment with boiling water. Jusol, in cold water, but swells and softens when immersed in it, gradually absorbing from five to ten times its own weight of water; sol. in hot water, acetic acid or glycerin; insol. in alc. Watery solutions of 2 per cent. or ever solidify on cooling. Precipitated by phenol or tannin; not by dilute solutions of metallic salts.

*Gelatinae Glycerinae* (Gelat. Glycerin.), U.S.P.—Equal parts of Gelatin and of Glycerin. Used for making bougies, etc.

STARCH

Uses.—Dry starch is used as a dusting powder. By boiling with water, starch is converted to a colloid condition, starch-paste. This is used as an emollient, in the form of the glycercite; in poultices; and to secure the retention of enemas (teaspoonful, rubbed smooth with a little cold water and poured into a cup of boiling water). It is a chemical antidote to iodin. It is also employed as a nutrient, especially as "arrow-root," the starch of Maranta, which has a somewhat finer flavor than the official corn starch.

PREPARATIONS—STARCH

*Amylum,* U.S.P.; B.P.; Starch.—Prepared from maize, U.S.P.; from wheat, rice or maize, B.P.

Glycer. Amyl., U.S.P.—10 per cent. of starch.

Glycer. Amyl., B.P.—20 per cent. of starch.
INDIFFERENT DUSTING POWDERS— ADSORBENTS

Very fine ("impalpable"), insoluble, non-irritant powders, such as talcum, chalk, starch, lycopodium, etc. are used as dusting powders to protect the skin, wounds and mucous. They form a protective covering, prevent friction, absorb secretions by capillary action, and are therefore drying. The insoluble bismuth salts also act largely in this manner. The bismuth salts, chalk, kaolin (clay, bole), fullers' earth and charcoal are used internally for similar protective effects, against gastrointestinal irritation.

The efficiency of the dusting powders is partly mechanical, as has been explained, and partly through adsorption. By condensing dissolved or suspended substances on their large surface, they diminish their concentration and absorption. This weakens the action of chemical agents, including bacterial products. At the same time, the drying renders the medium unsuitable for bacterial growth, and so diminishes infection.

Water Absorbing Power.—This is important when dusting powders are used for drying. Sollmann, 1919, found it to range from 70 to 80 per cent. for fullers' earth, kaolin and starch; and from 55 to 65 per cent. for chalk and talcum.

Selective Adsorption.—The affinity of adsorbents varies for different substances. In general, it is most effective for colloids of the opposite electric charge. The following give an idea of the selective phenomena (Koltof, 1919).

Adsorption of Toxins and Antitoxins.—Diphtheria toxin and antitoxin are both adsorbed by animal charcoal; not by kaolin, talcum, kieselguhr or wood charcoal. This does not apply to other toxins and antitoxins. Tetanus toxin, for instance, is adsorbed by all the above agents (Jacque and Zsuz, 1909; Zsuz, 1913).

Clarification.—Talcum and Kieselguhr are used to clarify turbid mixtures.

Decolorisation by Charcoal.—This is used to decolorize solutions. Different specimens vary greatly in activity. Tested by methylene blue, blood charcoal is generally the most active; graphite and lampblack are almost inactive (Koltof, 1919). Wood charcoal prepared from nut-shells is highly active; ordinary wood charcoal is poor.

Adsorbents as Antidotes.—Charcoal has been advised, especially against alkaloidal poisons (Wischowki). Its efficiency can not be great. Kaolin would be more effective, but it also is of little practical value.

The protective adsorption of alkaloids and organic bases has been studied by Loffler and Spier, 1920.

Colloidal Carbon (caramel) is harmless, even on intravenous injection. It antagonizes alkaloids (strychnin) when mixed in nitro, and even somewhat when the strychnin is given by mouth, and the carbon by vein; but this antagonism is too uncertain for practical application (Sabbatani, 1913 and 1914).

Skin Protection.—The protection afforded by dusting powders against the irritant action of weather on the skin is familiar. They also have a high protective value against chemical irritants, for instance "mustard gas" (Sollmann, 1919).
Charcoal Against Indigestion and Flatulence.—Freshly heated charcoal absorbs gases. This presumably led to its use against flatulence and heartburn. It is unsuccessful for charcoal not adsorb free gases when it is moistened.

Wood charcoal, which is generally used, is slightly alkaline, and this may account for what little efficiency it may possess. However, it would be a wasteful and inadequate means of introducing alkali, since 1 gm. neutralizes only about 5.5 cc. of N/10 acid, and is therefore equivalent to about 42 mg. (7/5 grain) of sodium bicarbonate.

Adsorbents in Diarrhea.—Bolus alba (Kaolin), fullers' earth, bone black (carbo animalis), and tripoli (silica) check watery diarrhea and dysentery. In acute bacterial dysentery, large doses are given, 30 to 45 Gm. three times daily, stirred into hot tea (after a preliminary cleansing by calomel). Smaller doses suffice in chronic dysentery (Stumpf, 1914; Steck, 1915). Hess, 1916, reports good results from fullers' earth in infantile diarrhea. It is administered in the food, or by a spoon; giving 1 to 2 tablespoons 3 times daily (Charcoal, H. Strauss, 1916).

The effects are explained by the more solid consistency of the stools; by the checking of bacterial growth; and by the adsorption of the irritant putrefactive products (Kraus and Barbara, 1913).

It has been reported that adsorbents restrain somewhat the activity of digestive fermenta (Strauss, 1910; Petersen, 1917); but this is probably unimportant.

Diphtheria Carriers.—The application of dry Kaolin to the nose and throat is being tried, with apparent success, to remove the bacteria of diphtheria carriers (Rappaport, 1916).

Toxic Effects of Adsorbents.—Kaolin is toxic when injected intravenously and hemolytic when added directly to blood (Friedberger and Tsuneoka, 1913).

PREPARATIONS—ADSORBENTS

Carbo Animalis.—Bone Black.—Used against dysentery, in dosage of 30 grs. Animal charcoal is preferred for this large dose, because the sharp particles of the vegetable charcoal might be irritant (Lichtwitz, 1914).

Carbo Ligustri (Carb. Lig.), U.S.P.; B.P.; Wood Charcoal.—Black, tasteless and odorless, very fine powder. Dose, 1 Gm., 15 grs., U.S.P., to 4 Gm., 60 grs.

Kaolinum, B.P.; Kaolin.—Native aluminum silicate (china clay; bolus alba), powdered and purified from gritty particles by dilution.

Cataplasma Kaolini, N.F.—Essentially a thick mass formed of about 2 parts of kaolin and 1 part of glycerin, together with a little boric acid (4.5 per cent.) and flavoring oils. It is applied hot in a thick layer and left in place for twelve to forty-eight hours.

Lycopodium (Lycopodo), U.S.P.; Lycopodium.—The spores of Lycopodium clavatum. A light yellow, very mobile powder, nearly inodorous and tasteless. Insoluble in water.

Fulmin Purificatum (Talc. Purif.), U.S.P.; Purified Talcum.—A purified, native, hydrous magnesium silicate. A fine, white or grayish-white powder; odorless and tasteless. Insol. in water and dilute acids or alkalies.

Terra Silica Purificata (Ter. Sil. Purif.), U.S.P. (Purified Kieselguhr, Purified Silicon Earth).—A form of silica (SiO₂) consisting of the fuselates and fragments of diatom, purified by boiling with diluted hydrochloric acid, washing and calcining.

POULTICE MASSES

Poultices or cataplasmis are used to convey heat, and to macerate the skin. A variety of pasty materials may be employed. The most common are linseed, starch, bread and clay. Linseed poultice is prepared by stirring 1 part of ground linseed into 3 parts of boiling water, to which a little laking soda may be added, to render it fluffy and less irritant. Clay or kaolin poultice is much heavier, but can be sterilized if desired. The rate of cooling of different poultice masses has been investigated by Pilcher, 1928. They do not differ materially. Whole linseed may be made into a semisolid decoction against bronchitis.

PREPARATIONS—POULTICES

Linum, U.S.P.; Linum Scam., B.P.; Linum Com. (crushed or ground, “meal”), S.P.; Linseed, Flaxseed.—The ripe seeds of Linum usitatissimum.
PLASTERS

These serve for protections against irritation, for mechanical support; and for the slow conveyance of drugs to or through the skin. They are somewhat irritant, partly by preventing evaporation from the skin, and partly by the small quantities of volatile oils contained in the resins from which they are often prepared. The official plaster-masses are unimportant, since the commercial plasters are usually made by private formulas from some rubber mixture. "Court plaster" is made of singlass (Ichthyocolla), a variety of gelatin prepared from the swimming bladder of the sturgeon.

PREPARATIONS—PLASTER MASSES

Emplastrum Elasticum (Emp. Elast.), U.S.P.; Rubber (Adhesive), Plaster.—A mixture of rubber, pitch, wax and an absorbent powder (starch, etc.), spread on cloth.

Emplastrum Plumbi (Emp. Plumb.), U.S.P.; B.P.; Lead Plaster (Diachylon Plaster).—A soap made by boiling lead oxide with olive oil and lard, U.S.P.; with olive oil, B.P.; Emp. Saponis (Emp. Sap.), B.P.; Soap Plaster.—Similar to preceding, with greater proportion of soap.

MECHANICAL PROTECTIVES

Certain substances which are used for this purpose may be mentioned in this place.

PREPARATIONS—MECHANICAL PROTECTIVES

* Colloidiun (Collod.), U.S.P., B.P.; Collodion.—A 4 per cent. solution, U.S.P., 2.5 per cent. B.P.; of Pyroxyl in (gun-cotton) in a mixture of 3 vol. of ether and 1 vol. of alc. Should be kept in a cool place remote from fire. Clear, or slightly opalescent, syrupy liquid; colorless, or slightly yellowish and having the odor of ether. Highly inflammable. Collodion dries rapidly into a firm film, which is used to protect small wounds. The film cracks easily and contracts considerably, exerting pressure on the tissues. Similar solutions may be prepared with acetone or other solvents.

* Colloidiun Flesile (Collo. Flex.), U.S.P., B.P.; Flexible Collodion.—Collodion rendered flexible by the addition of a little Castor Oil and Camphor, U.S.P.; Castor Oil and Canada Turpentine, B.P. It does not contract or crack, but does not adhere quite so well.

Pyroxylinum (Pyroxylin), U.S.P., B.P.; Pyroxylin (Soluble Gun-cotton).—Obtained by acting on cotton with a mixture of nitric and sulphuric acids. Consists chiefly of cellulose tetracetate, C6H12(ONO2)4O4. Slowly sol. in 25 parts of a mixture of 3 vol. of ether and 1 vol. of alc. (equal vol. of 90 per cent. alc. and eth., B.P.); Sol. in acetone. Colloidiun, N.N.R., is a purified form. Ordinary gun-cotton is a hexanitrate.

* Gossypium Purificatum (Gossyp. Purif.), U.S.P.; (Gossyp.), B.P.; Purified (Absorbent) Cotton.—The hairs of the seed of Gossypium herbaceum freed from adhering impurities and deprived of fatty matter (so as to make it absorbent) and often sterilised. Consists of almost pure cellulose (C6H10O5). Used in bandaging, etc., either as such, or as gauze (Tela, Carbasus), lint (Lintum), etc., or impregnated with antiseptics, astringents, etc.

Calcii Sulphus Essicus (Plaster of Paris, Burnt Gypsum), CaSO4 + 1/2H2O.—A fine white powder, which sets into a stone-like mass when mixed with half its weight of water. Used in bandaging. The "setting" takes place in fifteen to twenty minutes. It may be delayed by an hour by the addition of 5 per cent. of glycerin, or hastened by the addition of sodium silicate. Plaster of Paris must be kept dry.

Liquor Sodii Silicatis (Waterglass).—A colorless syrupy liquid, of alkaline properties, but not corrosive. Contains about 20 per cent. of sodium silicate. Forms a solid glassy mass on exposure. Used in bandaging.

Actions of Sodium Silicate.—When given by the mouth or skin, this acts like a typical mild alkali without showing any specific features. It is readily absorbed from the alimentary canal, and excreted by the urine. Injected intravenously it causes agglutination of blood corpuscles, and consequently intravascular clotting.

Silicates are normally present in all tissues, but in very small amount (Siegfried, 1901). There is no evidence that they play any physiologic role. Silica is also constantly present in hairs and feathers (Eppinger, 1901). It constitutes up to 77 per cent. of the total ash of the feathers of the dove (Gonnermann, 1918).
PHENOMENA COMMON TO LOCAL IRRITANTS, CORROSIVES AND ASTRINGENTS

Uniformity of Irritant Phenomena.—The local actions of drugs are, as a rule, simple and uniform, since they can occur ordinarily in only a few situations, especially the skin and mucous membranes. These agree closely in structure and functions. There are therefore many phenomena which hold true of all local irritant poisons. These may be studied once for all, and present only minor modifications in individual cases.

Chemical Basis of Irritation.—The majority of local poisons produce the typical phenomena of inflammation ("irritation"), by causing necrosis of protoplasm through coagulation, liquefaction, etc. Many of these reactions are purely chemical or physical, and can be reproduced in the test-tube with proteins. Remembering the extreme sensitiveness of protoplasm to reagents, it will be readily understood that almost all substances—even water—may be irritant under suitable conditions.

Degrees of Cutaneous Irritation.—The general phenomena of irritation can be studied very typically on the skin. They are identical with the familiar changes produced by scalds or burns of increasing severity.

Rubefaction.—The first degree of irritant action is shown in an arterial and capillary hyperemia, at first active, later passive. This constitutes the "dermatitis erythematosa" of the dermatologists. Or, speaking pharmacologically, it constitutes rubefaction, and the agents which produce it are therefore called rubeofacients. The dilatation involves at first the most superficial vessels, but progressively also those of the deeper subcutaneous tissue, partly directly and partly by reflexes.

The congestion is accompanied by sensory stimulation—by itching, burning or pain. The intensity of the pain depends upon the rapidity, rather than on the degree of the irritation. It is often succeeded by more or less anesthesia.

If the irradiant action does not go any further, resolution takes place without leaving any lesions, simply by a return of the vessels to normal. The pain may outlast the congestion. The upper layers of the skin are usually desquamated.

If the action is stronger than rubefaction, it may pass into vesication or paroxysm.

Inflammatory Edema.—Increased permeability of the vessels is one of the early phenomena of acute inflammation. It results in edema.

The permeability to dissolved substances is also increased. For instance, when papain is injected by vein, it appears much more abundantly in the aqueous humour of an inflamed, than of a normal eye (P. A. Lewis, 1916).

Urticaria.—Localized edema of the corium is a rather special mild inflammatory reaction to many drugs, particularly in susceptible individuals. It may occur on systemic administration, or more readily by application to the scarified skin. It is not sufficient therapeutically. The more important drugs producing this effect are: morphine and its esters; histamin and peptone. Milder grades occur with atropin, cocaïn, formaldehyde, urea and many amides (Sollmann and Pilcher, 1917; Sollmann, 1917).

Vesication.—This occurs if the inflammatory action results in the formation of an exudate greater in amount than can be carried off by the lymphatics. Every hyperemia is accompanied by an increase of exudation, but up to a certain amount, as in rubefaction, this is readily reabsorbed. When this limit is exceeded, an actual, visible effusion
results. The liquid accumulates in the parts of the tissues offering the least resistance to distention. In the case of the skin, it penetrates readily through the lower layers of the rete Malpighii, but is arrested by the impermeable stratum corneum. It is therefore confined between the upper and lower layers of the rete Malpighii, and separates them, in this way causing blisters or vesicles. The agents which produce these are called vesicants or epispastics.

The vesicles appear as small points which gradually coalesce into a large blister. The fluid is at first clear, but later becomes turbid by leucocytes. The sensory stimulation is stronger than in rubefaction.

Resolution takes place in these cases without loss of tissue by the formation of a new stratum corneum from the remaining rete Malpighii. The area may remain pigmented for years.

If the overlaying and separated layers of epidermis are removed, there is much chance of infection, the lower layers of the rete Malpighii offering but little resistance. In this way there may be a loss of substance from secondary infection.

Suppurative and Inflammatory Necrosis.—If the vesicant is allowed to act after the blister has been formed, the inflammation will become purulent, with deeper destruction of the skin, and healing with scar formation. This degree of action should be avoided.

Aseptic Pus Formation.—A few drugs possess a specific chemotactic power on leucocytes; so that their injection (hypodermic or into serous cavities) leads to the collection of pus, even when asepsis is perfect. Turpentine, croton oil, petroleum, mercury, silver nitrate, digitoxin, cadaverin, auroleon suspensions, etc., are the principal examples. Turpentine also stimulates the chemotactic action of b. coli extracts (Hamburger, 1913).

Pustulation.—This occurs if the irritant does not penetrate the epidermis, but only the cutaneous glands, especially if the acid secretion of these glands dissolves or liberates the irritant agent. Discrete and later confluent pustules are formed, which heal with more or less "pitting." They produce severe sensory irritation, but are now rarely used. The principal pustulants are croton oil and tartar emetic.

Influence of Systemic Conditions on Cutaneous Irritation.—Leithed, 1911, found that the local reaction to croton oil is increased by feeding with acids or oxalates and diminished by calcium. Different diets also modify the susceptibility. These systemic influences may be connected with the great variations in the susceptibility of different individuals to cutaneous irritants; and with such skin diseases as eczema, which do not seem to be explainable by local irritation. There are also, however, local differences in susceptibility, and if an irritative reaction has once been induced, the skin remains hypersensitive for some time.

Dermatitis from Systemic Drugs.—Many drugs cause a dermatitis when they are given by mouth (belladonna, arsenic, iodoform, quinin, salicin, antipyrines, iodidae and bromids, digitalis, chloral, chloroform, etc.). This is sometimes due to changes in the cutaneous circulation, sometimes to the excretion of the drug by the skin. It may take the form of scarlatinial, desquamating, urtiarificial or papular rashes or acne.

The most common sources of drugs eruption may be grouped, according to M. MacComar, as follows:

Erythematous or Polymorphous Eruption.—Antipyrin; arsenic (including salvarsan); benzoic acid; boric acid; bromids, copaiba, chloral, iodid, morphin, quinin, salicylates.

Scarlatiniform Rashes.—Antipyrin, atropin, benzoeate, belladonna, chloral, iodoform, ippecac, mercury, salicylates, sulfonal.

Urticaria.—Benzoeate, copaiba, cubeb, iodid, quinin, salicylates, valerian.

Pityriasis.—Antitoxin, arsenic, chloral, copaiba, cubeb, iodoform, mercury, quinin, sulfonal.

Morbilliform Eruptions.—Antipyrin, antitoxin, belladonna, copaiba, cubeb, mercury, opium.

Eczema does not result from the internal administration of drugs.

Corrosion, cauterization, or direct destruction of tissue results if the agent (cauterizant or escharotic) acts chemically on the protoplasma, as do strong acids or alkalies, iodin or bromin, some metallic salts, etc. This
leads to the production of a scab or "eschar," and resolution by scar formation.

Areas of Corrosion.—The chemic destruction of tissue is generally preceded by inflammatory necrosis. Chemic cauterezation therefore shows three areas: The first, situated at the depth and periphery of the ulcer, is simply an area of inflammation and hyperemia. Then follows a layer of necrotic tissue, the result of the inflammatory action; and last, a layer in which the chemic cauterezation results in solution of the cells which have already been killed by the inflammatory process. These three—hyperemia, inflammatory necrosis, and chemic solution—are to be considered as successive stages in the same action; and by proper dilution, the second or first degree of action may be obtained without the succeeding stages.

The Eschar.—This (scab) is formed after corrosion by the coagulation of the inflammatory exudate and by the chemical products (albuminates, etc.) of the interaction of the corrosive agent with this exudate and with the killed cells. According to whether the proteins are dissolved (as by alkali) or precipitated (as by most metals), the scab will be soft or hard. This has an important bearing on the penetration of the corrosive agent: if the scab is soft, the chemical will penetrate it, and will spread and extend deeply. On this account the alkali, for instance, are not practical for the purpose of cauterezation. If, on the other hand, the scab is solid, it prevents deeper penetration, so that the action can be easily confined to the desired areas.

Astringent Action.—Agents which have a strong precipitant action produce a relatively mild irritation; and if their concentration is not too high, their primary inflammatory effect does not proceed to necrosis; on the contrary, it leads to diminution of any existing inflammatory process. This "astringent" (drawing together) action is characterized by visible contraction of the tissue; blanching and wrinkling of mucous membranes; and diminished exudation, or secretion of mucus, according to the place of application. These agents also possess a peculiar "astringent" taste. The effects are probably due to precipitation and hardening of the cement substance of the capillary endothelium, producing contraction and decreasing the permeability of the capillaries; and thus counteracting the essential phenomena of inflammation (congestion and exudation).

Astringents are used therapeutically to check diarrhea, reduce inflammation of mucous membranes, promote healing, and to arrest hemorrhage (by coagulating the blood).

The principal astringents are: metallic salts, tannins, dilute acids, and strongly hypertonic solutions.

Explanation of Astringent Action.—The manner in which this astringent action is brought about is only imperfectly understood. All astringents produce precipitation of proteins, and this seems to be the cause of the astringent action. To explain this it has been assumed that these precipitates form a lining along the capillary walls, and in this way add an additional coat, as it were, to each capillary. It seems, however, much more likely that they act by coagulating the ordinary semifluid cement substance between the endothelial cells, and that this prevents the filtration of fluids and the emigration of cells. The silver "staining" of endothelia by silver nitrate is a visible illustration of this fixation of the cement substance. The diminished mucus secretion is perhaps due to a similar superficial coagulation of the cell envelope. The blanching and pickering (produced only by the more concentrated solutions) is due to the coagulation analogous to cooking. The absorption of already formed effusions, following the use of astringents, may possibly be explained by osmotic laws. By precipitating the proteins of these effusions, they lower their molecular concentration, and render them more diffusible. Not all protein precipitants are practical astringents. The pre-
cipitant action must be of a special kind. It must be produced very quickly, and the precipitate must be practically impermeable to the precipitant. Otherwise the precipitant action would extend so deeply as to lead to extensive necrosis, and would thus continue the inflammatory process.

Quantitative Estimation of Astringent Action.—This has been measured by Motelese, 1910, by noting the degree in which the extensibility of frogs' lungs is reduced after immersion in the astringent solutions (Dreser's method). With 1 per cent. solutions, the order was: silver nitrate > tannin > lead subacetate > picric acid > lead acetate > alum > zinc sulphate.

Astringency may also be studied by the suppression of mucus secretion from the frog's skin (Schuetz); and more simply by the tanning of blood corpuscles or even by quantitative precipitation of proteins (Soliman, 1920).

Astringent Effects are Strictly Local.—Since astringents are precipitated by proteins, they can not be absorbed nor exist in the blood or tissues, in effective form. It is therefore irrational to expect a remote action from astringents. The very facts of their action exclude such a possibility. Before this was well understood it was tried to obtain astringent action throughout the body by external application or by giving astringents by the mouth. The want of success confirmed what has just been said.

Astringents on Peristalsis.—In the intestinal canal the astringents form a deposit along the lumen of the intestine, and in this way diminish absorption, and also the penetration of other irritant substances, in this way lessening peristalsis.

Irritation of Mucous Membrane.—Differences in detail are seen when irritants are applied to other surfaces than the skin; for instance, to the mucous membranes. These are readily explained by anatomic peculiarities. There will, for instance, be less tendency to vesication, since the epithelium is not impermeable, as it is in the skin. The oral mucous membrane presents a transition; it blisters, but less readily than the skin. Pustulation can not occur since this depends upon the cutaneous glands. On the other hand, the mucous glands will be stimulated to an increased activity, producing "catarrhal" conditions.

Gastroenteritis.—The effects of irritants on the alimentary tract present some special features; the effects being stomachic, carminative, nauseant or emetic; diarrhea, dysentery; abortion; corrosion and perforation; according to the nature and degree of their action.

Respiratory Passages.—If an irritant poison is volatile, its main effects may fall upon the respiratory passages. The general phenomena are those of acute laryngitis, bronchitis, or pneumonia. Similar effects follow the aspiration of non-volatile irritants.

Local Irritation of Wounds and Ulcers.—The effects are usually more marked than on the intact skin. Even the milder irritants destroy the superficial cells, especially if diseased; but the deeper cells multiply more rapidly, partly through direct stimulation and partly through the hyperepithelium. Mild irritants therefore promote healing. Astringents, balsams, quinin, salts and even water have this therapeutic action.

Hydromic Injection of Irritants.—These produce more or less pain, and often aseptic abscesses. The danger of infection is also considerable if the tissues are killed by the irritant. With intramuscular injection, the pain is less severe.

Antiseptic Action.—All irritants are somewhat antiseptic for they destroy the protoplasm of the bacteria just as they do that of the tissue cells.

Concentration.—The degree of the local action depends usually upon the concentration, rather than on the absolute quantity of the irritant.
LOCAL IRRITANTS

A small quantity of concentrated acid will do much more damage than much larger quantities diluted; as a gram of MgSO₄ in solid form introduced into a solution may precipitate all its globulus, while an unlimited quantity may be added in 5 per cent. solution, without any such effect.

Specific Differences Between the Different Irritants.—These affect the strength of their action in different situations. Some, for instance, seem to act especially on the alimentary canal, and to a very small extent on the skin. This is probably connected with differences of absorbability. A drug which can not penetrate the skin, can not, of course, act upon it. It will be remembered that the epidermis is impermeable to most substances. In order to penetrate, these must be either fat soluble like crotin oil or turpentine; or they must actually destroy the epidermis, like caustics.

Irritant Effects after Absorption.—None of the irritants acts indiscriminately on the body at large. Many are not absorbed; and even when absorption occurs they are too greatly diluted to have much effect, except at the place of their absorption and excretion; i.e., the liver and kidneys. Other tissues are involved only if the administration is long-continued, as in alcohol or lead poisoning. Such chronic intoxications lead to increase of connective tissue, arteriosclerosis, cirrhosis, etc.

Drug Nephrites.—These are produced by all absorbable irritants and often occur acutely. The inflammation may involve all the renal tissues; or it may be predominantly glomerular or parenchymatous, according to the poison. Continued administration leads to interstitial nephritis. The inflammation is characterized by albuminuria, casts, and the histologic lesions. The urine flow is increased in the early stages, and decreased later (Schlaver and Hedinger, 1907). The excretory efficiency is diminished (Eisenbrey, 1911, 1913), as estimated by the phenolsulphonephthalein test of Geraghty and Rowntree, 1911. The changes in nitrogen and chlorid excretions are complex (Austin and Eisenbrey, 1911). The nitrogen excretion is decreased in tubular nephritis (uranium), not in glomerular (arsenic). Retention of nitrogen in the blood occurs, especially in tubular nephritis (Foster, 1915). Renal glycosuria may occur (E. Frank, 1913; Pollak, 1917); also hepatic edema (Opie, 1912), and sometimes slight myocardial changes (Walker, 1911). Hemorrhagic nephritis is seen with cantharides, turpentine, formaldehyde, etc. Edema occurs only with uranium, at least in animals. The restoration of the blood-volume after saline injections is delayed in uranium, chromate and tartrate nephritis (Bogart, Underhill & Mendel, 1916; Boycott, 1913 and 1914; Chiolholm, 1914).

Experimental Nephrites.—These have been extensively investigated (bibliography in S. J. Pearce, 1916). Tubular nephritis with little or no primary glomerular injury is produced by uranium, thorium, mercuric chlorid and aloe. The anatomic changes in the early stages of uraemia and chromate nephritis are confined essentially to the tubules, especially the convoluted; they consist of granular and fatty degeneration and necrosis. Mercury acts similarly but mainly on the ascending loops of Henle, with deposition of lime salts. The glomeruli are at first unaffected but later show thickening of the capillary walls, and vascular disturbances can be shown by physiologic methods.

Generalized Nephritis.—This, generally with some secondary involvement of the tubules, is produced by arsenic, cantharides and snake venom. Diphtheria toxin acts on all the structures; and many other irritants act diffusely. The anatomic changes vary according to the poison. Arsenic produces little or no anatomic change, except dilatation of the capillary tufts, filling Bowman's capsules. Physiologic methods, however, show serious vascular injury. The cantharides changes involve both the glomeru-
lar tufts and space. The capsules are filled with desquamated cells, whose origin is disputed. There is also functional vascular injury. The functional changes are not proportional to the anatomic.

Chronic Nephritis.—This is difficult to produce experimentally, the acute experimental lesions usually ending in rapid and complete recovery. Positive results have been obtained by Ophüls with lead, by Dickson with uranium, and by Klotz, 1914, with infections.

Reflex Effects of Irritants.—Stimulation of sensory areas acts reflexly on the vasomotor, cardiac, respiratory and other centers, producing changes in the circulation, respiration and other functions. These vary according to the place, extent, speed, intensity and kind of the stimulation. As "counterirritation" they are used extensively in therapeutics.

The Respiratory Reflexes.—These are of special therapeutic importance. They differ according to the state of the center: if the respiratory center is depressed, as in collapse, moribund poisoning, anesthesia, asphyxia, etc., moderate counterirritation produces marked stimulation; and if the collapse is not too deep, natural respiration may be restored.

If the respiration is normal, mild cutaneous irritation may either slow or quicken the rate. If the irritation is strong, the respiration is always slowed. Sudden and extensive stimulation, as by cold douches, produces momentary standstill, followed by deep inspirations.

Consciousness.—This is also often revived by counterirritation, f.i., in fainting or light coma. The usual measures for this purpose are dashing with cold water, slapping with wet towels, or inhalation of dilute ammonia vapor (smelling salts or aromatic ammonia).

Circulation.—Mild cutaneous stimulation (f.i., blowing on the skin) tends to produce widespread vasoconstriction and therefore some rise of blood pressure. Gruetzer and Hahn, 1877. The vasoconstriction involves mainly the cutaneous vessels, except those which are dilated by direct contact with the irritant. The renal vessels are also constricted, while those of the brain are dilated (Wertheimer; Roy and Sherrington). The cutaneous vasoconstriction tends to raise the internal temperature. The heart rate is quickened (Naumann).

Vasomotor Reflexes.—Mild stimulation of sensory nerves generally produces a slight depressor action; stronger stimuli cause a pressor effect, increasing with the intensity of the stimulation (Stiles and Martin, 1913).

With stronger stimulation of the skin, the vasoconstriction is soon followed by dilatation, fall of blood pressure and of internal temperature. The effects may be less than with mild irritation.

Hyperemic Injection of Mild Irritants.—The injection of ether, camphor, whiskey or oil of turpentine generally produces a slight and transient rise of blood pressure; the effect differing quantitatively according to the site of the injection, being, for instance, greatest from the nasal septum. The effect falls when the vasomotor center is depressed, as in deep anesthesia, shock or hemorrhage (Lieb and Herrick, 1917).

Gastro-intestinal Irritation.—Sollmann, Brown and Williams (1907) have shown that irritation of the stomach or peritoneum has practically no effect on the blood pressure in anesthetized animals, even when the anesthesia is light. There is generally a marked increase of respiration, and sometimes a slight and momentary rise of blood pressure, but no fall is noticed for several hours. This holds true both for mild irritants, such as peppermint, mustard or moderate heat; and for strong corrosives by formaldehyde, concentrated acids, or actual cautery, even when these measures produce perforation.

Irritation of the Mouth and Larynx.—This produces very much more marked effects (Sollmann); even contact with 5 per cent. acetic acid causes struggling, convulsive rise of blood pressure and dyspneic respiration.

Volatile Irritants on Blood-pressure.—The vapors of strong smelling substances, when applied to the nose of rabbits, raise the blood pressure; but lower it when applied to the trachea. Both effects are reflex (Yamada, 1920).
Reflex Shock.—Violent and extensive corrosion may produce immediate "shock," which may be promptly fatal. This appears to consist essentially in profound inhibition of the nervous system. Since it is not produced in anesthetized animals, at least with anything like the same rapidity, it must be due to psychic factors—apprehension, pain and others—rather than to reflexes in the ordinary sense. However, long-continued irritation of the viscera gradually produces, even in anesthesia, a condition (surgical shock), which is allied to, if not identical with, acute traumatic shock.

Metabolism.—Mild stimulation of extensive skin areas (salt-water baths) increase metabolism. Paazlow found increased oxygen consumption and carbon dioxide excretion on applying sinapism to animals; Zuntz and others have demonstrated increased nitrogen excretion.

"Derivative" Action.—The surface application of irritants may subdue inflammation in deep-seated organs. This counterirritation was formerly supposed to act by mechanical withdrawal of the blood from the invaded area to the area of "counterirritation." This explanation is incorrect. It is now believed that the circulation in the distant organs is modified by reflexes along homologous nerve paths—in a sense a reversal of the "referred pain" which occurs in definite skin areas when the corresponding viscera are irritated (Head). This would explain the old empirical observations that the counterirritation, to be most effective, must be applied at a definite place for each internal inflammation (Figs. 36 and 38).

Cold applied to one hand constricts the vessels of both hands, and heat dilates them (G. N. Stewart, 1913; Hewlett, 1913). Irritation of the hand by mustard does not in-
creases the local blood flow, as would be expected from the refraction (Wood and Weisman, 1912; Hewlett, 1913).

**Influence of Pain on Inflammation.**—Bardy, 1914, confirms Spiess and Bruce that inflammatory phenomena may depend on sensory disturbances (pain, reflex hyperesthesia, etc.). The reflex, however, is quite peripheral. For instance, mustard conjunctivitis is prevented by local anesthetics or by division of the peripheral nerves, but not by section of the ramus ophthalmicus. It is prevented by nicotine, so that the reflex must involve the ganglia. Central anesthetics, ether or morphin, also prevent the inflammation. Other substances having a similar effect are: calcium chloride, antipyrin, quinin, salicylates, atophan, bromids, etc.; and substances yielding available oxygen. (Amberg, Levenhart and McClure, 1917.)

Changes in the Blood.—Irritation of the skin produces changes in the blood which may influence inflammation: Winternitz, 1806, found at first leucopenia, then leucocytosis. Van den-Velden, 1912, claims that the coagulability of the systemic blood is increased by a number of local irritant and especially vasoconstrictor processes (ice to the skin; astringents or epinephrin to the mouth; cocain to the nose; turpentine inhalation, etc.).

Relief of Pain by Counterirritation.—This is partly explained by homologous reflexes; but largely also by the diversion of the attention of the patient from the disease-pain, to the usually more bearable sensations of the counterirritant.

Therapeutic Indications of Cutaneous Irritation.—This is employed mainly in the following conditions:

1. **In certain skin diseases,** for the local effects—alkalies, sulphur, chrysarobin, etc.
2. To promote diaphoresis—alcohol, frictions, heat, etc.
3. For reflex stimulation of the central nervous system, in fainting, collapse, narcotic poisoning, accidents of anesthesia, etc.—ammonia inhalation, heat or cold.
4. To alter the distribution of blood, to prevent colds—mustard; to relieve congestion of viscera—poultices, vesication; or to promote the absorption of exudates—iodin, vesication.

Counterirritation is, as a rule, useful only in chronic inflammation. In acute inflammation there is danger of increasing the process or of causing it to extend to neighboring organs.
5. To diminish pain, especially in neuralgic and rheumatic affections—menthol and other volatile oils, capsicum, chloroform.
6. As a general tonic, in the form of salt-water baths or alcoholic frictions.

Therapeutics of Cauterization.—Cauterization—the destruction of tissue—is sometimes employed for severe counterirritation, but particularly to remove tissue: (1) In cases of poisoning, snake-bite, etc.; (2) for the removal of pathologic tissues, tumors, warts, etc.; (3) indolent granulations, etc.; (4) to cause cicatricial contraction of hypertrophied mucous membranes (nose, etc.); (5) for removing the nerves of teeth; and (6) to remove superficial hair.

In many cases the chemic cautery has been replaced by galvanic- and thermocautery, which are more prompt and permit a more exact limitation of the cauterized area. On the other hand, the slower effect of chemic caustics is of advantage in permitting a pulsation in the strength of the action, or in confining it to certain tissue elements. Pathologic formations, being less stable, are in this way more profoundly altered than normal tissue.

The caustics may be applied in solid form (sticks, or fused at the end of a probe), in paste or in solution—the first being the most strictly localizable, the last the most diffuse. In the latter case, or when the eschar liquefies, the surrounding tissue should be protected by court-plaster.

General Toxicology of Irritants.—The phenomena produced by irritant poisons depend in the first place upon the part of the body with which they are brought into immediate contact. The most prominent symptoms arise from the skin, alimentary canal, or respiratory organs; the last only in the case of volatile poisons. Later symptoms may appear in the urinary organs.

The extent of the action depends upon the concentration of the poisons, the time during which they act, and the extent of surface with which they come into contact—less upon their absolute amount. If taken by the alimentary canal, their action is also modified by the presence of food.

Cauterization of the Skin.—This may be accidental or criminal. In the latter case it is usually by sulphuric acid ("Vitriol"). The results are the same as in the case of extensive burns. The diagnosis offers no difficulty. The character of the stains is that described in the next section. Sufficient of the corrosive can generally be collected from the clothing, etc., to establish its identity by chemical means. The treatment is precisely like that for burns, after previous neutralization and removal of the corrosive agent. Salves and ointments are useful.

Caustics in the Eye.—These are best washed away by liberal application of water.

Caustic Poisoning by the Alimentary Canal.—The introduction of caustics by the mouth is generally accidental or suicidal. The effects are so painful, appear so promptly, and the lesions are so persistent, that they would scarcely be used in criminal poisoning—except possibly in infanticide. Caustic are sometimes taken by mistake for syrup or other medicine,
and may be swallowed before the difference is noticed. However, certain organic irritants, usually insoluble, such as croton oil, do not produce their action for some time.

The phenomena vary according to whether the irritant produces actual cauterization—a destruction or solution of the tissues; or whether it causes only inflammation.

Irritants Which Do Not Destroy the Tissue.—To this class belong elaterium, croton oil, and most of the other organic irritants, such as volatile oils, formaldehyde, etc.

The symptoms are those of a violent gastroenteritis: nausea, vomiting, and diarrhea. If the poison acts only when dissolved, and is insoluble in the stomach, as is croton oil, the nausea and vomiting may not be present, but only the diarrhea. The symptoms will appear correspondingly late. The abdomen is usually distended and extremely painful, especially upon pressure. As a result of the gastroenteritis, there is extensive dilatation of the splanchnic area, and consequently withdrawal of blood from other parts of the body. This produces marked changes in the circulation. The pulse is soft, small, and quick. The lowered circulation reacts upon other organs, and most conspicuously upon the central nervous system. There is great anxiety, vertigo, delirium, convulsions, then collapse, and finally coma and death. This picture is common to the entire series of irritant poisons.

Abortion.—The hyperemia is not confined to the intestine, but extends to all the abdominal organs, which therefore partake in the inflammation, although they do not come into direct contact with the irritant. The most important organ involved in this is the uterus, and the organic irritants have been used to procure criminal abortion. Oil of savin, of tansy, and of pennyroyal enjoy a special reputation in this connection, but any other irritant produces the same result. The ecobic effect is only secondary to the gastroenteritis, and the latter is very often fatal without accomplishing the object for which it was produced.

The postmortem appearances are those of gastroenteritis, and in cases of suspected criminal abortion this must be of sufficient extent to explain the fatal issue. The pathologic condition consists in an intense congestion of the entire alimentary canal, often with inflammatory exudate into the lumen of the intestine. The congestion may be so violent as to produce echymoses. If these are present, the vomit and stools are tinged with blood during life. Destruction of tissue is rare. It may, however, occur from gangrene due to the interference with the circulation.

The Fixed Caustics.—The most important are the mineral acids; oxalic acid, which, however, stands apart on account of its specific toxic action; other organic acids, the alkalis and their carbonates; the haloid substances, bromin, chlorine, and iodin. Phenol and the metallic salts are also to some extent corrosive, but not usually sufficiently so to produce perforation. The alkalis and bromin produce the most extensive destruction of tissue, because of their deep penetration. With them, the scar formation is also the most extensive.

Corrosive effects occur especially in those situations which are in prolonged contact with the caustic: the lips; mouth and pharynx; esophagus at its beginning and end, and where it crosses the left bronchus; and the stomach, especially the pyloric end (because the caustic follows the lesser

1 E. Y. Hoffmann, Atlas of Legal Medicine, W. B. Saunders, 1868. Figs. 186 and 187.
Corrosion and accumulates at the pylorus. The firm closure of the pylorus furnishes more or less protection to the intestines.

**Characteristic Appearance of the Corrosives and Stains.**—These are of diagnostic importance, since they may be recognized about the mouth during life:

Alkalis cause transparent swelling of the epithelium, which will detach as a gelatinous mass, exposing the scarlet-colored inflamed area beneath. The other corrosives, which precipitate proteins, produce at first a grayish-white opaque stain. This persists in the case of the metallic poisons. The acids, however, change the hemoglobin in the neighboring area into the dark acid-hematin, and the color of the stain consequently becomes dark or black. Nitric acid is an exception: its stain takes on a yellow color. This differs from that of picric acid by being changed to orange by alkalis, while the picric acid stain remains unaltered. Bromin produces a characteristic light brown or orange stain; iodin stains a mahogany color. The silver stain turns black after a time.

**Removal of Stains.**—The stains of iodin and silver are frequently a source of annoyance. They can be readily removed: The iodin by ammonia water or by thiosulphate; the silver by potassium cyanid, or by painting first with iodin and then with ammonia.

**Symptoms of Corrosive Poisoning.**—These begin in the mouth, with burning pain, dysphagia, and loss of tissue. The taste of many of these substances is characteristic—acid, alkaline, metallic, astringent; etc.

The further symptoms are those of gastroenteritis, similar to those described under non-corrosive irritants, but generally more severe. The vomiting and diarrhoea are more frequently bloody. In the case of acids the vomited blood is frequently very dark in color on account of the formation of acid hematin. This is the so-called "coffee-grounds" vomit. The pain is very much more marked with corrosive poisons. The destruction of the tissue gives rise to reflexes which may take the form of "shock." The absorption of the chemic products of corrosion may produce fever; or the temperature may be lowered by collapse. If perforation occurs, the clinical picture turns into that of peritonitis.

**Death.**—This may occur from shock before the local symptoms have time to develop; or it may follow after one or two days of more gradual collapse; or it may result later from peritonitis; or finally, after recovery from the acute effects, the formation of scar-tissue in the corroded areas may lead to stenosis and thus to gradual starvation.

**Postmortem Examination.**—This shows the characteristic stains and corrosions in the mouth, esophagus, stomach and duodenum; with the metallic corrosives, the cecum and large intestines may exhibit the principal changes since many metals are excreted in these situations.

When the action has not progressed to actual corrosion, there is often very marked hyperemia and ecchymosis. The color is frequently much darker than corresponds to the amount of congestion, especially in the case of acids (due to acid-hematin).  

**Treatment of Poisoning by Corrosives.**—The first measure is dilution, since the action is proportional to the concentration. The drinking of water in abundance and the washing out of the stomach are therefore important. If corrosion is already advanced, it is not advisable to pass the stomach-tube. The further treatment consists in the administration

2. Plate 27.
3. Plate 34, 35 and 36.
of demulcent substances, such as mucilage or boiled starch; or white of egg; or milk. The proteins are especially useful against the metallic poisons, since they form rather insoluble albuminates.

The pain may require the exhibition of narcotics in free doses. Most of the irritant poisons can be treated by chemic antidotes; in the case of alkalies, by acids (vinegar, lemon juice, or any acid diluted to 1 to 5 per cent.); in the case of acids, by means of non-corrosive alkalies; preferably magnesium oxid; or in emergencies by soup.

The free alkalies are usually too caustic, and the carbones involve danger of rupturing the corroded stomach by the evolution of carbon dioxide gas. Potassium compounds are objectionable because of the danger of toxic absorption from the corroded mucosa. In case of necessity any alkali may be used, such as whitewash or chalk. Lodo, chloric or bromic may be neutralized by sodium bicarbonate.

Volatile Caustics.—These comprise ammonia, chlorin, bromin, the fuming mineral acids, the gaseous acids, such as sulphurous, nitrous, etc.; and certain organic acids—acetic, formic, etc. Also other organic substances, such as formaldehyde; and the volatile oils, especially the oil of mustard; and the various “War gases.”

When swallowed, these produce the symptoms already described. When inhaled, they irritate mainly the respiratory passages and other exposed mucous membranes, causing coryza, conjunctivitis, bronchitis, pulmonary edema, pneumonia, etc. Through the irritation they produce profound nervous effects, at first mainly stimulant. The respiration stops at first in expiration, the glottis closes spasmodically, and the bronchial muscles contract. This is a conservative mechanism, and explains why fatal poisoning is not more common. During this stage there is cardiac inhibition through vagus stimulation, and also dilatation of peripheral vessels. The inhalation irritants may prove promptly fatal by spasm or edema of the glottis; or the course may be slower, passing through bronchitis, pneumonia, etc. (cf. L. Lewin, 1908). The irritation may also involve the esophagus and stomach, with protracted hemorrhagic gastritis (Loeper et al., 1913). The inhalation of irritant vapor is especially deleterious to asthmatic individuals.

Bronchodilator drugs (atropin, etc.) have a limited efficiency against the acute respiratory distress of irritant gases (Symes, 1913). The effects of small quantities of volatile irritants in the air has an economic importance, in view of their escape from chemical factories, etc. There can be little doubt that even a small proportion tends to produce bronchitis, and to diminish the resistance to infections (Ronzani, 1908: low concentrations of CI, SO₂, NO₂). They may possibly cause cachetic conditions; but it is difficult to assign the limits between which these poisons are harmless, objectionable, and dangerous.

Volatile Irritants in Warfare.—The study of the toxicology of gases has been greatly stimulated by their employment in war. The use of “gas-shells” has extended the significance of this term beyond those substances that are gaseous at ordinary temperature, so that it includes liquids and even solids that can be vaporized or simply atomized by the heat or force of the explosion of the shell.

Available Substances.—Practically every substance of sufficient heat stability and toxicity may thus become an implement of “gas-poisoning.” The choice of the substances is limited by the fact that they must be able of producing their effects even when highly diluted. In practice,
The requirement is best met by irritants. Curiously, it has largely excluded such substances as hydrocyanic acid, arsin, phosphin and hydrogen sulphide—substances that owe their sinister reputation mainly to rapidity of action, but which apparently cannot be used with sufficient concentration in ordinary military operations.

The substances actually used are numerous, as has been said. They can, however, be reduced to a few types, from the standpoint of their action, or more precisely, according to the usual location of the irritation; viz., Pulmonary Irritants, Lachrymators and Blistering "Gases." These last will be discussed in another section.

The actions are not sharply localized, but differ according to circumstances, especially according to the concentration and duration of exposure. However, the effects adhere pretty closely to the type-classification under ordinary conditions.

Absence of Direct Systemic Toxicity.—Most of the irritant gases are not absorbed as such from the lungs. They therefore do not have direct systemic actions. All their effects are explainable as direct or indirect results of the local irritation. The indirect effects are produced by asphyxia or by reflexes.

The fatigue and exhaustion of the mild cases, and the loss of consciousness in severe cases are asphyxial. Retching and vomiting result from pharyngeal irritation and from the cough. Diarrhea is emotional.

The kidneys are practically unaffected.

PULMONARY IRRITANTS

The principal representatives of these are Chlorin; Bromin; Nitrous Vapors; Sulphur Trioxide and Dioxide; Phosgen; Superphalite; and Palite, and Chlophoricrin.

Phenomena of the Group.—The distinguishing feature of this group is the production of profuse pulmonary edema. This leads to asphyxia and to circulatory collapse.

In addition, they may cause more or less irritation of the respiratory passages, depending largely on whether they are irritant directly, like chlorin, or whether they must first undergo chemical decomposition, like phosgen.

The irritation of the respiratory passages causes pain, choking, coughing and asthmatic phenomena.

The irritation also affects other mucous, especially the conjunctive, causing lachrymation.

CHLORIN

Use in "Gas Clouds."—Chlorin was the first gas used in the war, being the sole constituent of the original "gas-cloud" attacks of Ypres in April of 1915. It was efficient, but because of the ease of protecting against it, it has been replaced almost entirely by phosgen mixtures, which were used almost exclusively in the gas-clouds of 1916.

Effective Concentrations.—The concentration of the toxic gas in cloud-attacks probably never rises above 1 in 10,000, and more commonly is nearer 1 in 10,000. These are effective concentrations. With concentrations below 1 in 100,000, chlorin gas is practically ineffective under military conditions, although long exposure is followed by bronchitis.

Symptoms of Poisoning by Pulmonary Irritants.—These are alike in man and animals, under similar conditions.
Chlorin produces a very prompt painful irritation of the mucous of the upper air passages. These local symptoms start with the first two or three inspirations. With the concentration at 1:10,000 there is irritation of the eyes (relatively slight), spasm of the glottis, and a choking sensation. Continuation of the inhalation becomes more and more difficult.

The respiration becomes dyspneic and spasmodic, superficially resembling asthma, although the bronchioles may not be contracted. There is also violent coughing, with frothy expectoration. Acute asphyxia develops, with cyanosis and great anxiety. The asphyxia also produce mental confusion and lethargy, and finally unconsciousness. Eventually, the condition passes into pulmonary edema and circulatory collapse. These, rather than the immediate phenomena of irritation, are the facts features of the intoxication.

In case of survival, this asphyxial stage lasts some 36 hours, and the improves, to be succeeded by bronchitis. This is usually of light degree but may be intense, according to the severity of the poisoning. With higher concentrations of chlorin, the primary irritant effects reach their acme more rapidly. However, death does not occur acutely under military conditions, as it does with much higher experimental concentrations (1 to 5 per cent.).

**Acute Effects of High Chlorin Concentrations.**—With these, death occurs usually before the stage of edema is reached. The symptom are those of violent respiratory irritation, and rapid asphyxial syncope. Death seems to be due, mainly to the obstruction in the pulmonary circulation.

The experiments of Schaefer, 1915, showed that 1 per cent. of chlorin in the air may be ineffective for several minutes; then, often suddenly, the respiration becomes deep convulsive, and arrested. The blood pressure falls. Rapid recovery occurs in fresh air.

With 5 per cent., death is rapid and inevitable. The respiration becomes slow and is arrested in one to three minutes. The blood pressure falls to zero in three to four minutes, the heart still beating well. Artificial respiration does not cause recovery.

The bronchioles are not constricted, air passing at least as well as normally. Secrecion of mucus is also unimportant, for the course is not modified by atropin. The systemic circulation is also unaffected directly, the changes being secondary to the asphyxia. Even the right heart is not especially congested.

The essential changes are seen in the pulmonary circulation. The lungs are intensely hyperemic, microscopic examination showing engorgement of the capillaries and edema of the interstitial tissue and alveoli. The epithelium proper is normal. Perfusion of the pulmonary vessels with Ringer's solution shows marked obstruction of the flow when chlorin is injected into the trachea or perfusion fluid. Schaefer assumed that this phenomenon occurs during life and that this obstruction is the cause of all the symptoms.

It is probable that chlorin coagulates the endothelium, as do other astringents. Bronin vapor is more irritant, but less fatal.

**Bronch.—**Inhalation of air containing chlorin (1:5000 to 1:1000) produces quickening of the respiration and transient broncho-constriction; due partly to edema of the bronchial mucosa (Aszi, 1918). There may also be a direct action on the bronchie musculature; for excised rings are strongly contracted when placed in Ringer's solution containing fairly high concentrations of chlorin. Low concentrations relax. Rings of pulmonary artery and vein behave similarly; but it is doubtful whether they are expose sufficiently in life.

**Minor Toxic Effects of Chlorin.**—These have arisen mainly from its use in the air. Air contaminated with chlorin produces irritation of the conjunctiva and respiratory mucous membranes, etc.; 0.001 to 0.002 per thousand of air is said to be harmless; 0.003 is disagreeable, and 0.004 irresistible (Matt. 1889). Continuous exposure produces cæshæma. The foliage of plants is destroyed by concentrations which are not noticeable for man.
Peculiarities of Irritative Pulmonary Edema.—This edema is the essential danger-factor with the volatile pulmonary irritants; its mechanism, phenomena, and treatment being essentially the same for all.

The pulmonary edema as produced by gas differs from the pulmonary edema of ordinary civilian practice in several important respects; in the manner of its production, as well as in its phenomena:

Ordinary pulmonary edemas are either early stages of pneumonia, in which case they are more circumscribed; or they are due to disturbance of the pulmonary circulation, in which the alveolar endothelium is involved secondarily.

In gas poisoning, the order is reversed; the endothelial injury is primary, and the circulatory disturbance is secondary.

Other Forms of Experimental Pulmonary Edema.—The methods that have been employed are reviewed by Schmolzewits, 1930. They may be arranged into the following groups:

1. Embolism of artery by fat, lycopodium, etc.; intravenous collargol.
2. Injury to pulmonary capillaries by excessive hydrenia; excessive blood concentration and anoxemia.
3. Injury to pulmonary capillaries by intravenous acetic ether, or ammonia.
4. Injury to respiratory epithelium; irritant gases.
5. Clinical inflammatory type; mainly by vascular injury.
6. Disproportion in the work of the right and left ventricle; compression of the left ventricle (Welch); epinephrin-injection; mucarin; asphyxia.

1. Eating of Acute Epithelial Injury by Gases.—This increases progressively in inverse ratio to the robustness of the cells, from the trachea to the alveolar endothelium. The functional injury may be much greater than the histologic changes. In acute gas cases, particularly, severe edema may occur before the cells present any morphologic abnormalities.

2. Chlorosis and other direct irritants including "mustard gas" produce a more or less violent inflammation of the larynx, trachea and bronchi. In case of survival these are likely to lead to secondary infections; to laryngitis, tracheitis, bronchitis and lobular pneumonia.

Those gases which liberate chlorin only on contact with water (phosgen, palate, superpalite, etc.) cause little or no inflammation of the upper respiratory tract. They are also somewhat less liable to secondary pneumonia.

Stages of Poisoning.—The phenomena of gas poisoning may be advantageously grouped into several stages:

(a) The immediate sensory reflexes, coughing, choking and vomiting. These are conspicuous in the case of direct irritants, such as chlorin; and delayed or absent with the slower acting poisons (phosgen). They have been sufficiently discussed.

(b) The pre-epithelial phenomena, constituting the first stage in phosgen gassing.

(c) The stage of pulmonary edema, the second stage of phosgen poisoning, progressing to acute death or toward recovery.

(d) The phenomena of restoration, the third stage of phosgen.

(e) Secondary infections of the respiratory tract, generally responsible for the delayed death.

(f) Persistent lesions, induced either by the chemical irritation or by the secondary infections.

The rapidity of the development, and the severity of the earlier symptoms, and the acute and subacute mortality, vary directly with the concentration of the gas, and the duration of the exposure, as well as with the nature of the irritant.

The details of these phenomena and of their treatment have been studied on animals; under standard conditions, with greatest detail perhaps on dogs exposed to phosgen for about 1:15,000, for half an hour.

Pre-epidemic Stage. (First Stage of Phosgen Poisoning).—This is characterized by congestion and stasis in the pulmonary circulation; dilation of the right heart, dilation and increased volume of the blood.

Thrombosis of the Pulmonary Vessels.—This is especially prominent in chlorin poisoning. Many of the pulmonary capillaries are occluded by agglutinated red cells. The process reaches its maximum rapidly, in one or two hours at the latest, and then gradually diminishes.

The thrombosis may be partly the result of the usual inflammatory stasis; but
probably is largely due to the direct action of the acid gases on the blood corpuscles; for agglutination may be produced in vitro by dilute chlorin, phosgen or hydrochloric acid.

Hemoglobin and blood volume in the pre-edematous stage.—The hemoglobin and corpuscle content of the blood is materially diminished during the first stage, thus producing a hydremia. This may be partly attributed to the withdrawal of corpuscles from the systemic circulation by their stagnation in the pulmonary vessels (Meek and Eyster, 1920). However, direct estimations show an actual increase in the total blood-volume in most cases (although it is not strictly parallel to the hemoglobin dilution), so that there must be a flow of fluid from the tissues into the blood. The cause of this has not been established.

During this stage, the chlorid content of the blood drops sharply, this being accompanied by a marked increase in the chlorin and water content of the lungs.

Oxygenation of the Blood and Tissues: Respiration. — The oxygen content of the blood decreases considerably, nearly parallel to the deficiency of the hemoglobin. This, together with the obstruction in the pulmonary circulation and the venous stasis, produces some asphyxia and dyspnea; but the respiratory symptoms in this stage of phosgen poisoning are not severe. There are no physical signs, but an X-ray examination of the lungs in the pre-edematous stage shows a diffuse cloudiness.

Dilatation of the Right Heart.—Prior to the edema, the right heart dilates considerably as shown, f.i., by X-ray measurements. The left heart is never dilated.

The changes are doubtless due to the increased resistance in the pulmonary circuit, and to the increased volume of the blood. The dilatation persists for two to four hours, then gradually disappears as the edema sets in.

The pulse in this stage is practically normal.

Acidosit.—Chlorin poisoning is always accompanied by temporary acidosis. This is indicated by the urinary constituents, and by diminished alkali reserve (diminishing CO2 capacity) of the blood.

In case of survival, the acidosis is only temporary, the blood recovering its normal values rapidly, often in a few hours. The alkali reserve of the tissues was therefore not seriously depleted.

In fatal cases, however, the reserve alkali of the blood continues to fail progressively. This is of prognostic importance.

In Phosgen poisoning, acidosis occurs only shortly before death; i.e., there is only the terminal acidosis that is likely to precede death from any cause.

Changes in Urine.—In dogs, gassing by chlorin is followed by increased protein metabolism, shown by increased elimination of total nitrogen, ammonia, creatinin, uric acid, and phosphatase.

Acidosis indicated by increased output of ammonia, and by increased H-ion concentration of the urine. These changes are generally absent in phosgen poisoning.

The kidney-function tests give normal values. Other signs of renal disturbance are also absent (negative albumen, glucose, blood, etc.).

Pulmonary Fibrosis.—Chlorin, of course, is not absorbed as such. However, the chlorid content of the plasma is said to be increased for a few hours after gassing, and the concentration in the urine is raised on the second day following severe gassing. Presumably, chlorin-protein compounds are formed in the lungs and are absorbed, especially by the corroded tissue. These would break down in the tissues, liberating chlorid ions, which would then appear in the urine.

Stage of Pulmonary Edema. (Second Stage of Phosgen Poisoning).—The pulmonary capillaries, which were irritated and obstructed in the first stage, become gradually permeable, leading to pulmonary edema.

Heubner, 1910, believes that the pulmonary stasis plays a greater part than the direct irritation of the endothelium.

The edema results in diminished blood-volume, concentration of the hemoglobin, and decreased size of the heart. This is apt to develop quite rapidly, especially in chlorin poisoning, and may reach extreme degrees; affecting the circulation as well as the respiration. Most of the fatalities occur in this stage, from anoxemia and decreased blood-volume (Meek and Eyster, 1920).

Blood Concentration.—The dilution of the blood, which was characteristic for the pre-edematous stage, rapidly returns to normal as edema develops, and is then replaced by progressive concentration, so that the blood-count and hemoglobin content and viscosity rise. In chlorin, the concentration occurs rapidly; in phosgen very slowly, reaching its maximum about the 4th to 8th hour. It may then remain stationary for some time.

The rapidity and degree of the concentration is proportional to the severity of the intoxication, and is therefore of prognostic importance. In dogs poisoned by phosgen,
f.d., a hemoglobin content above 1.30 forecasts death during the edemic stage (about the 35th hour) if the hemoglobin figures below 1.10 occur only in cases that are not fatal (unless by infectious complications).

The increased blood concentration is partly responsible for the circulatory phenomena.

Blood Volume.—This decreases with the loss of fluid and the concentration of the blood. It doubtless contributes to the circulatory and respiratory disturbances.

Size of the Heart.—The dilatation of the pre-edemic stage gradually disappears as the edema comes on. This is seen first in the left heart, perhaps because of the impeded access of the blood to the left auricle; after 2 to 4 hours, however, all chambers become distinctly smaller. Establishment of compensatory capillary channels in the lungs and the diminished volume of blood, explain the change in the heart.

The fatal cases, the heart continues to diminish in size until the approach of the terminal asphyxia, when the heart again dilates somewhat.

Circulatory Collapse.—Severely gased patients suffer more or less from circulatory collapse, as shown by a gray pallor; by rapid and feeble pulse; and by venous congestion and dilatation of the right heart (never of the left). The collapse is often the immediate cause of death.

The circulatory collapse is due mainly to the asphyxia; but is aided by the local conditions in the lungs; by the increased viscosity and thrombosis; and by the compression of the capillaries and veins through the edema.

In intact mammals, inhalation of concentrated chlorin often produces prompt temporary arrest of the heart. If the heart resumes, the pulse and respiration remain greatly slowed. These effects are absent if the vagi have been divided.

The exposed frog or terrapin's heart and especially the mammalian heart are immediately depressed by chlorin in Ringer's fluid, or in the air (Schults, 1918).

Temperature and Pulse-rate.—The effects of chlorin have been investigated by Behr, 1910. Low (irritant) concentrations (12 to 16 per million) produce considerable rise in temperature. Medium (irritant to depressant) concentrations (75 to 200 per million) cause considerable fall in temperature, with slowing of the pulse rate, during the inhalation. Both disappear soon after removal from the chlorin.

Lethal concentrations (850-900 per million) produce more persistent effects. The pulse becomes slow, later weak and rapid. The temperature falls, and with the collapse the animals become practically poikilothermal. Excessively warm environment may then be as detrimental as cold.

Development of the Pulmonary Edema.—The fluid exudes first into the air sacs and from here overflows into the bronchioles and bronchi. Here it is churned into foam by the tidal air. As this foam mounts toward the larger air tubes, it provokes the cough-ref, and is more or less effectively expelled, until, if the condition progresses, the edema of the lungs become so excessive that they produce fatal asphyxia.

The edema compresses the pulmonary capillaries, this being another factor in the impeded pulmonary circulation. Some of the exudate may also form in the pleural cavity but usually in scanty amount.

During this stage, the chlorid content of the blood returns toward normal, while the water and chlorid content of the lungs reach a maximum, later falling gradually.

The edema fluid comes largely from the blood. This becomes more concentrated, as is already explained, whereas there is no change in the water-content of the edema.

Respiration.—The minute volume of respiration is always increased after the symptoms of gassting develop. With chlorin, the sensory phenomena dominate the respiration. With phosgen, the increase of respiration is asphyxial, and therefore increases with the edematous stage.

Inhalation of high concentration of chlorin (admitted directly into the trachea) arrests the respiration completely, for 20 seconds or longer. This is followed by periodic, above-mentioned abdominal movements; and this by restoration of practically normal respiration. Further chlorin does not again arrest the respiration (Schults, 1918).

Durhäm Emphysema.—This is especially serious in chlorin gassting, because of the violent coughing and inspiratory efforts provoked by the irritation of the gas. These efforts tend to tear the partitions between the alveoli. The pulmonary tissue may be ruptured so extensively that air escapes even into the subcutaneous tissue of the neck.

The much milder sensory irritation of phosgen poisoning leads to less violent muscular efforts, and emphysema is therefore less prominent. However, the air hunger leads to super-ventilation; and this may cause some emphysema, especially when the air-tubes are narrowed by broncholiths or bronchiolar spasm.
In any case, disruptive emphysema diminishes permanently the breathing area; so that the surviving patients are apt to suffer indefinitely from shortness of breath.

Gas-exchange in Irritative Pulmonary Edema.—This is best studied in phosgene poisoning, in which the phenomena are not so complicated by sensory irritation.

In chloria poisoning, air hunger sets in very rapidly. On the other hand, soldiers gassed with phosgene do not complain of air hunger for some time, although they may show an intense grayish cyanosis, and may even die. This is a condition of anoxemia analogous to mountain-sickness.

If the patient survives, his cyanosis gradually changes to the ordinary blue tinct, and he develops air-hunger and intense hyperpnea. These are the phenomena of carbon dioxide poisoning. In other words, the patient passes first through a condition of pure anoxemia; this is then complicated by the accumulation of CO₂, which develops much more slowly.

Haldane explained the early dissociation of the oxygen and carbon dioxide factors of asphyxia by the relative solubility of the two gases. CO₂ is twenty-five times more soluble in water than is oxygen. Consequently, when the exudate begins to form and interposes an extra film, as it were, between the alveolar air and the alveolar blood, this film will interpose a much greater obstacle to the passage of oxygen, than to the passage of CO₂, to which it is quite freely permeable. This would result in the anaemia without carbon-dioxide accumulation, as noted clinically.

However, these conditions change when the edema becomes more abundant; when it fills the alveoli, and its foam mounts more and more into the bronchioles and bronchi. When this happens, the air is totally prevented from reaching the alveoli. The respiratory exchange stops in that part of the lung, and CO₂ accumulates.

The edema develops with unequal rapidity and severity in different parts of the lungs. At first, therefore, some parts of the lungs will still be in communication with the air. The tendency to the accumulation of CO₂ produces more or less hyperpnea, and this produces an over-ventilation of those functioning portions of the lung. Their CO₂ will therefore fall below the normal level.

The blood returning to the left heart will be a mixture derived from the over-ventilated and from the unventilated parts of the lung—the first with a deficiency of CO₂, the second with an excess of CO₂. These two factors will tend to balance each other, so that the CO₂ excess of the mixed blood is not at first very great. It increases, naturally, in proportion as more and more of the lung is thrown out of function.

On the other hand, over-ventilation does not increase the oxygen of the blood anywhere, since the hemoglobin in the functional part of the lung is practically saturated with oxygen by ordinary ventilation. This oxygen saturation cannot be increased by over-ventilation. Therefore, the over-ventilated portions of the lung do not compensate the over-ventilated portions. The uncompensated oxygen deficit therefore continues greater than the more or less compensated CO₂ excess.

The administration of oxygen reverses these conditions: oxygen diffuses gradually through the foam, and thus the foam near the alveoli becomes so much enriched in oxygen, that a sufficient quantity of the oxygen can diffuse into the alveolar exudate. The CO₂ excess is of course not aided in any way by this. So that oxygen inhalation abolishes asphyxia and diminishes the danger of asphyxia death; but it does not diminish the hyperpnea. The air-hunger, the amplitude and rate of respiration, are not changed by the oxygen.

Since the oxygen must diffuse through the foam before it can be effective, the relief is rather slow, coming on only after about five minutes. This contrasts with the instantaneous response to oxygen in ordinary obstructions.

Blood-gas.—In untreated gas poisoning, the oxygen of the blood falls, often to very low values. This is especially conspicuous in the venous blood. The carbon dioxide content increases more slowly, as has been explained.

Post-mortem Findings.—These differ somewhat for chlorine and phosgene (Wintermets, 1910).

Chlorine, Followed by Acute Death (Inside of Twenty-four Hours).—The trachea and bronchi are red and congested, edematous, and may be more or less filled with serous exudate. The lumens of the bronchioles may be filled with debris. The lungs are heavy and edematous with overdistended, emphysematous areas scattered through the purplish collapsed and depressed structures. On section, serous fluid flows abundantly.

Post-mortem Findings for Phosgene.—When death has occurred within two hours after exposure, the lungs are found uniformly edematous, airless, and purple. There is little or no emphysema. The lungs exude abundant fluid on section. There is also considerable fluid in the pleural cavities.

When death occurs later (second or third day) the pulmonary edema is lighter, the
IRRITANT GASES

lungs containing some necrotic areas. This may be because all the cases of severe edema die early. However, it is conceivable that in non-fatal cases a reabsorption of the edema occurs from the second day; since even deeply cyanosed patients may ultimately recover.

The degree of the pulmonary edema may be determined accurately post mortem by the water-content of the lungs; or by the ratio of the weight of the lungs to that of the heart.

Prognosis in the Edema Stage.—Experience with animals indicates that the severity of the intoxication and the direct fatality in phosgen poisoning may be judged with fair certainty by the course of the blood concentration and by the temperature. The more rapidly the blood concentration sets in, and the higher its degree, the more grave is the danger. The temperature does not change in light cases. In severe cases, there is a preliminary rise, followed by a later fall. This fall is rapid in fatal cases, gradual in those that survive.

Phenomena of Restoration (Third Stage of Phosgen Poisoning).—If the patient does not succumb to the pulmonary edema, the excessive concentration of the blood gradually disappears, so that it finally becomes slightly more dilute than normal. The edema is slowly reabsorbed; and there is a fairly rapid re-adjustment and eventual return to a practically normal condition.

However, the stage of restoration is often complicated by secondary respiratory infectious mucousm or bronchitis, which may run a fatal course.

Late effects of Irritant Gases.—Inhalation of phosgen, dichlorethylsulphid, and specially of chlorin is often followed by chronic disturbance of the respiration. Four months after miscellaneous "gassing," the physical findings were normal in about 50 per cent. of the patients, chronic bronchitis was present in 30 per cent.; emphysema in 20 per cent. (Berghoff, 1920).

Exceptional cases develop persistent gastro-intestinal or nervous changes, due to hemorrhages into these situations.

Treatment of Poisoning by Pulmonary Irritants.—This is directed against the immediate local irritation and bronchial spasm; against the anoxemia and acidosis; against the abnormal blood-volume; against the circulatory collapse; and against the later bronchitis and secondary infections.

Since these factors vary in importance and urgency at different stages of the intoxication, and in different patients, the treatment must also vary. However, the pulmonary edema, and the consequent asphyxia and circulatory collapse dominate all other indications.

In this discussion the individual measures are arranged generally in the order of their application.

Rest.—Rest is the simplest and perhaps most important single factor in the treatment of gas casualties. Men and officers are warned in advance that when gassed even slightly, they must refrain from all exertion, even the shouting of orders. Paint-taking arrangements are made that they receive the practical minimum of disturbance in their transportation, etc.

This emphasis is based on the difficulty of combating the edermal and emphysema- tous asphyxia directly. More or less asphyxia is always present. In this state, every exertion, even standing, means a more rapid exhaustion of the difficulty obtainable oxygen; a more rapid accumulation of the difficulty excretable CO2; and an added mechanical and chemical strain on the overloaded heart, which may easily bring on acute insufficiency.

The rest must be as absolute as circumstances permit. Sleep should be encouraged, as it generally brings improvement. Restless and excited cases must have morphin. The indication of rest must be observed absolutely or relatively as long as the patient resists to exertion by cyanosis or dyspnea, or extra rapid pulse. Usually, if the rest is thorough in the start, the patient can return to light duties in a few weeks.

Warmth.—This is a useful precaution against collapse. Severe cases should there- for be heated. Ordinary cases should at least be protected against chill, but they should at the same time receive the benefit of fresh air.

Morphin.—This is used as a sedative, to secure rest, and to check spasmodic cough and mechanical trauma. It should be used only when these indications exist, and should be avoided when there is deep cyanosis. However, if the patient is very restless, he may receive morphin, even though he be deeply cyanosed.
The objection to morphin lies in the fear that it would depress the respiration at a time when the maximum respiratory ventilation is needed to offset the diminished lung-area. This is largely obviated by employing rather small doses, not to exceed 0.015 to 0.03 of morphin.

From pharmacologic and physiologic considerations, small doses of morphin would be expected to improve the respiratory conditions. The characteristic effect of therapeutic doses consists in a slowing but deepening of the respiration. This would counteract the rapid and shallow respiration that follows as a vicious circle on oxygen deficiency (Haldane and Meaking, 1918).

Barbour et al., 1910, found in animals gassed with chlorin (0.08 per cent.) that large doses of morphin (50 mg. per Kg. twice daily) were rather unfavorable. Smaller doses (3 to 5 mg. per Kg.) did not materially effect the fatality.

Amonia Inhalation.—Amonia was carried in ampuls, and a few whiffs inhaled at intervals, during the first day. It acts as a respiratory stimulant, usually making breathing easier and less exhausting. Its benefits were so universally admitted, that its use had been established as a routine. A few patients are made more uncomfortable by it, and in such cases it is not continued.

Ammonia as Antidote.—Some early attempts were made to neutralize the inhaled chlorin, by the continuous inhalation of ammonia. They were entirely unsuccessful, since the ammonia could only reach the chlorin excess in the upper air-passage. These would not require the neutralization, since they would be quickly flushed by fresh air. On the other hand, the irritant action of the ammonia tends to add itself to that of the chlorin, so as to increase the local injury.

Anaphylaxis.—Brandy (small sips) is rather useful, until collapse becomes established.

Camphor and ether have been used hypodermically, against the later collapse, with the usual discordant opinions as to their efficiency. Pulmonary Solution, 0.5 c.c. every three hours, intramuscularly, and strychnin are useless.

Atropin.—This was proposed originally with the object of diminishing “pulmonary secretion.” Naturally, it proved entirely useless, since the exudate of pulmonary edema is of inflammatory origin, and therefore is not affected by atropin.

Atropin might be of advantage against bronchial spasm (Cow, 1915). However, this is a serious feature of gassing; and besides, the ordinary doses of atropin are apparently not sufficient to relieve it. On the other hand, the tendency of atropin to accelerate the heart would be detrimental in asphyxia.

For these reasons, it is not advisable to use atropin in the early stages. It may find employment later on against bronchitis.

In animals gassed with chlorin, Barbour, 1910, found the fatality unchanged by atropin.

Epinephrin.—This has been used especially to relax bronchial spasm. It is efficient, although the relief is only temporary (1 c.c. of 1 : 1000, hypodermically). However, it is not employed extensively, probably because the bronchial spasm is not an important factor in gassing. Barbour, 1910, found it inefficient in animals.

Oxygen Inhalation.—As has been explained, the dominant indications, with the oxygen inhalation, would be to facilitate the access of oxygen, and later the elimination of carbon dioxide. The control of the carbon dioxide is difficult; but the anoxemia can be relieved considerably by oxygen inhalation. The mechanism of this relief has been discussed.

Clinically, the efficient administration of oxygen generally diminishes the cyanosis, and is believed to increase the chances of survival. By its persistent use, patients may recover after being cyanosed and unconscious for two days. It may be recalled that it does not diminish the air-hunger; nor would it be desirable to have this diminished, since it is needed for the elimination of carbon dioxide.

The reported clinical benefits of oxygen inhalation have not thus far been reproduced in animal experiments. In these, oxygen had practically no influence on the fatality from chlorin, and not very much on that from phosgen. However, there is a distinct increase in the oxygen of the arterial blood at the time when it is most needed; and whilst this may not be enough to do much good in a restless animal, it may be of greater benefit in a resting patient.

Administration of Oxygen.—Since the oxygen exchange must be effected through a more or less thick layer of lamn, it must be given in concentrated form, through a valved mask. Inhalation through a funnel over the mouth, or even through a tube in the mouth, is said to be useless.

On the other hand, the oxygen need not be supplied more rapidly than it is absorbed; that is, the important point is the concentration, not the absolute quantity of the oxygen. Therefore the administration need not be continuous. It suffices to breathe
the gas for three or four minutes every quarter hour; but this must be done night as well as day, as long as the cyanosis tends to be permanent. The intermittent administration was of military importance, for the difficulties of transportation to the front made the utmost economy imperative. For this reason, the oxygen was not given to all patients, but was restricted more or less to selected cases. It is not necessary in mild cases and it is superfluous in hopeless cases. It is most useful in borderline cases that verge on the desperate; especially those who are still deeply cyanotic on the second day.

Hypodermic or intravenous injections of oxygen would be more economical, but less convenient. They are at present considered "useless" under field conditions.

Venesection.—This was introduced early in the gas-war, and has maintained itself for all forms of irrigant gases. Neither the clinical nor the experimental data are quite conclusive as to its efficacy for saving life; but the balance of the evidence is in its favor. The relief is often striking, especially in the more severe cases, with deep-blue cyanosis and full pulse (corresponding to acute asphyxial dilatation of the heart). Under such conditions, the abstraction of 1½ to 2½ ounces of blood is said to relieve the asphyxia, ease the breathing, and often lead to strengthening sleep. The relief, however, may be only temporary.

Bleeding must not be used when collapse has started, as indicated by a poor pulse, or when the condition of the patient is in any way immediately dangerous. This confines the usefulness of bleeding to the pre-edematous stage. It is advised to apply it as soon as possible after gassing, generally in half an hour or an hour; after that, it may be useful up to 4 hours.

The benefits of venesection would naturally be attributed to relief of the distending right heart. This diminishes not only the immediate results of the venous engorgement, but also conserves the heart so that it can meet more successfully the conditions of the subsequent edema. If the distention and asphyxia have already weakened the heart too extensively, the abstraction of blood would tend to be harmful. It might also be assumed that the relief of the pulmonary circulation, and the diminished blood-volume, would tend to lessen the liability to edema. Practically, however, this tendency does not appear to be important; for venesection has not been found to modify the subsequent edema in gassed animals.

The best conditions for venesection and transfusion have been worked out experimentally; but these details have not yet been tried under actual field conditions. Even in animal experiments, the results of different workers have not been uniform.

Venesection Treatment of Chlorin Gassing.—Since this runs a rapid course, the measures must be applied in prompt succession; as soon as possible after the gassing, the patient is to be bled about a per cent. of the body weight. This is followed at once by the intravenous injection of an equal volume of normal saline. After this, sodium bicarbonate may be given freely by stomach. The reasons for these measures will be discussed presently.

Venesection Treatment of Gassing by Phosgen, Sperberitale, Etc.—The relatively slow course necessitates modifications of the treatment, so that the successive measures may be applied at the proper time. This is controlled mainly by the hemoglobin content of the blood, as the most convenient index of the concentration and volume of the blood.

Bleeding is practiced as soon as practical after gassing, if possible within an hour; but it may be beneficial even after four hours. At first ½ per cent. of the body weight is withdrawn. The hemoglobin and temperature are then observed at half-hour intervals.

If the temperature remains normal, and the hemoglobin concentration does not diminish, no further treatment is necessary. If the temperature rises rapidly, with a simultaneous fall of hemoglobin concentration, a second venesection of ½ per cent. of the body weight is made. This may be repeated once more if necessary.

This treatment prevents the development of pulmonary edema in most of the animals gassed with standard doses of phosgen. If, however, in spite of this treatment, the blood becomes markedly concentrated and the temperature falls materially, the condition is critical. In this case, fluid should be administered freely; either by mouth, or by rather slow infusion of normal saline. This is only necessary in serious cases. The injudicious use of infusion is dangerous. Alkali is not needed in phosgen poisoning.

Saline Febrifugation.—During the stage of pulmonary edema, the blood becomes markedly concentrated, more viscous, and diminished in volume. Injection of normal saline (1 per cent. of the body weight, i.e., equal to the quantity of blood withdrawn at the venesection) has been tried to relieve this condition, but with doubtful benefit. Simple saline remains in the circulation at most half an hour and generally less, so that the
benefit would at best be temporary; and the use of hypertonic salt or glucose solutions was found not only to increase the fatal tendency to collapse, but to speed recovery, when used after bleeding at the time of the greatest concentration.

Alkaline Treatment.—The most hopeless element in the treatment of the severe cases is the acidosis, due to the inability of the edematous lung to eliminate carbon dioxide. A moderate restriction of lung area may be compensated automatically by hyperpnea. This, however, soon reaches its effective limit. Beyond this, the carbon dioxide must continue to accumulate and use up the reserve alkalii of the blood, and thus lead gradually to a fatal acidosis. There is no method of increasing the elimination of carbon dioxide when the lungs become inadequate. Some good may be accomplished by introducing alkalii into the blood; but the efficiency of this is also limited when carbonic acid is not being excreted. This is an essential difference from other forms of acidosis.

Consequently, the success of the alkalii treatment has not been brilliant. Intra-venous injection of sodium bicarbonate would be useless, since this is already saturated with carbon dioxide. Oral administration of bicarbonate is more promising. Sodium lactate has been used for the same purpose, 8 Gm. as 50 cent. solution, by stomach, every four hours; but the official comment is: "The main features of gas poisoning are not influenced by this method of treatment."

Digitalis and Ouabain.—These would conceivably be effective against the cardiac dilatation. Digitalis has been tried by mouth, with much benefit, but could much be expected from the slow absorption of the small doses that were generally used. Ouabain (crystalline Strophantin) has been used intravenously with better effect. The usual dosage is 0.25 mg., then 0.5 mg. per day, till a total of 1 to 1.75 mg. is reached. Barbour, 1910, however found it useless with chorin gassing. Acetophenoldin and Acetyl-salicylic Acid.—These were tried against the headache; but a large number died, for a fear of stimulating the tendency to collapse.

Quinin, Calcium Lactate.—These did not affect the fatality in chorin inhalation (Barbour, 1910).

Diuresis of the Exudate from the Lungs.—Attempts have been made to remove at least some of the exudate from the air-passages mechanically, especially during the first day; but they are not promising.

The coughing is a natural device for this purpose. However, it tends to become so violent as to threaten mechanical injury to the lung, and therefore generally rather needs to be allayed.

Sometimes this can be accomplished by position. The head is turned to the side, and the foot of the stretcher or bed raised two or three feet or higher, for a few minutes at a time.

Scafe's method of artificial respiration has been applied. It is not likely to do good, and may do harm.

Emetics.—These were tried rather extensively with the hope that the movements of vomiting would also expel more or less of the contents of the lungs. They appear to be ineffective for this purpose; and in the later stages the depression is certainly detrimental. This is true especially of the emetic drugs, such as apomorphine, or large doses of ammonium carbonate.

In the first few hours after gassing, emesis is often beneficial, not by emptying the lungs, but by relieving nausea. If, therefore, the patient feels inclined to vomit, soon after being gassed, he may provoke vomiting with the finger in the throat, or by drinking a pint of water containing a tablespoonful of salt.

Expectorants.—On the first day ordinary expectorants are useless, and may indeed be harmful by exaggerating the tendency to nausia. An exception may be made for demulcents.

On the second day, if the general condition is good, treatment of the bronchitis may be begun, with ammonium carbonate, 0.3 Gm. or Tr. Ippec, 0.5 c.c. every 6 hours.

Lar, the treatment of the bronchitis should be continued by the ordinary methods. Steam inhalation charged with Eucalyptus oil or Comp. Tr. Benzoin is used extensively.

Protection Against Poison-gases.—Perfect protection against all gases so far employed is provided by simple respirators and filters. These are masks, covering the eyes, nose and mouth, and communicating with the air through layers of absorbent and neutralizing chemicals. These chemicals now used (charcoal, permanganate and soda-lime) protect at once against all the gases so far used; in their
IRRITANT GASES

ordinary concentrations. This is obviously a great advantage under field conditions, although special chemicals for each "gas" might have advantages for experimental conditions.

British Type.—This contains essentially active charcoal and alkaline permanganate.

German Type.—This contains three layers: The inside layer is puritex with hexamethylenamin; this protects against phosgen. The middle layer is active charcoal; the outer layer is a mixture of baked earth, potassium carbonate, and fine charcoal.

Special Absorbers for Chlorin.—Chlorin is so highly reactive that it can be easily neutralized. Even water is fairly effective. Thiosulphate and alkalies are the special absorbents.

BROMIN

This is a reddish brown, very volatile and intensely corrosive liquid. Only a few instances of swallowing bromin are recorded. In one of these (Snell, 1850), death occurred seven and one-half hours after taking an ounce. The antidotes would be eggs and starch.

Inhalation of Bromin Vapors.—These irritate the respiratory organs with effects similar to chlorin. They are more irritant, but rather less toxic. 1 : 1,000,000 of air is disposable, 10 : 1,000,000 is said to be dangerous.

Prolonged inhalation of bromin is said to produce marked physiological changes in the thyroid (Pellegrin, 1917). The observation requires confirmation.

Bromin was used somewhat in the war in hand-grenades.

PHOSGEN; CARBONYL CHLORID; COCl₂

Mechanism of Action.—The effects produced by phosgen are very similar to those described for chlorin. The differences arise from the fact that phosgen acts only after decomposition into hydrochloric acid, in the presence of moisture. Its effects are therefore relatively slight in the upper air-passages, where the moisture is relatively small, and reach their maximum in the alveoli, where the air is saturated with water. With prolonged inhalation, however, there will be sufficient decomposed in the bronchi and trachea to produce corrosion.

The site of action, as determined by the decomposition, probably also explains the greater toxicity of phosgen, as compared with chlorin.

The slight degree of the irritation of the sensory nerves in the upper air passages does not suffice to deter from the inhalation of the gas, so that the patient is likely to inhale it more deeply than he would equivalent concentrations of chlorin or other directly irritant vapors.

Moreover, the reactive chlorin would be partly neutralized and bound in the upper air passages, whilst the indifferent phosgen would escape this destruction.

History and Use.—Previous to the war, this substance was known in toxicology mainly as the irritant product of the combustion of chloroform. Its use in gas-clouds followed soon after that of chlorin. It incapacitates the men more slowly than chlorin, but is more dangerous in the end.

For physical reasons, it is generally mixed with some chlorin when used as clouds. It is also employed extensively in shells.

Properties.—Phosgen is a gas at ordinary temperatures, but liquefies at 8.3°C. It may be prepared by passing a mixture of carbon monoxid and chlorin over heated charcoal.

It is fairly indifferent in itself; but in the presence of moisture, it decomposes with the production of hydrochloric acid:

\[ \text{COCl}_2 + \text{H}_2\text{O} \rightarrow \text{CO}_2 + 2\text{HCl} \]
MANUAL OF PHARMACOLOGY

Limits of Tolerance.—The highest concentrations that can be breathed without prompt distress are 1:50,000 to 1:500,000; generally about 1:125,000. Even this, however, produces definite eye irritation. Gas clouds generally contain about 1:10,000.

The high mortality may be judged by the result of animal experiments: Of dogs exposed for half an hour to concentrations of 1:7,000 to 13,000 about 42 per cent. die within two days; with concentrations 1:13,000 to 1:30,000, the deaths are 62 to 60 per cent.

Differences in Symptoms from Chlorin.—The eye-irritation is stronger than with chlorin.

The sensory irritation of the respiratory passages is much less than with chlorin; for the irritation begins in the finer bronchial division, beyond the sensory nerves. Consequently there are generally no acute symptoms or cough. If cough occurs, it is less violent than with chlorin, so that there is much less emphysema.

Although cyanosis and asphyxia may develop promptly, the ordinary onset is slow and insidious. The soldiers usually felt little inconvenience for an hour or two, except some weakness; and then developed progressive pulmonary edema, with "grayish-white" collapse, that might soon terminate in death.

Phosgen gas is much more likely to be followed by circulatory collapse; i.e., it is much more likely than chlorin to develop irrecoverable pulmonary edema.

Phosgen poisoning is especially likely to be followed by persistent respiratory lesions of chronic bronchitis, emphysema, and symptoms resembling tuberculosis (Achards, 1902; Berghoff, 1910).

Anesthesia.—Animals exposed to 1:20,000 or 1:10,000 show considerable anesthetic effect in leaving the gas chamber. The nerve-trunks, however, are still sensitive.

Symptoms of Phosgen Poisoning.—Although these have been fully discussed, their importance justifies a brief recapitulation.

Onset.—There is some lachrymation. The throat and chest feel constricted. Breathing becomes difficult, but not impossible. Coughing develops after a quarter hour. Nausea and vomiting are early, so that the soldier may vomit into the mask.

Headdache and throbbing sensations in the body occur.

Rapid Cases.—The coughing and retching increase. Hyperpnea sets in, the breathing being hurried and labored, but shallow. The face becomes purple. The patient is weak, confused, unconscious, and may die in one or two hours. More acute death has not been reported, even when a cloud attack was sustained without protection.

Slower Cases.—These develop headache, precordial and epigastic pain. There is extreme restlessness and anxiety, or semiconsciousness, with muttering delirium. The cough varies, but is usually not violent; laryngitis is practically absent.

The respiration becomes hyperpneic and irregular. The lips and ears are blue, the face becomes grayish. Expectoration may be slight or frothy. The pulse becomes rapid and soft, and the patient is generally collapsed. The usual prognostic signs are the color, pulse, and rate of respiration; although the concentration of the blood gives more accurate information.

The clinical picture varies in detail, according to the relative predominance of the pulmonary edema, bronchitis, emphysema, cardiac dilatation, bronchiolar spasm; and later the bronchitis, and the hemorrhagic gastritis or encephalitis.

Danger Period.—A man who at first seemed but lightly gassed may develop cyanosis and die in a few hours; but after the second day, no danger need be apprehended from the lighter cases; except from secondary infections. Most of the deaths (four-fifths) occur in the first 24 hours; few after the third day.

Recovery.—In favorable cases, the sputum becomes more viscid on the second day. The dyspnea is apt to persist, and the temperature is somewhat raised. Bronchitis and pneumonia may develop. Usually, however, the patient improves rapidly from the third day, and at the end of the week is fully convalescent; but however, he requires a prolonged rest.

Pathology and Treatment.—These were fully discussed under Chlorin.
IRRITANT GASES

Protection.—Phosgen is not nearly as reactive as chlorin, and caused considerable difficulty in the early days. The first special masks contained alkaline sodium phenate. Later patterns were saturated with hexamethylenamin. However, the ordinary respirators confer complete protection.

SUPERPALITE

DIPHOSGEN, TRICHLOROMETHYL-CHLOROFORMATE

CI COOC Cl₂

This was the chief constituent of the "Green cross" shells, where it was usually mixed with some chloropicrin ("vomiting gas") or diphenyl chlororamine ("sneezing gas"). It was perhaps the principal "killing" gas for shells, and is highly effective, acting essentially like phosgen, i.e., by the liberation of hydrochloric acid on contact with water. The pathology and treatment are identical with those of phosgen.

It is an oily liquid, of disagreeable, suffocating odor.

PALITE

CHLOROMETHYL-CHLOROFORMATE

CI COOCH₂ Cl

This is a liquid also used extensively in shells. It belongs to the same class as superpalite and phosgen.

CHLOROPICRIN

"VOMITING GAS," NITROCHLOROFORM, NITRO-TRICHLORO-METHANE

C₂H₅NO₂

All irritants, even the asphyxiants, are likely at times to provoke vomiting; but chloropicrin was used in the war particularly for this purpose.

It is a neutral, colorless fluid, boiling at 115°C. It was therefore used in shells, but may be used in gas clouds if mixed with more volatile substances. It was intended partly for the purpose of inducing the men to remove their masks, and thus inhale the more toxic substances (diphenogen, diphenyl-chlororamine), with which it was generally mixed. However, it is itself a potent pulmonary irritant, intermediate between chlorine and phosgen.

Effect.—Chloropicrin irritates all surfaces. It therefore produces lacrimation, bronchitis, and pulmonary edema, as well as vomiting. It also irritates the skin.

Lacrimation.—Dilutions of 1:1,000,000 are detected by the eyes of most subjects. Concentrations of 1:100,000 would incapacitate victims within ten minutes. The eyes smart and pain, as with all lacrimators.

Respiratory Effect.—There is considerable irritation of the throat, cough, etc. Exposure is generally followed by bronchitis and asthmatic attacks. Death may follow from the pulmonary complications.

Blood Concentration.—In experimental exposures of dogs to moderate concentrations the blood picture is that of phosgen poisoning, i.e., a pre-ecctic fall in hemoglobin, followed by a rise as edema develops. With high concentrations, the edema may set in so rapidly that the hemoglobin appears increased almost from the start.

Emetic Effect.—This is presumably due to direct gastric irritation from swallowing saliva impregnated with the poison.

Skin.—Contact with the liquid causes severe burns, usually with blistering, and may lead to necrosis. Abrasions, if exposed to the vapers, tend to become septic.

Kidney.—These appear to be injured more frequently than with any of the other "gases." For this reason prolonged exposure is dangerous even in very low concentrations.

After-Effects.—Chloropicrin poisoning is likely to be followed by serious sequelae: severe anemia, with general asthenia; weak and irregular heart; sometimes cardiac dilation; the patient ages rapidly.

There is a liability to recurrent asthmatic attacks, leading to emphysema. (These are treated like ordinary asthma, by epinephrin, morphin, and atropin.)

Those who have been poisoned appear to be hypersensitive to the poison. This is also observed in animals.
NITRIC VAPORS CHIEFLY NITRIC PEROXID (NITROUS ACID) NO₂

Occurrence.—These constitute the brown vapors arising from the action of nitric acid on metals. They may be formed in various chemical industries, by all kinds of nitration processes, especially in the manufacture of nitrocatechol and picric acid, and thus give rise to "fume-sickness." They are also produced in large amount in the combustion (not in the explosion) of nitroglycerin and gun-cotton. When they develop in confined space, they may be very dangerous.

Effects.—These are peculiar by the lung delay in the onset of the pulmonary edema. The cause of this has not been explained.

Immediate Effects.—During exposure, there is some irritation of the eyes, and of the respiratory mucous; but this subsides promptly when exposure ceases. The patient may then feel perfectly normal for four to eight hours.

Delayed Effects.—If the primary exposure has been sufficient, this latent period is followed by the rapid development of pulmonary edema, entirely similar to that of phosgen, and often ending fatally within 48 hours (F. C. Wood, 1916; A. Hamilton, 1917).

The treatment and the post-mortem findings correspond to those of chlorin and phosgen.

Protection.—The fumes are freely soluble in water, and a damp cloth furnishes considerable protection. A sponge wetted with sodium carbonate solution, or the army gas-masks, are more effective.

Sulphur Trioxide, SO₃.—This belongs to the simple respiratory irritants, and resembles chlorin. It is a solid, forming strongly acid fumes on contact with moist air. It is used somewhat in grenades and shells.

Dimethyl Sulphate, (CH₃)₂SO₃.—This is a liquid of high boiling point (188 degrees C.), said to have the odor of onions. It is used in hand-grenades. It is a strong corrosive of all surfaces, producing lachrymation, skin-corrosion, and pulmonary edema.

The edema may be localized in a single part of the lung, probably as a consequence of obstruction of a bronchus by inflammatory pseudomembrane. This would produce the effect of a cupping-glass on the corresponding portion of the lung (Auer, 1918).

A peculiar analgesia of the skin has been described, which in animals is said to last for six months after exposure. It does not include the nerve-trunks. (Auer, 1916).

The treatment is as for chlorin. The local effects are treated with alkalies.

LACHRYMATORS

Benzyl and Xylyl Bromid.—These are used in "tear-shells." The original lachrymators were benzyl bromid (C₆H₅.C₂H₅Br) and xylyl bromid (C₆H₅.C₆H₅.C₂H₅Br). These are liquids of rather high boiling point (175 and 215°C.), made by bromating the higher fractions of coal-tar distillates. Their odor is reminiscent of mustard; most of the lachrymators have a similar odor.

Effects.—Dilutions of 1:1,000,000 make the eyes water severely. Somewhat stronger concentrations also make the eyes smart; and as the concentration increases the tears and the burning pain in the eyes blind the man and thus put him out of action. Ordinarily, the symptoms go no further, and recede rapidly after exposure ceases. Within an hour or two the man is practically normal, except for slight hyperemia of the eyes, which may last twelve hours.

There are no toxic after-effects, and the men are fit for duty as soon as the eye irritation lets up. No special treatment is needed. Lavage with 5 per cent. carbonate sol. is advisable.

The lachrymators also produce pulmonary irritation; but the benzyl and xylyl bromids do not reach a sufficient concentration to produce respiratory symptoms.

Other Lachrymators. Benzyl chlorid, C₆H₅.C₂H₅.Cl.—This acts like the bromid, but is less effective. It has been used in shells.

Bromo Ketone.—C₆H₅.C₂H₅.CO.C₂H₅.H₃.Br,—CH₃.CO.C₂H₅.H₃.Br.—These, along with the bromo ketones, produce more respiratory irritation, and thus approach the chlorin and phosgen types.

CAUSTIC ALKALIES

Chloro-acetone.—CH₂Cl·COCH₃ (Grenades).
Dichloromethyl ether.—(CH₂Cl)₂O (Shell).
Chlorouslyphoric Acid.—SO₃·HCl (Grenades and Smoke-pots).
Methylchlorouslyphoric.—CH₃·Cl·SO₃ (Grenades).
Phenyl-carbamyloxychlor.—C₆H₅NC·Cl (Shells); at present probably the principal lacrymator used by the Germans.
Acrolein.—CH₂·CH·CHO.
Stannic Chloride.—SnCl₄.
Promacetic Ether.—CH₃·Ir·COOC₂H₅.
Indacetic Ether.—CH₃·COOC₂H₅.

**NEEZING GAS**: DIPHENYL CHLOROARSININ “BLUE CROSS SHELLS”
(C₆H₅)₂AsCl

Uses.—This was used in shells, mixed with high-explosive shells, shrapnel or other gas-shells. It is quite toxic, but apparently was used more with the idea of producing sneezing and thus enable it to keep on the masks. It is not considered a military success.

Stimulatory Effect.—The substance is solid, and was used as a very fine powder. Diffused in the air in the proportion of 1:1,000,000, it produces intolerably violent sneezing for some 15 minutes. Even more diluted mixtures are effective sneezing agents.

Higher Concentrations.—These act as respiratory irritants. With animals, fatal concentrations produce inflammation of the whole respiratory tract; stenous bronchitis, pulmonary edema, or pneumonia. The toxicity is as great as that of phosgene (Uderhill, 1918).

Intraperitoneal injections also produce pulmonary congestion. There is a conspicuous absence of the intestinal and renal changes produced by ordinary arsenicals.

FIXED CAUSTIC ALKALIES

Members.—These comprise NaOH and KOH, which corrode even the skin; the carbonates of sodium and potassium which are not caustic, but which irritate the mucous membranes violently; and quicklime, which on account of its limited solubility, is caustic only when used in substance.

Manner of Action.—The free alkalies combine with the tissue elements to form alkaline derivatives, or with the fats to form soaps, and in this way produce a destruction of substance. They are also very hygroscopic, and withdraw water from the cells, which contributes to the necrosis. The scab which they produce is very soft, and the compounds which they form are very soluble; consequently the alkalies penetrate very deeply, are very painful, their action continues for several days, and leads to extensive scar formation. It is therefore difficult to circumscribe their effects. This is only partly remedied by mixing them with the non-diffusible quicklime as in the "Vienna Paste," a mixture of equal parts of KOH and CaO, stirred into a thick paste with alcohol.

Actual and Potential Alkalinity.—The "actual" or immediately effective alkalinity of a solution depends on the dissociated OH ions; but as these combine with the tissues, further OH ions are split off ("potential" alkalinity), which continue the action. The total effect, therefore, depends upon the total quantity of OH ions which can be split off under the conditions of the body (Dreser, 1910). This can be estimated by appropriate indicators.

Poisoning by Caustic Alkalies (Lytes).—This is quite common. Half an ounce of potassium carbonate or an ounce of the liquors would generally be fatal. Sodium carbonate is less toxic. On account of the deep action, stenosis of the esophagus is a frequent sequel, and the fatality is fairly high.

PREPARATIONS—CAUSTIC ALKALIES

"Potassium Hydrosulphate" (Pot. Hydrosulph., U.S.P.; Potassa Caustica (Potass. Caust., R.P.; Potassium Hydrosulphate (Caustic Potash; Potassium Hydrate); KOH.—White flakes or masses of pinkish; odourless; caustic. Very sol. in water (1:500), freely sol. in alc. (1:5). Used as caustic, to remove warts, etc; and to soften epidermis (x per cent.).
**Liq. Pot. Hydros., U.S.P.; Liq. Potas., B.P.—5 per cent. Sometimes used interchangeably as alkali.** 

Dose, 1 c.c., 15 minims, U.S.P.; 0.6 to 1.8 c.c., 10 to 30 minims, B.P.; freely diluted.

**Potas. Carbonas (Pot. Carb.), U.S.P., B.P. (Salts of Tartar); Na₂CO₃.**—White granular powder; odorless; strongly alkaline taste. Very deliquescent. Very sol. in water (1:1), practically insol. in alc. 
Dose, 1 Gm., 15 grs., U.S.P.; 0.3 to 1.2 Grm., 5 to 20 grs., B.P.

**Sod. Hydros., U.S.P. (Caustic Soda); NaOH.**—Dry, white flakes, or fused masses or pencils. Very sol. in water (1:0.0) and alc.

**Liq. Sód. Hydros., U.S.P. (Solution of Soda)—5 per cent. Dose, 1 c.c., 15 minims, U.S.P.**

**Sodii Carbonas Monohydratus (Sod. Carb. Monohyd., U.S.P.; Na₂CO₃ + H₂O.**—A white, crystalline, granular powder; strongly alkaline taste. Freely sol. in water (1:1), and in glycerin (1:2); insol. in alc. Used as lotion (0.5 per cent.). Is nearly twice as strong as the original crystallized carbonate. 
Dose, 0.25 Gm., 4 grs., U.S.P.

**Sod. Carb., B.P.; Sodium Carbonate (Washing Soda); Na₂CO₃ + 10 H₂O (equivalent to 17 per cent. of Na₂CO₃).**—Freely sol. in water (1:2). Dose, 0.3 to 2.0 Grm., 3 to 30 grs., B.P.

**Sod. Carb. Exsic., B.P.; Na₂CO₃.** 
Dose, 0.2 to 0.6 Gm., 3 to 10 grs., B.P.

**Calc., U.S.P., B.P.; Calcium Oxide (Lime, Quicklime); CaO.**—Hard, white or grayish-white masses, or a white powder; odorless; caustic taste. Slightly sol. in water (1:800); sol. in glycerin; insol. in alc. When sprinkled with about half its weight of water, calcium oxide becomes heated, and is gradually converted into a white powder (calcium hydroxide or slaked lime). When this is mixed with about 3 or 4 parts of water, it forms a smooth magma (milk of lime).

**Calc. Hydr., B.P. (Slaked Lime); Ca(OH)₂.**—White powder.

**Liquor Calcis (Liq. Calc., U.S.P., B.P.; Solution of Lime (Lime-water).**—A saturated solution of Ca(OH)₂, containing about 0.14 per cent. Clear colorless liquid; odorless; alkaline taste. **Incompatible** with carboneses or "hard" water. Used as antacid, against diarrhea and externally against burns. It is often added to milk (1:4). 
Dose, 15 c.c., 4 drams (about 0.02 Gm. of the hydroxide), U.S.P.; 5 to 120 c.c., 1 to 4 ounces, B.P.

**Liq. Calcis Siccatus (Liq. Calc. Sacch., B.P. (Syrup of Lime).**—Contains about 2 per cent. of CaO. Antacid, and antidote for phenol poisoning. Dose, 1 c.c., 3 minims.

**Linimentum Calci (Linc. Calc., U.S.P., B.P.; Lime Liniment (Carross Oil).**—A mixture of equal volumes of lime-water and oil (olive, B.P.; linseed, U.S.P.). Applied to burns, on cloths, frequently renewed.

**AMMONIA**

This differs from other alkalis by its volatility.

**Use as Counterirritant.**—It passes through the stratum corneum of the epidermis, and, acting upon the lower layers of the skin, may produce blisters. It is sometimes used for this purpose instead of cantharides, especially in nephritis, where the latter cannot be employed. It is, however, more painful.

It is frequently used in more dilute form as liniment for counterirritation.

**The Inhalation of Ammonia.**—Free, or in the form of aromatic spirit, or of carbonate, this is used for reflex stimulation in fainting, etc. Care must be used, since too high concentrations of the vapor may produce bronchitis or pneumonia.

**Poisoning by Swallowing Ammonia.**—This presents the same phenomena as other caustic alkalis except that the respiratory passages are more involved by the inhalation of the vapor.

Five to 10 Gm. of the official solution would be toxic; 30 Gm. are generally fatal, although recovery has occurred from 60 Gm.

**Inhalation of Ammonia.**—This produces the effects described under volatile irritants. Persons exposed to 1:1,000 become insupportable.

For "Preparations," see Index.
ALKALIES

ALKALINE SALTS AND SOAPS

The soluble bicarbonates, basic phosphates, borates, sulphides and soaps, act as milk alkalies; since their watery solutions undergo hydrolytic dissociation, with the liberation of OH ions.

Actions and Uses.—By their alkalinity, they dissolve mucus, soften the epidermis and hair, and emulsify and dissolve fats. They are therefore employed in catarhal conditions; in skin diseases (scurvy, acne, ichthyosis, psoriasis, and epidermal proliferations); to facilitate the penetration of antiseptic remedies into the skin (in scabies, favus, ringworm); to emulsify cutaneous remedies (mercury, tar, sulphur); as lubricants for broken or irritated skin (Bainment); as cleansing agents (detergents) especially in the form of soaps and borax; and as depilatories (especially the sulphides).

Laxative Action.—In the rectum, soap secures prompt evacuation. It is used for this purpose as warm soap-suds enemas; or solid, formed into a suppository.

The Detergent Action of Soaps.—This is due to the mechanical effect of the foam, the emulsification of the grease, and the softening of the epidermis, so that the superficial layers are readily removed with the adherent dirt.

Potassium soap is the more energetic. They are semiliquid (soft soap); sodium forms hard soaps.

Alkaline Baths.—In skin diseases, these are best administered at bedtime. Any of the alkaline salts can be used; such as sodium carbonate or bicarbonate, potassium carbonate, or borax, in the proportion of about 100 Gm. per bath; for lotions, 7 per cent.

Antiseptic Action.—Strong soap solutions are fairly antiseptic. Even weak solutions are mildly fatal to treponema pallidum (Reasoner, 1917).

Irons and Bates recommend 2.5 per cent. solution of common yellow soap as non-irritant wound antiseptic.

Hemolytic Action.—Alkalies, and especially soaps, are hemolytic. These also sensitize pernicious to serum-lysis (Flechner, 1912).

Pneumocytosis.—This is stimulated by soaps, even in fairly high concentrations; but exceedingly strong solutions are detrimental (Hamburger and de Haan, 1913).

PREPARATIONS—SOAP

* Sapo, U.S.P., Sapo Duras (Sap. Dur.), B.P.; Soap (White Castle Soap).—Prepared from sodium hydoxid and olive oil. A white solid; sol. in hot water and alcoh.

Sap Animal., B.P.; Card Soap.—Hard soap prepared from animal fat.

Sapo Mollic (Sapo Moll.), U.S.P.; (Sap. Molli., B.P.); Soft Soap (Green Soap); Sapo Verda, Sapo Kalkmus.—Made from potassium hydroxid and vegetable oil (cottonseed, U.S.P.; olive, B.P.). A soft, unctuous, yellowish mass.

Luminaeum Saponis (Lin. Sapon.), U.S.P.; Soap Liniment (Opudoloe).—An alcoholic solution of 9 per cent. of soap, 4.5 per cent. of camphor, and 1 per cent. of rosemary oil.

Lin. Sap., B.P.—Similar to the preceding.

Lin. Sapone Moll., U.S.P. (Tincture of Green Soap).—Parts of the soap, 1 part of alcohol, flavored with lavender oil.

ALKALINE SULPHIDES

When applied to the skin, the sulphides (K, Na, Ca) soften the stratum corneum, much like the alkalies, and they are used in the same conditions. Their action on hair is even greater, so that they are valuable as depilatories, especially cau sulphurates. When taken by mouth, they act as irritants and corrosives, through the liberation of sulphuretted hydrogen and free alkali.

Toxic Doses.—These produce the systemic effects of hydrogen sulphide. Death has occurred from 12 to 15 Gm. Smaller doses have little systemic action, as they are rapidly oxidized. They are excreted in the urine mainly as sulphates; but there seem to be also some organic sulphur compounds.

A small amount of some volatile sulphur compound is also excreted by the lungs, giving the peculiar H2S odor to the breath, and causing some expectorant action.
When injected intravenously, the sulphides produce violent convulsions, followed by depression of the medullary centers. This is due to a direct action. Outside of the body, sulphides form a peculiar compound with hemoglobin, but this does not occur during life, in mammals.

**Thera peptic Uma.**—The sulphids are used externally, in skin diseases (psoriasis, acne, etc.) and as parasiticides in scabies (solution of the skin and eggs of the mite). The sulphids have been proposed as an antidote for hydrocyanic acid, since they would form sulphuric acid, which do not have the hydrocyanic acid action. This has not been tested. It is possible that the reaction goes too slowly to be of value.

**PREPARATIONS—SULPHIDS**

**Calcii Sulphidum Crudum** (Calc. Sulphid, Crud.), U.S.P.; Calis Sulphurada (Caix Sulphur.), B.P.; Crude Calcium Sulphid, Sulphurated Lime.—A mixture containing about 55 per cent of CaS. A pale gray or yellowish powdér; faint odor of hydrogen sulphid; nauseous alkaline taste. Very slightly sol. in cold water; more readily sol. in boiling water with partial decomposition; insol. in alc. Used as depletory, mixed with an equal quantity of starch and made into a paste. Internally it is used against boils and other suppurations. Its efficiency is doubtful. **Dose, 0.06 Grm., 1 gr. U.S.P.; to 10 to 20 mg., 1/4 to 1 gr. B.P.**

**Vleminghian's solution** is a solution of calcium polysulphides, used in scabies (1:1), and as a bath in skin diseases (3 drams per gallon).

**Posey, 1920, recommends it against warts.** These are just covered with a dressing soaked in the undiluted solution, applied every night until irritation is produced; then less frequently till the wart disappears or can be removed.

**Pot. Sulphuran.** U.S.P.; (Potass. Sulphur., R.P.); Sulphurated Potash (Liver of Sulphur).—A mixture composed chiefly of potassium polysulphides and potassium thiosulphate. Freely sol. in water (1:2). Used in baths (to 200 Grms., 1 to 6 ounces, per bath).

**HYDROGEN SULPHID (H₂S)**

This gas is extremely toxic, much more so than is commonly realized.

**Actions.**—These are partly local and irritant, due to its acid character; and partly central, somewhat resembling asphyxia. In *vivo*, it forms a firm compound (sulphhemoglobin) with the blood pigment. Thick layers have a brown color. Thin strata appear a dirty green, which is responsible for the postmortem discoloration. Lewin believes that the effects are due to the interference of the compound with oxygenation; however, it is generally believed that only traces are formed during life (E. Meyer, 1890) and that the sulphid is directly toxic to the nervous system.

**Occurrence.**—Hydrogen sulphid is formed in putrefaction, particularly of sewarger.

"Sewer gas" consists essentially of CO₂, H₂, CH₄, and 2 to 8 per cent. of H₂S. Small quantities are also formed in intestinal putrefaction, giving rise to diarrhoea and possibly to some of the symptoms of "intestinal auto-intoxication." It may be removed by the administration of bismuth salts, and its further formation checked by cathartics and intestinal antiseptics.

**Concentrations in the Respired Air.**—0.02 per cent. produces symptoms, particularly irritation of the conjunctiva and bronchial mucosa; 0.05 per cent. produces asphyxial symptoms; hyperpnea, nausea, giddiness, headache, cerebral excitement, and finally narcosis; 0.07 per cent. produces death after about an hour under coma, often with convulsions; 0.12 per cent. is fatal to dogs in one and one-half minutes. The after-effects resemble those of carbon monoxide. Edema of the lungs and pneumonia are common sequels (Lehmann, 1892).

**Inhaled by the Lungs.**—The urine is also said to contain sulphides. It is readily detected in air by its odor and by blackening lead or silver-paper. In case of death, it may be recognized by the blackening of a silver coin laid on the skin.

**Sulphur Springs.**—Hydrogen sulphid is contained in small quantity in a number of mineral waters (sulphur springs). These are recommended for a variety of obscure disorders—rheumatism, gout, diabetes, etc. When these waters are administered for some time, they cause diuresis and diaphoresis, irritation of the urinary passages, intestinal irritation, and muscular pains. Their therapeutic effects are probably to be referred to their laxative, diuretic and diaphoretic actions, although the general hygienic conditions must contribute largely to the results, as with other mineral waters (Boeckler, 1895).
SULPHUR

Uses.—Sulphur is employed as a parasiticide in itch; as a mild cutaneous irritant in skin diseases (sulphur ointment); and internally as a laxative for softening the stools, especially in hemorrhoids (as Compound Licorice Powder, or mixed with an equal amount of Potassium bitartrate). Like other intestinal irritants, sulphur somewhat increases the elimination of uric acid (Abl. 1913).

Manner of Action.—Sulphur itself is inactive, but by contact with proteins and alkalies it is slowly converted into the active sulphides. This process is so gradual that the action is always mild and protracted, unless the finely divided “precipitated” sulphur is used. Ordinary or “washed” sulphur therefore deserves preference. Sulphur is somewhat soluble in ointment bases, and this facilitates its action (Sabbatani, 1913). Sulphur is also burned for fumigation, the disinfectant action being due to the formation of SO₂. It is highly effective against most insects, especially mosquitoes and bed bugs; but is quite ineffective against lice (Bacot, 1918).

Formation of Sulphides.—This is effected on the skin by the cutaneous secretions. No change occurs in the stomach; but a considerable amount (to 10 per cent.) is converted into H₂S in the intestine, as may be readily seen from the increased secretion of sulphate by the urine. The conversion was formerly referred to the alkalies of the intestine; but Heifter (1904) points out that the alkali exists as bicarbonate, which can not affect the conversion. He showed that it is produced by proteins of all kinds even after these are boiled. The hydrogen sulphid is formed most abundantly in the large intestines (Tuerken, 1912). (Frankl, 1917, claims that the effects are due to the formation of sulphones.)

Colloid Sulphur.—A new modification of sulphur in “colloid solution” produces H₂S much more rapidly, also on intravenous injection; and thus causes typical H₂S poisoning without other visible effects (Sabbatani, 1908, 1911, 1914). Its preparation is described by Luman, 1917.

Alopexia.—Sulphur (5 to 10 per cent.) is used in the seborheic form, as also other irritants (salicylic acid, 1 to 2 per cent.; mercuric chloride, 0.1 to 0.4 per cent.; benna- napthol, 1 to 2 per cent.; pilocarpin, 0.15 per cent.; cantharides; resorcin (1 to 2 per cent.; discolors the hair). These agents may be dissolved in water, glycerin or oils, or applied as ointments (Dore, 1914).

PREPARATIONS—SULPHUR

*Sulphur Sublimatum (Sulph. Sublim.), U.S.P.; (Sulphur Sublim.), B.P.; Sublimed Sulphur (Flowers of Sulphur).—A fine, gritty, light yellow powder, of slight odor, and faintly acid taste. Insol. in water; nearly insol. in alc.; slightly sol. in fat solvents and oils; freely sol. in carbon disulphid. For fumigation, it is used in the ratio of 2 pounds per 1,000 cubic feet. It contains some free acid and other impurities, but is sufficiently pure for medicinal use, although the Washed should be preferred. It enters into all the B.P. preparations, whilst those of the U.S.P. are made from Washed Sulphur. *Dose, 4 Grm., 1 dram, U.S.P.; 4.2 to 4 Grm., 20 to 60 gr., B.P. Sulphur also enters into Fulvis Glycyrrhizae Co. (see Index).

*Sulphur Lactum (Sulph. Loti), U.S.P.; Washed Sulphur.—This is prepared by washing the preceding with ammonia water to remove the acid. Its properties are similar to the preceding, but it is tasteless and odorless. *Dose, 4 Grm., 1 dram, U.S.P.

*Sulphor Precipitatum (Sulph. Precip.), U.S.P., (Sulphur Precip.), B.P.; Precipitated Sulphur (Lac Sulphuris, Milk of Sulphur).—This is prepared by precipitating sulphurated lime with acid. An amorphous, pale yellow powder. It is a much finer powder than sublimed sulphur and is therefore rather more active; but its dose is the same.

*Sugentum Sulphuris (Ungh. Sulphur.), U.S.P., B.P.; Sulphur Ointment.—15 per cent. of sulphur, U.S.P.; 20 per cent., B.P.; in benzoinated lard.

Con. Sulphur., B.P.—4 per cent. of sulphur, 11 per cent. of Potass. Bitartr. *Dose, 4th to 8 Grm., 60 to 120 gr., B.P.

Fusc. Sulphur., B.P.—0.5 Grm. of Sulphur.
ICHTHYOL

Uses.—Peculiar value has been attributed to the incompletely oxidized sulphur occurring in organic compounds. The pioneer product of this kind is ichthyol, which contains 10 per cent. of sulphur as sulfons, mercaptans, and sulphides.

This has been employed extensively, but has probably little value other than emollient. It is weakly antiseptic and mildly irritant. Taken internally, it produces gastro-intestinal irritation, with diarrhoea. Its influence on metabolism is in dispute. It has been used locally to cause absorption of swellings and effusions, in contusions, burns, etc., and especially in gynecologic practice. It has also been used in skin diseases, acting somewhat like sulphur. Internally, it has been endorsed against the greatest variety of diseases of digestion, respiration, genito-urinary tract, tuberculosis, etc. These claims bear the stamp of exaggeration.

The commercial success of ichthyol has led to the substitution of a number of synthetic products, formed by saturating mineral oils with sulphur. Linseed oil saturated with sulphur has long been used in domestic medicine under the name of Harlem Oil.

PREPARATIONS—ICHTHYOL

* Icthyol, N.N.R. (Ammonium Sulpho-icthyolate).—A mixture prepared by sulphuring the tar-like distillate obtained from bituminous shales found in Tyrol, and which contain the fossil remains of fishes. A dark brown syrupy liquid of characteristic empyreumatic odor and burning taste; of faintly acid reaction. Miscible with glycerin, oil or fats; incompletely soluble in alc. Insoluble in water (Hostmann, 1915). Dose, internally, 0.5 to 2 c.c. (7 to 30 minims) mostly in simple suspension in water, or peppermint water, sometimes in the form of pills or capsules; locally, in vaginal, uterine or rectal suppositories; in 0.06 to 0.18 c.c. (1 to 3 minims) bougies or 1 to 3 per cent. solution for gonorrhoeal treatment.

THIOSINAMIN

Uses.—This is allyl-sulphocarbamid, prepared by heating volatile oil of mustard (allyl thiocyanate) with alcoholic solution of ammonia. It was introduced by Hebra and Unna, 1895, and has been credited with causing the absorption of exudates, lymphantic swellings, scar-tissue, etc.; and with the cure of lupus. The administration must be continued for weeks, and combined with massage and other adjuvant measures. It is therefore difficult to judge whether it has any value. The clinical opinions are contradictorv, and so satisfactory explanation has been offered for its reputed effects. It probably does little, if any good, and it may produce toxic systemic effects, although it is usually well borne, except for the bitter taste and gastric ercitations.

Toxic Effects.—In man, 1 Gm., or 0.5 Gm. on repeated use, have caused headache, nausea, vomiting, lassitude and fever (J.A.M.A., 26: 815, 1911; Charteris, 1910; Seifert, Nebel, 1915, p. 122). These may be set in suddenly after it has been used for a time uneventfully. In animals, Tyrode, 1916, found impaired respiration, occasionally cessation, and death; sometimes pulmonary edema and hyperpnea (Lange, 1893). The circulation is not affected in mammals, but high concentrations paralyze the frog’s heart. Smaller doses produce severe changes in metabolism, with loss of nitrogen and rapid emaciation; and fatty degenerations of parenchymatous organs, especially the heart and kidneys. Normal connective tissue showed no changes.

Other Allyl Compounds.—Allyl acetic acid, allyl urea and dimethylallylamine are indifferent; allyl loddic is strongly irritant; allyl formate produces necrosis of the liver and kidneys; allyl amin is highly toxic. The effects are described by Piazza, 1915.

PREPARATIONS—THIOSINAMIN

Thiosinamin, Thiosinamine; (NH₂)₂CS-NHCH₂-C:CH₃—Colorless crystals, of slight garlic odor and bitter taste. Slightly sol. in water, with decomposition; dissolves in alc. or glye. The oral dose is 0.05 to 0.1 Gm. in capsules. It is usually administered by hypodermic injection (which need not be made at the site of the lesion), daily to every third day, 0.05 to 0.5 Gm. in 10 per cent. alcohol or 10 per cent. glycerin. Since the solvents produce local irritation, Fibrolysin may be substituted (Mendel, 1903). Fibrolysin, (Liq. Thiosinam. Sodio-Sulphydralis).—15 per cent. of a double salt of thiosinam and sod. salicyl. Dose, a c.c. local, corresponding to 0.2 Gm. of Thiosinamin.

CAUSTIC ACIDS

Members.—The most typical acids in regard to the local action are sulphuric and hydrochloric acid. Nitric acid produces the same effects, but differs from these in its chemic action, producing santhoproteic acid from the proteins. Sulphurous acid has
also a marked corrosive power. Hydrochloric acid has a specific toxic action, penetrates very deeply, and is especially strongly corrosive, producing obstinate ulcers. Its inhalation from air containing 0.05 per cent. produces acute catarhal irritation. Of the organic acids, those of the fatty series act similarly, but are weaker. The trichlor-acetic acid is the most corrosive of these. Oxalic acid occupies a place by itself on account of its specific action, produced probably by the precipitation of the calcium. The compound acids—such as ethyl-sulphuric, etc.—act like organic acids. The aromatic acids act partly as acids, but this is greatly obscured by their collapse action.

The irritant action of the acids is also shared to some extent by the acid salts, acid tartrates, acid sulphates, etc.

Manner of Action.—This varies to some extent with the constituents of the tissues. But, on the whole, it consists, with concentrated acids, in withdrawal of water; in the formation of acid albumins; in softening of the conjunctive tissue and epithelium; and in special situations, in solution of calcareous material.

The concentrated acids have an affinity for water, and withdraw this from the cells. This affinity is so strong in the case of concentrated H₂SO₄, that if only the formed water is withdrawn from the tissues, but the elements H and O are split off from their chemic combinations with carbon, leading to carbonization.

All acids convert proteins into acid albumins, which are insoluble in moderately strong, but soluble in concentrated or very weak acids. Upon this precipitation of proteins depends their astringent and styptic action.

The connective tissue undergoes a rather peculiar change. It is not dissolved, but is softened and rendered more soluble in boiling water. (This explains why meat becomes more tender on keeping.) The concentrated acids have a similar effect upon epithelium. Without actually dissolving it, they soften it in such a manner that it is readily detached. Dilute acids, on the other hand, harden it.

Poisoning by Concentrated Acids.—This presents the usual phenomena of caustic poisoning. It is extremely painful. The "coffee-grounds" vomit is characteristic. Scar formation and stenosis are frequent.⁴ The prognosis and toxic dose depend upon the concentration, and the parts affected. The treatment has been discussed. Sulphuric acid poisoning is the most common.

Continued exposure to the vapors of acids, such as occurs in certain trades, gives rise to chronic bronchitis. They also attack the teeth and from these the necrosis may spread to the jaw, as with phosphorus.

Diet.—Because of the intense pain, deep penetration and extensive scar formation, acids are not desirable carminatives. Nitric and tri-chlor-acetic acid form relatively firm spherols, so that their action is more circumscribed and less painful. Sulphuric acid has been made into a paste with various inert powders (charcoal, sawdust, lead sulphate, etc.) to localize its action, but is still painful and difficult to control (Pusey, 1913). Lactic acid has a relatively mild action on normal tissues. Chromic acid may cause poisoning when used as a caustic.

Antiseptic Action.—The destruction of proteins makes acids efficient antiseptics. Even quite dilute solutions, such as the gastric juice, suffice to limit the growth of bacteria. The concentrated acids destroy them outright.

PREPARATIONS—CAUSTIC ACIDS

Acidum Hydrochloricum (Acid. Hydrochlor.,) U.S.P., B.P.; Hydrochloric Acid (Muriatic Acid).—About 37 per cent. of HCl. Colorless, fuming liquid, Pungent odor. The commercial acid (strength = 30 to 33 per cent.) has a golden yellow color due to Fe and free Cl. Since it often contains As, it should not be used in internal medicine.

Acidum Lacticum (Acid. Lact.,) U.S.P., B.P.; Lactic Acid.—A liquid containing Lactic Acid (optically inactive alpha-hydroxypropionic acid, CH₂CHOHCOOH) and lactic anhydrides. A colorless, or slightly yellow, syrupy liquid, nearly odorless, acid taste, absorbing moisture on exposure to air. Miscible with water, alc. or ether. Dilute, 2 c.c., 20 minutes, U.S.P.; to 2 c.c. to 10 to 60 min. B.P. Used as caustic, especially in laryngeal tuberculosis, and for dissolving pharyngeal membranes.⁵

⁴ See v. Hoffmann’s Atlas of Legal Medicine, Plates 23, 34, 35, 39 and 37.
Acidum Nitricum (Acid. Nit.), U.S.P., B.P.; Nitric Acid.—About 70 per cent. of HNO₃. Fuming liquid, very caustic and corrosive. Viscous somewhat suffocating odor. Used as a caustic for warts (glass rod); against hyperhydrosis of feet (1 to 2 ounces to 1 pint of water); as disinfectant (corroses metal vessels or pipes).

Acid. Nitrohydrochloricus, U.S.P.; Nitrohydrochloric acid (Nitromuriatic acid, Aqu. Regia).—A strong solution containing hydrochloric acid, nitric acid, nitrosyl chloride and chlorine. Made by mixing 18 c.c. of nitric acid with 82 c.c. of hydrochloric acid. golden-yellow, fuming, and very corrosive liquid; strong odor of chlorine. Dose, 0. c.c. 3 minims, U.S.P., diluted.

Acid. Nitrohydrochloricus Dil., U.S.P.—Nitric acid, 10 c.c. Hydrochloric acid, 45.5 c.c. Water, 101.5 c.c. Colorless or pale yellowish liquid. Faint odor of chlorine. Dose, 1 c.c., 15 minims, U.S.P., diluted. On account of the free chloroform, it may be supposed to have a stronger local irritant action than HCl. It is popularly supposed to “stimulate the liver,” but its action does not differ in kind from that of other acids.

Acid. Nitra-ureiderma, Dil., B.P.—Nitric acid, 24 c.c. Hydrochloric acid, 32 c.c. Water, 200 c.c.; kept fourteen days before use. Dose, 0.3 to 1.2 c.c., 5 to 20 minims B.P., diluted.

Acidum Osmicum, Osmic Acid, OsO₄.—Intraneural injections are used to produce degeneration of nerves for the relief of persistent neuralgias (Bilroth and Neube 1889). The treatment is best applied by injecting ½ to 1 c.c. of a fresh 1 to 2 per cent solution directly into the, preferably exposed, nerve. The result is sometimes immediate, but more commonly it is not complete until after one or two weeks, or it may even fail entirely. If successful, the effects persist at least for several months, when they may become necessary to repeat the injection. They are rare if ever permanent. The local reaction is always painful but not serious. It is probably not advisable to use osmic acid in the presence of renal disease (Eastman, 1920).

Acid. Sulphuricum (Acid. Sulph.), U.S.P., B.P.; Sulphuric Acid.—About 95 per cent. of H₂SO₄. An oily, colorless liquid, acquiring a brown color if exposed to dust. Very intensely corrosive, choking organic substances. Miscible in all proportions with water or with the evolution of much heat. (Such mixing must be done very carefully by slowly pouring the acid into the water, under constant stirring.) The Compound hypobromuric acid (Oxal of Vitriol) is very apt to contain arsenic, and should not be employed in medicine.

Acidum Trichloracetici (Acid. Trichlorat.), U.S.P.; Trichloracetic Acid.—A monobasic organic acid, CO₂-CH₂-C₂H₃Cl₃. Colorless, deliquescent crystals, having a slight, characteristic odor. Very sol. in water or alc. Used in substance or strong solution, especially against warts, less painful than nitric acid.

**DILUTE ACIDS**

Local Effects.—Dilute acids produce a mild irritation, and at the same time harden the epithelium, without destroying it. They differ from the volatile organic irritants in that they do not penetrate so deeply, and do not cause necrosis. They may be used in the form of baths, in the strength of about 30 c.c. (1 ounce) of concentrated acid to the bath (30 gallons). Or they may be applied as lotions. Formic acid especially is applied in the strength of about 4 per cent. or 5 per cent. in alcohol. Acids are used in excessive secretion of sweat (sweating feet) to harden the epidermis. For this purpose 5 or 10 c.c. of concentrated hydrochloric acid are put in a basin of water and the feet placed in this until they become painful. This is done about twice a week.

The irritant action of the volatile acids is sometimes employed to produce reflex stimulation of the central nervous system by inhaling vapor, etc.

Acidum Formicumar.—Formic Acid, HCO₂H.

**THE HALOIDS**

These comprise bromin, iodin, chlorin, and the hypoklorites. Their corrosive action is determined by their entering very easily into chemical reaction with all kinds of organic substances, taking from them hydrogen and forming hydrobromic, hydroiodic, and hydrobromic acids, which have the ordinary acid actions.

If water is present they set free oxygen in the form of ozone, by combining with the hydrogen of the water; this is also a strong irritant. The halogens furthermore enter directly into the protein molecule.
Uses.—The tincture or solution, painted on the skin, produces a mild but deep and persistent irritation which can be easily graduated by successive applications. This irritation is used to secure the correction of chronic inflations and the absorption of inflammatory exudates (pleura, joints, etc.). Formerly iodin was employed to secure adhesive inflammation of serous cavities and cysts. At present the most extensive use of iodin is as an antiseptic. The internal uses are discussed under "Iodide."

Antiseptic Action.—This is used especially for disinfecting wounds, and for preparing the skin for operations (Woodburg, 1907; Strattan, 1909, 1915). For the latter purpose, 4.3 per cent. alcoholic solution is painted over the dried skin of the operative field on the preceding day, and again just before operating. The official tincture is used on recent wounds. The clinical results are excellent; even dirty wounds healing rapidly. The simple alcoholic solution deserves preference for skin disinfection. Sometimes there is rather severe irritation (Herzog, 1914). The stain may be removed by warm concentrated solution of sodium thiosulphate (Stoy, 1911) or by ammonia.

The action has been attributed to the formation of antiseptic compounds with the tissues (Schumacher, 1913). Staphylococci in cultures are destroyed by iodin, 1: 1000, in 15 minutes, even in moderately albuminous fluids (Albert and Taylor, 1914).

Experimental results with infected wounds were also good, the iodin being effective within five hours after infection, i.e., until the bacteria had spread too deeply (Brunner, 1911).

On the other hand, bacterial tests from the skin after iodin application, have given only equivocal results.

Experiments with tissue-cultures showed that iodin is rather more toxic to bacteria than to human connective tissue-cells. It tends to dissolve the fibrin of the cultures (A. Lambert, 1916).

Sporidote cultures are not especially susceptible to iodin; the fatal concentration is 1:15 in KI solution (Akatia, 1917).

Iodin Against Burns.—A 20 per cent. tincture has been used. It causes severe pains for 3 or 5 minutes, said to be succeeded by complete relief of pain (Mercier, 1910). Its advisability is doubtful.

Pharmacetic Preparations.—Simple alcoholic solution of iodin spreads more evenly and stimulates more readily. These are advantages in skin infection. The skin should be dry, to avoid precipitation of the iodin. The presence of KI, as in the ideal Tincture, and in Compound Solution, delays precipitation and favors penetration, and is therefore better for wound disinfection. It is not more irritant to the skin. The presence of an iodid is essential if the iodin is to be diluted with water. It also neutralizes the formation of HI in the tincture. Several proprietary "soluble iodines" use HI in place of KI. This has no advantage, either as to efficiency or irritation (Sollmann, 1910). Benzeno which dissolves up to 10 per cent. of iodin has been used as a solvent in war-practice.

"Starch Iodid," the blue adsorption product of iodin and starch, combines slowly with protein and is therefore but slightly irritant. Starch containing 2 per cent. of iodin has been used as an antiseptic wound dressing (Lancere, 1927).

Local Phenomena.—Applied to the skin iodin produces a mahogany color, smarting, erythematous inflammation, infiltration of subcutaneous tissue, desquamation of the epidermis in large shreds; if repeated, vesication results. The effects on mucous membranes are more severe and may produce corrosion. Its action is chemical; since it precipitates proteins in easily dissociated compounds. It is absorbed somewhat from the skin and excreted mainly in the urine as iodid.

Employment as Counterirritant.—Iodin is used especially in chronic pleural effusions, chronic rheumatism, diseased joints, enlarged lymph
glands, lymphangitis, etc. It has also been employed in erysipelas, painting the tincture from the periphery toward the center, five or six times daily (Ferrari, 1911); but Wood warns that the action must be graded very mildly, or it will produce extensive necrosis.

The "absorptive" effect of iodin has been demonstrated experimentally on the fibrous nodules following intradepinic injection of local anesthetics (Sollmann, 1919). Positive results were obtained only if the iodin was applied daily for 8 days, and pushed to considerable irritation of the skin. Shorter continuance was ineffective, even if a larger amount of iodin was applied and the irritation was more intense.

Preparations for Counterirritation.—The officinal tincture is effective and more constant in its effect than the simple acoholic solution. Iodin ointment is milder and correspondingly less effective.

Iodin Absorption from Human Skin.—Iodid does not appear in the urine after a single application of the tincture or ointment, so that only very little is absorbed (Wetzel and Sollmann, 1920). More is probably absorbed if the skin has been injured by repeated applications. Luckhardt et al, 1920, report some absorption from large doses.

Injections into cysts, hydrocele, empyema, etc., produce at first increase of the fluid, then adhesive inflammation. The injections are painful, and have often caused serious poisoning. They are now displaced by surgical procedures.

Toxic effects from iodin absorption from cysts consist in cystasis, salivation, vomiting, skin eruptions, high fever, and collapse. The urine is scanty and albuminous. The intoxication may persist for several days and then end with sudden death.

The toxic effects of swallowing iodin are successively: gastric uneasiness; disagreeable metallic taste; violent vomiting; abdominal pain; and sometimes purging. The vomit has the color of iodin, or is blue if starch is present.

The fatal dose is usually to about 2 gr. 3 Gm.; but recovery is said to have occurred after 10 Gm.

Toxic Effect in Mammals.—Boehm, 1876, found that the intravenous injection of 0.04 Gm. per Kg. is fatal. Symptoms set in only after 6 or 8 hours, with exhaustion, dyspnea, and death in 12 to 24 hours. Necropsy shows bloody pulmonary and pleural exudate and renal congestion and hemorrhages.

Circulatory.—Perfusion of excised frog hearts with dilute iodin solutions produces irregularities, followed by depression. Stronger solutions result in diastolic arrest. Intravenously, it depresses the circulation greatly in cats, not in dogs (Salant and Livingston, 1910).

Toxicity of Iodin Foods.—The inhalation of iodin vapor produces pulmonary irritation (dyspnea, etc.). The inhalation of more than 18 mg. per Kg. is fatal. The danger is increased by the presence of respiratory disease, bronchitis, etc. This should caution caution in the therapeutic use of iodin inhalations. The iodin is partly absorbed, appears promptly in the urine, and produced histologic changes in the thyroid (Luckhardt et al, 1920).

The treatment of iodin poisoning consists in evacuation; demulcents (eggs, milk, oils, and cooked flour or starch, which form loose compounds with iodin); dilute alkalies (NaHCO₃); and 5 per cent. sodium thiosulphate ("Hypo"). The last binds the iodin: 2Na₂S₂O₃ + I₂ = 2NaI + Na₂S₂O₅ (Sabbatani, 1913). The further treatment would be symptomatic.

PREPARATIONS.—IODIN

Iodin, U.S.P., B.P.; Iodin, 1. Bluish black, friable scales, of distinctive odor and acid taste. Not soluble in water (t: 250°C); sol. in alc. (1: 125 g), or glyc. (1: 80), freely sol. in fat solvents or aqueous solutions of iodides. Dose, 5 mg. 1/2 gr, U.S.P., diluted; maximal, 50 mg., 1/2 gr.

Iodine. B.P.; Tincture of Iodine.—7 per cent. iodin; 5 per cent. KI; in alc. Dose, 0.1 to 0.5 c.c., 1/4 minims, U.S.P.; diluted; maximal, 0.5 c.c., 5 minims. The KI in the tincture makes it miscible with water and insures against loss of strength on keeping.
METALLIC SALTS

157

(Wetterstroem, 1908). (When iodin is administered in milk, it is largely converted into iodid and albuminates.)

The principal incompatibilities of iodin are: alkaloids; alkalies and carbonates; tannin; turpentine and volatile oils.

Eighteen per cent. of water may be added to saturated alcoholic solution of iodin before precipitation occurs (Schoeell and Regenbogen, 1910).

Tr. Iodid Pow., B.P.—10 per cent. iodin, 0 per cent. KI.
Tr. Iodid Mil., B.P.—2.5 iodin, 1.5 per cent. KI. Dose, 0.1 to 0.3 c.c., 2 to 5 minims, B.P., diluted.

Liq. Iodid Co., U.S.P. (Lloyd's Solution).—5 per cent. iodin, 10 per cent. KI, in water. Dose, 0.2 c.c., 0.5 minims, U.S.P., diluted.

Ung. Iodid, U.S.P., B.P.—4 per cent. each of Iodin and KI, in lard base.

When free iodin is rubbed with fat, it combines almost immediately and completely; but when KI and glycercin are added, as in the official ointment; this combination is arrested; these ointments contain permanently about 3 per cent. of free iodin (Pallen, in Fried, 1912; Warren, 1914).

The most stable ointment is made with yellow petrolatum (Ever, 1920). Iodin is soluble in liquid petrolatum to 1.4 per cent., practically without combination (A. M. Clark, 1919).

THE LOCAL ACTIONS OF METALLIC SALTS

Mechanism of Action.—Metallic salts combine with proteins to form more or less diffusely soluble compounds containing varying amounts of the metal and proteins. The acid of the metallic salt is thus set free. If, for instance, a solution of ferrous chloride is added to egg-albumen, the result is an albuminate of iron, and free hydrochloric acid.

The local effects of metallic salts, therefore, rest on two factors: the precipitant action of the metal, and the irritant action of the liberated acid. Both influence the total effect.

Corrosive and Astringent Metallic Salts.—Some of the metal albuminates are almost insoluble in water; some are soluble in excess of protein, especially when neutral salts are present; others are not. If the precipitate is soluble, there is no obstacle to the penetration of the metal, and its action, irritant or caustic, is deep. If, on the other hand, the precipitate is insoluble, as in the case of lead salts, penetration can not take place; the irritation is confined to the surface, and an astringent action results. In regard to this, the metals stand in about the following order: The most astringent is lead; then comes aluminum; then iron; then zinc, copper, silver, and tin, which are about on a level; the most caustic is mercury. As to the liberated acids, the strongest caustic action appears in hydrochloric acid; then comes nitric acid; then sulphuric acid; then phosphoric acid, the weakest of all are the organic acids—acetic, citric, and tartaric.

By proper combination, then, between the metals and the acids, one may obtain any grade of action from pure caustic to pure astringent. The most typical caustic would be mercuric chloride, the most typical astringent, lead acetate.

The strength of action depends also upon the concentration in which the salt is used, and this is often limited by its solubility. The chloride of silver would, theoretically, be a stronger caustic than the nitrate, but since it is not soluble, it can not be used in the same concentration.

It must not be forgotten that the irritant, the astringent, and the caustic action, are merely degrees of the same process. The astringent action always precedes the caustic action and, consequently, by proper dilution, one may obtain astringent effects from salts which are ordinarily purely caustic. For instance, silver nitrate can be so gradually strengthened as to have a purely astringent action, without any caustic effect whatever.
It is, therefore, impossible to establish a perfectly definite classification between the metallic salts. An approximation to it is given in the following table:

Mainly Caustic: All Hg salts; ZnCl₂; SnCl₄; SbCl₅; tartar emetic; CuSO₄.
Both Caustic and Astringent: Fe salts; ZnSO₄; ZnAc₄; CuAc₂; AgNO₃; Pb(NO₃)₂; PbI₂.
Mainly Astringent: Alum; PbAc₂; PbOAc₂; ZnO; Bi subnitrate; white precipitate.

The Caustic Action of Metallic Salts.—This was formerly used quite extensively, but it has now been largely abandoned. Most are not sufficiently powerful for this purpose; others, again, are too toxic, being absorbed in sufficient amount to produce poisoning. To the latter class belong arsenic, antimony, and mercury. Zinc chloride and antimony chloride (Burgess of Antimony) are very active caustics, but rather too difficult. Their scab is so soft that their action cannot be kept within bounds. In fact, of all the metallic caustics, silver nitrate in the form of sticks (Lunar Caustic), and to a less extent copper sulphate, are alone used to produce a purely caustic action. Arsenic, were it not for its toxicity, would be a very useful corrosive. Its action is so slow that it can be very readily limited. It was believed to destroy only pathologic formations, leaving healthy tissue intact. This would be easily understood, from the fact that the former are much less staple. Silver nitrate is also quite easily controlled, since its action may be stopped at once by washing with NaCl, which converts it into AgCl.

Metallic Salts used for Astringent Action.—The soluble zinc salts are most commonly used on mucous membranes and ulcers; the aluminum salts are employed especially on the skin. Iron salts are used in gargles. Silver nitrate is applied in dilute solutions. Lead salts are effective astringents, but should not be used internally, nor for any length of time externally, because of the danger of chronic poisoning.

Mixtures of astringents are sometimes employed; but they have no serious advantage, and their penetration cannot be controlled as exactly.

Insoluble Metallic Compounds.—These are also somewhat astringent; partly because of their mechanical action, partly because small quantities of the metal are dissolved by the protein of the tissues. To this class belong zinc oxide and carbonate, and bismuth subnitrate and subcarbonate.

Therapeutic Applications.—For use on open wounds, ulcers, abscesses, etc., for the astringency and a mild stimulation leading to repair, silver nitrate is used extensively, also the soluble zinc salts and alum. They are applied in strengths of from 1/2 per cent. to 5 per cent. The insoluble astringents may be used as dusting-powders, or in the form of ointments—5 per cent. to 20 per cent. It must not be forgotten that absorption is fairly free from open surfaces, and calomel, bismuth, lead, etc., must be used with caution. Zinc oxide is quite safe, and is one of the most useful.

The mucous membranes which are easily accessible to the local action of astringents are those of the mouth, conjunctiva, nose, genito-urinary tract, and rectum. The same salts as in the case of open wounds can be used, as also tannin. They are employed in somewhat weaker solution, as gargles, washes or injections. The usual strength is from 1/2 to 1 per cent. For vagina or rectum, double this; in the conjunctiva and nose, perhaps one-fourth of this. In the case of the genito-urinary tract, irritation is particularly undesirable. For this reason non-irritant protein compounds of silver have become popular.

Astringents cause actual constriction of the mucous membranes, and may in this way bring about the complete disappearance of small polypi.

In the alimentary canal the astringents are useful mainly by diminishing results of inflammation; i.e., the vomiting and diarrhea.

*Ac = Acetate.
Against vomiting, especially when caused by ulceration, bismuth subnitrate or subcarbonate seem to be the most useful. These act not only in virtue of their astrigency, but also somewhat after the manner of inert dusting-powder, affording an artificial protective covering to the walls of the viscus by adhering to them. Silver nitrate is also sometimes used in doses of about 1 cg. (1/6 grain), dissolved in water and given three times a day.

Their action on diarrhea is entirely similar. Bismuth is again preferred; silver nitrate is often very useful in the summer diarrhea of infants. Further details will be found under the respective metals.

TANNINS AND VEGETABLE ASTRINGENTS

Actions and Uses.—The tannins are a group of widely distributed vegetable principles, which precipitate proteins and are therefore astringent; and which give blue or green compounds with iron salts. They are less destructive than the metals; and being practically non-toxic they are especially suited for use in the alimentary canal. They do not decrease peristalsis directly, but do so indirectly, by allaying the underlying inflammation. Their employment in diarrhea dates back at least beyond the fourth century B. C.

Methods of Testing Astringent Action.—Ordinarily astringent action depends on the precipitation of the proteins (Mitscherlich, 1842; Lewin, 1881; Harnack, 1889). This may be tested directly; or by measuring the diminished extensibility of tissues, for instance the lungs (Dresner); or by the shortening of tissues which ensues when their proteins are precipitated (Crawford, 1818); or by the property of rendering red corpuscles resistant to hemolysis (Sollmann, 1920); or by the suppression of secretion on the frog’s skin (Schnett); or by observation of blood-vessels in the exposed mesentery (Klein); or by the clinical response in catarrh or diarrheas; or very simply and with rather surprising accuracy, by the taste.

Influence of Reaction (H-ion Concentration).—The tannin protein precipitates are soluble both in acids and alkalies beyond a certain concentration; i.e., precipitation and astringency occurs only within a limited range of H-ion concentration. The exact range varies somewhat with conditions; but under ordinary conditions, this lies between $P_H = 1$ and 6.5, i.e., between the acidity of 0.35 per cent. hydrochloric acid or the maximum acidity of the gastric juice; and the alkalinity of a sodium bicarbonate solution, or of the extreme alkalinity of the intestinal juice. The optimum reaction is somewhat toward the acid side, i.e., $P_H = 3$ to 5, or about the turning point of methyl orange which is at $P_H = 3.1$ to 4.4 (Sollmann, 1920).

These differences are important for the therapeutic action of tannin. The reaction of most mucous membranes and tissues evidently falls within the precipitation range; but in the intestinal tract the conditions are rather complicated.

Behavior of Tannin in the Intestinal Tract.—The reaction of the stomach varies. The empty stomach, when resting, has reactions within the precipitation range; and tannin would thus be astringent. With the secretion of acid juice, the reaction would at first become more favorable to precipitation, and astringency would increase.

When taken with food, the food proteins would combine with much or most of the tannin, and the astringent action on the gastric mucosa would be slight. The degree of precipitation would again vary with the reaction: It would at first increase with the acidity; but as this approached a maximum, part of the protein-tannate would be redissolved. The gastric digestion of protein would not modify the conditions materially, since albumoses and probably peptones are also precipitated by tannin.
In the duodenum, the tannin would arrive mainly as tannin-proteinate; partly precipitated and partly in solution, depending on the reaction. Some tannins may have been adsorbed by the precipitate, and thus be present in free form.

On arriving in the duodenum, the unfavorably high acidity of the chyle would be partly neutralized, and the reaction would thus be most favorable to protein-tannin precipitation and therefore to astringency.

In the ileum, the reaction becomes gradually more alkaline and correspondingly less favorable to precipitation. The tannin can therefore precipitate less protein than in the duodenum; and therefore there can be no astringency by the tannin proteinate that arrive from the duodenum; although, if free tannins were added directly to the ileum some precipitation and astringency would occur.

The level of the ileum where astringency ceases varies with the difference in reaction and perhaps still more with the length of the sojourn in the duodenum. The shorter this sojourn, the less marked will be the difference in the reaction of the chyle at the several levels, and the greater will be the chances of prolonging the astringency. This may be determined by the cumulative effects of tannin and may produce more pronounced diarrhea than in normal individuals. In no case, however, does the astringency extend into the large intestines.

Some free tannin is actually added by the complete cleavage and absorption of the proteins; but this also does not extend very far, since the alkaline intestine gradually decomposes tannin into non-astringent compounds.

**Masked Tannin Compounds.**—The astringent and irritant action of free tannin on the gastric mucosa is undesirable. This has prompted the introduction of various preparations that hold their tannin in such a form that its solution or action is delayed; ideally, until it would reach the intestines; or better still, so that the liberation of the tannin would extend through the whole course of the intestine.

**Astringent Plant-extracts.**—Preparations of krameria, gambir (catechu), kino, etc. have been supposed to act more slowly than tannic acid, because of the protective influence of their colloids. In vitro, they precipitate proteins just as readily; but the colloids probably protect the gastric mucosa somewhat by hindering its contact with the tannin. In practice, however, they have been generally displaced by the synthetic compounds.

**Synthetic Tannin Compounds.**—The general aim in devising the synthetic compounds has been to make them insoluble in water and acid fluids, and soluble in alkaline solutions. This idea was based on mistaken views as to the true reaction of the intestinal contents; but these properties are still commonly claimed, although they have not been realized in any instance (Leech, 1920). All the commercial preparations are somewhat soluble in water; and most are about as soluble in dilute alkali. This is rather fortunate; for the reaction of the small intestines is more often acid than alkaline. The real advantage of the compounds lies in the fact that their tannin is dissolved or becomes active quite slowly, whatever the reaction. The slower this process, the smaller will be the effect on the stomach, and the farther will the astringency extend into the intestines.

The two compounds that have established themselves in practice are excised tannin albuminate and acetyl-tannic acid.

**Excised Tannin Albuminate (Albutannin; Tannalin).**—Contrary to the prevailing opinions, these dissolve rather better in artificial acid-gastric juice than in bile-pancreatic-trypsin solutions. However, their solubility is so slow that they can only be slightly astringent in the stomach. Considerable astringency would develop in the duodenum when the acidity is reduced; and the effects would continue somewhat into the large intestine, following the cleavage of the undissolved proteinate (Sollmann, 1920).

**Excised and Acetylated tannin (Tannigen).**—Commercial brands are mixtures of varying quality; some specimens containing considerable free tannin. The best specimens, however, appear fairly uniform, and both slightly soluble and astringent in
TANNINS

ac solution. Bicarbonate dissolves them and hydrolyzes them slowly. The astrin-
gency goes parallel to the hydrolysis, so that the action would continue for several
hours, and could thus extend into the lower intestines. However, they do not deserve
full confidence until the commercial products are more uniform (Sollmann, 1920).

The official “tannic acid” is derived from nut-galls.

In the course of its absorption, tannin is decomposed into the non-
astirgent gallic acid, pyrogallol, etc.

Varieties of Tannin.—Ordinary “tannin” or gallo-tannic acid is derived chemically
by the elimination of a molecule of H₂O from 2 molecules of gallic acid (Tri-hyrox-
benzoic acid, C₆H₄(OH)₃-COOH). The numerous other varieties are of different
compositions, in many cases unknown. Some are compounds of gallic acid with sugar
or with phosphorbin.

Comitative Action.—This has been studied on cats with the X-ray method by
Iseman, 1913. In the absence of diarrhea, tannin has no effect on the intestinal
movements beyond a slight delay in the emptying of the stomach; nor had it any in-
fluence on the diarrheas produced by milk-feeding or sena; but little on the ca-
tharsis of castor oil. However, it arrested certain diabetic diarrheas (bread), and that
produced by the colon-action of colubryn. Its action is therefore not on peristalsis,
but on the inflamed mucosa.

Pharmacologic Peculiarities.—Tannins form more or less insoluble compounds with
many metals, alkaloids, glucosides, etc., and are therefore useful as antitoxins. They also
precipitate proteins, gelatin and connective tissue (leather), and thus act as astrignents,
syptrophics, and antiseptics (mainly by depriving the bacteria of food). The different
tannins are not equivalent in these respects. Some (which are perhaps misnamed,
such as those of coffee and specia, are practically non-precipitant. Others present dif-
fferences in the firmness and solubility of the precipitate, which, when better known,
may prove of therapeutic importance.

 Fate.—This is imperfectly known; but all of the tannin, even if injected intra-
venously, undergoes decomposition into gallic and pyrogallol acid and other decom-
position products, before being excreted. These appear both in the urine and feces
(C. Root, 1867; the older contradictory statements were based on faulty tests for tannin).
Only the insoluble tannates (Tannogen, Tannabio, etc.) pass in part undecomposed
into the feces. The decomposition must, therefore, take place to a large extent in the
intestines. With oral administration, the urine contains at most 1 per cent. of the
gallate of the tannin.

The use of tannin as antidote has been discussed under “General Toxilogy.”

The insolubility of tannin compounds has been utilized in securing a more prolonged
local action of the bations. It will be remembered that this is one reason for the more
lasting local effects of galenics as compared with alkaloids. It has been suggested to
 preserve such combinations artificially, but these have not come into general use.

The effect of the continued administration of small amounts of tannins has consider-
able importance, because they are contained in a number of beverages; as tea and certain
wines. A mild astrignent action may be locally tonic and beneficial; but larger quan-
tities prove actually irritating, and may lead to gastroenteritis.

Even small amounts of tannin interfere somewhat with aborition. This is largely
due to their precipitating properties. But these combinations are again decomposed in the
alimentary intestine, so that the interference is not large.

In the actual experiments of Bilherfield (1905) on the absorption of normal saline
solution from a Vella fula, this was accelerated by 0.01 per cent. of tannin; 0.04 per
cent. had no effect; 0.1 to 1 per cent. delayed absorption.

On the whole, one may say that the small quantities of tannin ordi-
narily taken with the food and drink are not injurious; but that large
quantities (excessive tea drinking) are probably deleterious. The tannin of
coffee is scarcely astrignent, and therefore lacks this action.

Effects of Larger Doses.—These produce irritation and corrosion, especi-
ally if the stomach is empty; pain, vomiting, diarrheas or obstipation.

PREPARATIONS—TANNIC AND GALIC ACIDS

[Text continues]
on keeping, although they still color iron. *Incompatible with alkalis, alkaloids, salts of iron and most other metals, proteins and gelatin. *Dose, 0.5 Gm., 8 gr., U.S.P.; 0.3 to 0.6 Gm., 5 to 10 gr. B.P. Locally, for urethra, 1 to 2 per cent.; vagina, 5 per cent.; enema, 1 to 2 per cent.; rectal irritation (cholera) 1/4 to 1/2 per cent.; skin and ulcers, 5 to 20 per cent., or the Glycercite.

*Uns. Acid. Tann., U.S.P.—20 per cent.

Supp. Acid. Tann., B.P.—0.2 Gm., 1 gr. (against hemorrhoids).

Tech. Acid. Tann., U.S.P.—0.06 Gm., 0.1 gr.

Trock. Acid. Tann., B.P.—0.00 Gm., 0.1 gr.

*Albutammin (N.N.R.): Tannin; Exsiccated Albumin Tannate, containing about 50 per cent. of tannic acid (Gottlieb, 1869). Light brown, odorless and almost tasteless, powder, slowly and incompletely soluble in water, gastric juice and dilute alkalies (intestinal and pancreatic juice). Used in diarrhea, especially of children. *Dose, 1 to 4 Gm. (15 to 60 gr.) in powder or tablets, followed by water; infants, 0.3 to 0.5 Gm. in gruel.

Actionmin (N.N.R.): Tannin, Diacetethyltannin (H. Meyer, 1894); insoluble in stomach, slowly soluble in intestine.

Acidum Gallicum (Acid. Gall.), U.S.P.; C6H5(OH)2CO2H + H2O—Occurs in many plants, usually with tannic acid. It does not precipitate alkalis, albumin, or glue. The reputed astringent effect is perhaps due to a small quantity of tannin which is usually present (Sollmann, 1920). Sol. in water (1:5); freely sol. in alc. (1:4.6) or glyc. (1:10). *Dose, 1 Gm., 15 gr., U.S.P. Externally, 1 per cent., as weak astringent.

TANNIN-DRUGS

These are very numerous, and many might well be dispensed with. Gambrir (Catechu) would fulfill all indications.

Acacia Corteis, B.P., Acacia Bark.—The dried bark of Acacia arabica and decurrens. Astringent and demulcent.

Dec. Acac. Corteis, B.P.—6 per cent. *Dose, 15 to 60 c.c., 1/2 to 2 ounces, B.P.

Bela Fract., B.P.—The fresh fruit of Aegle Marmelos.

Ext. Bela Liqu., B.P.—Dose, 4 to 8 c.c., 1 to 2 drams, B.P.

Butea Sem., B.P.—The seeds of Butea frondosa.

Butea Gum., B.P. (Bengal Kino).—The inspissated juice of Butea frondosa.

Galic, U.S.P., B.P.; Nut-gall.—An excrecence on the young twigs of Quercus infaictoria and other allied species of Quercus (Oak), induced by the punctures on the leaf-buds and by the deposited ova of a wasp, Cynips tinctoria. Contains 50 to 60 per cent. of tannin, 2 to 5 per cent. of gallic acid. *Dose, 0.5 Gm., 8 gr., U.S.P.

Uns. Gall., U.S.P., B.P.—20 per cent. It is used especially against external hemorrhoids.

*Uns. Gall. C. Opio, B.P.—The preceding, with 7.5 per cent. of powdered Opium.

Catechu, B.P.; Catechu (Pala); identical with Gambrir, U.S.P.—A dried extract of the leaves of young shoots of Uncaria Gambir.

*Fr. Catechu, B.P.—20 per cent., with Cinnamon. *Dose, 2 to 4 c.c., 1/4 to 1 dram, B.P.

Pulv. Catech. Co., B.P.—Catechu, 40 per cent.; Kino and Krameria, each 20 per cent.; Cinnamon and Nutmeg. "Dose, 0.0 to 4 Gm., 10 to 60 gr., B.P.

Trock. Catech., B.P.—0.06 Gm., 1 gr.

Catech. Nigrum (Catech. Nigr.) B.P.; Black Catechu.—An extract from the wood of Acacia Catechu.

Emblica (Embelf), B.P.—The dried fruit of Ribes Embelia and robusta. *Dose, 4 to 16 Gm., 60 to 240 gr., B.P.

Gambir, U.S.P.; Gambrir (Pala Catechu); identical with Catechu, B.P.—A dried extract prepared from decoctions of the leaves and twigs of Ourocuparia Gambir. Contains 33 to 47 per cent. of catechu-tannic acid. *Dose, 1 Gm., 15 gr., U.S.P.

*Fr. Gambir Co., U.S.P. (Compound Tincture of Catechu).—5 per cent. in 50 per cent. alcohol; flavored with cinnamon. *Dose, 4 c.c., 1 dram, U.S.P.

Hamamelis Co., B.P.—5 per cent. in 50 per cent. alcohol; flavored with cinnamon. *Dose, 4 c.c., 1 dram, U.S.P.

Hamamelis Bark (Witch Hazel Bark).—The dried bark of Hamamelis virginiana.

Tr. Hamam., B.P.—10 per cent. of bark. *Dose, 2 to 4 c.c., 1/2 to 1 dram, B.P.

Hamam. Fol., B.P.; Hamamelis Leaves.—Fresh or dried. 8 per cent. of tannin (Schrab, 1890).

Est. Hamam. Liqu., B.P.—50 per cent. of dried leaves. *Dose, 0.3 to 1 c.c., 5 to 15 minims, B.P.
TANNINS

**Ung. Hamam.**, B.P.—15 per cent. of the preceding.

**Hammatolitum Lignum**, B.P.; Logwood.—The heart-wood of Hammatolylon campechi-anum. 12 per cent. of Hamatoxylin.

**Dec. Hematoxyli**, B.P.—5 per cent. **Dos.**, 15 to 60 c.c., ¼ to 1 ounce, B.P.

**Kino**, U.S.P., B.P.; Kino.—The dried juice from the trunk of Pterocarpus Marsupium. 75 per cent. of Kino-tannic acid. **Dos.** 0.5 Gr., 5 gr., U.S.P.; 0.5 to 1.2 Gr., 5 to 20 gr., B.P. It is used especially in gargles, but its popularity is waning. **Tr. Kino**, U.S.P., B.P.—10 per cent. **Dos.**, 4 c.c., ½ dram, U.S.P.; 2 to 4 c.c., ¼ to 1 dram, B.P.

**Pulv. Kino Co.**, B.P.—5 per cent of opium. **Dos.**, 0.5 to 1.2 Gr., 5 to 20 gr., B.P.

**Kino Eucalypti** (Kino Eucalypti.), B.F. (Eucalyptus Gum, Red Gum).—An exudate from the stem of Eucalyptus species. **Dos.**, 0.3 to 1.2 Gr., 5 to 20 gr., B.P.

**Trock. Kino Eucalypti**, B.P.—0.00 Gr. to 0.05 Gr. **Kramer. Rad.**, B.P.; Krameria (Rhatany).—The dried root of Krameria species. **Dos.**, 0.3 to 1.2 Gr., 5 to 15 gr., B.P.

**Tr. Kramer.**, B.P.—10 per cent. **Dos.**, 2 to 4 c.c., ¼ to 1 dram, B.P.

**Inf. Kramer.**, B.P.—5 per cent. **Dos.**, 15 to 30 c.c., ½ to 1 ounce, B.P.

**Trock. Kramer.**, B.P.—0.00 Gr. to 1 Gr., B.P.

**Myrobalanum**, B.P.; **Myrobalans.**—The dried immature fruit of Terminalia Chebula.

**Dos.**, 2 to 4 Gr., 30 to 60 gr., B.P.

**Ung. Myrob.**, B.P.—20 per cent.

**Ung. Myrobal. C. Opio.**, B.P.—The preceding with 7.5 per cent. of Opium.

**Sappan.**, B.P.—The heart-wood of Caesalpinia Sappan; similar to Logwood.

**Dec. Sappan.**, B.P.—5 per cent. **Dos.**, 15 to 60 c.c., ¼ to 2 ounces, B.P.

**Diarrhoea Mixtures.**—These are generally “shot-gun” prescriptions of which the following are types:

- **Mistura Comita Diarrhoeam.**, N.F. (Sun Cholera Mixture).—Equal parts of Tincture of Opium, Capsicum, Rhusbarb, Campher, Peppermint. **Dos.** to one teaspoonful.

**ASTRINGENT STYPTICS**

All the metallic salts, the irritant as well as the astringent, and also the vegetable astringents, act as local styptics: i.e., arrest capillary hemorrhage. They do so mainly by the formation of precipitates which occlude the lumen of the small vessels, just as it is occluded ordinarily by fibrin. They also injure the vessel walls and thus tend to produce thrombosis. This is claimed especially for zinc chloride.

Astringents can act only when they come into actual contact with the bleeding vessels. They can not act through a large drop of blood, and if such exists, it must first be removed. At one time they were used internally with the idea of producing astringent action in remote places; iron was given by the mouth to check bleeding in the uterus. This was entirely irrational. Their action can not even extend beyond the stomach, since they are precipitated or decomposed in the intestine.

The indications for the use of styptics are to lessen bleeding, especially capillary oozing. They have no effect on spurting arteries or large veins. They are sometimes injected into hemorrhoids, and have even been injected into aneurisms. Their injection into larger vessels is dangerous, as it may produce embolism.

The most useful of the metallic styptics are the iron salts, especially ferric chloride and ferric sulphate. The ferric chloride is used either as the solution, or tincture, quite largely diluted with water. Cotton may be steeped in this, forming “styptic cotton.” Next comes alum, especially the burnt alum. Then the soluble tannins in any form.

**Other Hemostatic Measure.**—Any substance which gives a precipitate with proteins may act as astringent styptic; e.g., dilute acids in concentrations which need not be caustic (vinegar and lemon juice). A number of purely mechanical measures
favor the formation of clot; for instance, ordinary cotton or Pengawhar Djambie (this also contains tannin). Cobwebs form a popular and effective means for producing the same result, but are usually septic. One may obtain the same effect by fine powders which have a strong attraction for water. In case of emergency powdered or granulated sugar is a good styptic, and is at the same time antiseptic. Rephasin and tissue extracts hasten coagulation in vitro but are of little use on wounds. Other styptic measures are position, raising the limb and keeping it quiet so as to reduce the local congestion; local pressure; depression of the vasomotor center by narcotics; direct constriction of the vessels by the application of cold, or by drugs, such as epinephrin, cocaine, etc.

**Efficiency of Local Stypics.**—This has been tested experimentally by noting the quantity of blood lost when a skin-wound is irrigated with the styptic (Hanvik, 1918). The efficiency was in the following order; epinephrin, the most active, being taken as the standard:

- Epinephrin = 1; pituitary solution = 14; tyramin = 34; acetic acid = 3/50; ferric chloride = 3/50; tannin = 3/50; cocaine = trace.

The following actually increase bleeding: antipyrin; atropin, procain, and other synthetic local anesthetics; chloramin T, cotarnin salts, Dakin's solutions, emetin, hydrastis, orthoform, peptone.

**IRRITANT VOLATILE OILS AND RELATED DRUGS**

**General Statement.**—Most volatile (or "essential") oils are complex mixtures, generally containing terpenes and oxidized aromatic derivatives. The balsams and resins, which contain volatile oils, may be included in the group. These oils occur in numerous plants, and determine their use as flavors, aromatics, carminatives, antiseptics and irritants. Their chief application is for their local effects, consisting in deep irritation with a minimum of tissue destruction. The sensory stimulation is followed by some anesthesia. They exert a favorable influence on chronic inflammations; partly by their mild antiseptic and irritant action, and partly by chemotactic attraction of leucocytes. In acute inflammations they are more apt to do harm. Their antiseptic action is, in practice, relatively weak, since they are but slightly soluble in water.

After their absorption they are excreted mainly in combination with glycuronic acid. They irritate the kidneys and produce diuresis.

Central effects are only seen in poisoning, and agree broadly with those of camphor, which really belongs to this group. These effects are more or less convulsive, followed by narcosis; on direct application, stimulation of cardiac muscle; and curare action on the muscle-nerve endings.

**The Flavoring and Aromatic Oils are considered in another place.**

**Composition.**—A convenient tabulation of the constituents of volatile oils is given by Rippeto and Wise, 1912. The terpenes are "aromatic, cyclic compounds of the general empirical formula, C₅H₈. Related to them are the semi-terpenes (C₅H₁₀); sesqui-terpenes (C₅H₁₄); and di-terpenes (C₅H₂₀). Other constituents are oxidation products of these and aromatic phenols, ketones, aldehydes, acids and their compounds.

**The Antiseptic Effects.**—These have been investigated especially by Robert, 1906; Bruning, 1906; Ginzitz, 1923; and Rippeto and Wise, 1912.

**Chemotactic Action.**—The value of volatile oils (particularly those enumerated as urinary antiseptics) in various abscess and chronic inflammations seems confirmed by clinical observations and laboratory experiments. They are also said to lessen aseptic inflammations at points remote from the site of their application, by decreasing the formation of exudates and by hastening their absorption. The explanation may be chemotactic attraction for leucocytes (Léméire, 1891; Borsissow; Hamburger, 1912).

In this way they withdraw these cells from the inflamed area into the blood (Wintersitz, 1902).

**Excretion.**—Terpenes are for the most part excreted in the urine in combination with glycuronic acid (Mated, 1907), sometimes after partial oxidation.
VOLATILE OILS

Systemic Actions of Volatile Oils.—The principal central effects of volatile oils are reflex. With the ordinary doses, no direct action whatever can be observed. Large doses act on the nervous centers, especially the brain and medulla. These are first stimulated, then depressed. The details have been investigated especially by Rimini, 1909; Hildebrandt, 1902 and 1903; Mattel, 1905; and Ginits, 1912. The degree of stimulation varies for the different oils. Turpentine has scarcely any effect, whilst absinth, thujon, fenchon, carvon and camphor produce violent epileptic convulsions. The depression is more uniform: The majority (valerian, fennel, chamomile, eucalyptus, mint, rosehip, salvia, citral, turpentine) diminish the reflex excitability, so that large doses entirely prevent strychnin convulsions in rabbits. The effective doses are, however, entirely too large to make it possible to employ this action in man.

The Curare-actions have been studied by Hildebrandt and by Mattel; the cardiac effects by H. Schwabl, 1912.

Barth (1902), the intravenous injection of volatile oils causes a peculiar dilatation of the cerebral vessels, the volume of the brain increases, whilst the pressure in the circle of Willis falls. This effect is strongest with absinth, weak with anise or lemon. Camphor has a similar effect. The general blood pressure also falls in most cases, but quite independently of the changes in the cerebral circulation.

If volatile oils are injected hypodermically, they produce at first the reflex action, in a more marked degree than when they are applied to the surface of the skin. Later their systemic, and still later the renal, actions take place.

Isolated Intestinal Segments are stimulated by oil of anise, turpentine and chenopodium, in concentrations of 1/50,000 to 1/25,000. Higher concentrations of all volatile oils depress the movements (Muirhead & Gerald, 1910).

Hemolytic Action of Terpenes.—Ishizaka, 1914, found that this varied mainly with the surface tension; but that the alcohol or ketone character also has an influence. Some form methemoglobin.

OLFACTORY STIMULANTS

Odorous substances produce pronounced reflex effects. Pungent and aromatic drugs cause in this way a prompt medullary stimulation, increasing the respiration and blood pressure, and slowing the pulse. They are especially useful in fainting. They are employed by inhalation. Tinctura Lavandulae Composita (U.S.P., B.P.) and Aromatic Ammonia are used for this purpose. Any pungent substance will answer in an emergency; the burning of a feather under the nose of the patient is a standard house- hold measure.

Substances which produce sneezing (sternutations or et rhinhe) act in a similar manner, but have passed out of fashion. They are sometimes useful as local counterirritants in nasal catarrh (snuff).

HYSTERIC SEDATIVES OR ANTISpasmodics

Actions and Uses.—Asafetida, valerian, and some other malodorous drugs have been used since antiquity as sedatives in hysterical and similar nervous conditions. They are often effective, presumably by olfactory and psychic reflexes. Asafetida is also carminative, and has been used by mouth and enema (emulsion) in tympanites; but it imparts its odor to the excreta and eructations. Very large doses (1/4 ounce) have been taken without other noticeable effects. Large doses of valerian produce systemic action, but it is very doubtful whether these occur with the ordinary doses. Valerian was formerly used as a perfume, and as a spice for meat, and asafetida is said to be similarly employed in Persia.

PREPARATIONS—HYSTERIC SEDATIVES

Asafetida (Asafet.). U.S.P.; Asafetida (Asafet.). B.P.; Asafetida.—The gum is obtained by incising the rhizome and roots of Ferula Asafetida. Characteristic odor and acrid taste; forms milk-white emulsion when triturated with water. Contains: 5 to 9 per cent. volatile oil; 20 to 30 per cent. gum; 45 to 70 per cent. resin. The alcoholic preparations yield turbid mixtures with aqueous liquids. Dose, 0.01 gr. to 0.1 gr.; 0.5 to 1 gr., 1 to 15 gr., best as pills.

Pl. Asafet., U.S.P.—0.2 Gm., 3 Gt. Dose, 2 pills, U.S.P.
Emul. Asafet., U.S.P. (Milk of Asafoetida, Asafoetida Mixture)—Made by rubbing 4 parts of asafoetida with 100 parts of water. Dose, 1 to 3 c.c., 4 drams, U.S.P. Used especially as enema against tympanites.

Tr. Asafet., U.S.P., B.P.—20 per cent. Dose, 1 c.c., 15 minims, U.S.P.; 2 to 4 c.c., 15 to 1 dram, B.P.

Sp. Ammon. Fet., B.P.—An alcoholic distillate of Asafoetida, mixed with Ammonia, Dose, 1 to 2 c.c., 20 to 40 minims, repeated; single, 4 to 6 c.c., 60 to 90 minims, largely diluted, B.P.

Valeriana (Valer.), U.S.P.; Valer. Rhiz., B.P.; Valerian.—The dried rhizome and roots of Valeriana officinalis. Dose, 2 to 4 gr., U.S.P.; Contains 15 to 2 per cent. volatile oil, valeric and other organic acids; tannin and resins. The oil consists of esters of valeric (valerianic) acid, especially with bornole. These are the bearers of the action, free valeric acid and its salts being quite ineffective. The fresh root is also ineffective, the esters being formed only during drying, by the action of oxidases (Kochmann, 1904). The juice of the fresh plant also produces different effects from the dried valerian (Pouchet and Chevalier, 1909). The esters again deteriorate by oxidation on keeping. Certain synthetic esters are said to be more stable (Kloka, 1902).

The Injection of Valerian.—This produces the usual effects of volatile oils (Pouchet and Chevalier, Kloka, 1904); in small doses, psychic excitation and rise of blood pressure from cardiac and vasomotor stimulation; in larger doses, central sensory and motor depression.

Excised Uterus.—This is stimulated by valerian oil (Pilcher, 1916).

Excised Intestine.—The contractions are depressed by valerian oil (Deluzel, Burman and Pilcher, 1916).

Tr. Valer., U.S.P.—20 per cent. Dose, 4 c.c., 1 dram, U.S.P.

*Tinctura Valerianae Ammoniata* (Tr. Valer. Ammon.). U.S.P., B.P.—20 per cent.; with Sp. Ammon Arom., U.S.P.; with ammonia and aromatics, B.P. Dose, 2 to 4 c.c., 30 to 60 minims, U.S.P.; 2 to 4 c.c., 1 dram, B.P.

Valer. Ind. Rhiz., B.P.—From Valeriana Walach. (Tr. Valer. Ind. Ammon.). U.S.P.—Dose, 2 to 4 c.c., 1 to 1 dram, B.P.

Minor Drugs of this group.—Sambul (Musk-root), Moschus (Musk), Castoreum Cataria (Catnip); and Synamlocarpus (Sunk-cabbage).

Moschus, U.S.P., Mus.—The dried secretion from the preputial follicles of Moschus moschiferus. Dose, 0.25 Gr., 4 gr., U.S.P.

Tr. Mosch., U.S.P.—5 per cent. Dose, 4 c.c., 1 dram, U.S.P.

Oil of Turpentine

Actions and Uses.—Applied to the skin, this produces simple reddening and burning, and is used as a counterirritant; undiluted, or mixed with 1 to 5 parts of oil in liniments. It is often used as “Stipes,” i.e., flannel wrung out of hot water, and then out of warm turpentine, and applied for ten to thirty minutes. In susceptible individuals it may cause severe eruptions, and if left on for several hours, blistering.

Oil of turpentine is used externally in bronchitis, neuralgic and rheumatic pains, and to relieve meteorism. It causes more severe irritation on mucous membranes.

Inhaled or taken internally it diminishes bronchial secretions (Rosbach and Fleischmann). It was used for this purpose (a teaspoonful inhaled from a pint of hot water) in chronic bronchitis. It is now displaced by the more pleasant terpene hydrate by mouth and pine-needle or eucalyptus oil.
VOLATILE OILS

167

for inhalation. Its use as anthelmintic (2 to 15 c.c.) and as diuretic and urinary antiseptic has also been discontinued.

Turpentine Abscess.—The injection of oil of turpentine produces localized aseptic abscess. Fehl and Pilling, 1914, propose such abscesses, formed by its hypodermic injection into the abdominal wall, is the treatment of all sorts of infections—pneumonia, whooping cough, measles, etc. This is somewhat analogous to the obsolete "setons."

Absorption, Fate and Excretion.—Oil of turpentine is readily absorbed from the skin, lungs and intestines. It circulates for a time unchanged in the blood, and is excreted mainly in the urine as terpenals, paired with glycuronic acid. The urine has the odor of violets. Neither turpentine, nor eucalyptol nor menthol, is excreted by the lungs or putam (Falk, Hofbauer, 1915).

Systemic Actions.—These do not occur with small doses.

Turpentine Poisoning.—Half an ounce has been fatal to children, 6 ounces to adults. The symptoms in man are those of gastro-intestinal irritation; nausea and vomiting, colic and diarrhea, wild excitement and delirium, ataxia, painful, micturition, hematuria, albuminuria, glycuronia, skin eruptions.

Treatment.—This comprises evacuation, demulcients and coffee.

Inhalation.—Fatal poisoning has been reported from inhalation of varnish in a confined space (Drescher, 1903); largely by exclusion of air (Wolf, 1911). There is rapid breathing, palpitations, vertigo, stupor, convulsions, and other nervous disturbances; pain in chest, bronchitis and nephritis. The latter may also occur on chronic exposure.

PREPARATIONS—TURPENTINE

"Oleum Terpentinum" (Ol. Tereb.), U.S.P.; Oil of Turpentine (Spirit of Turpentine). The volatile oil recently distilled with water, below 200°C, from the concrete oleoresinous (Terpentine) obtained from Pinus palustris and from other species. It consists mainly of pineace, C_9H_8O, with small quantities of other terpenes and traces of organic acids. A thin, colorless liquid, of characteristic odor and taste, becoming stronger and more unpleasant by age and exposure to air. Practically insol. in water, sol. in 3 vol. of alc., and in all proportions of oils. The rectified oil should be employed for internal use.

"Ol. Tereb. Rect." U.S.P.; Ol. Tereb. Rectif., B.P.—Rectified (by distillation with NaOH, U.S.P.) Dose, 0.2 c.c., 5 minims, U.S.P.; 0.12 to 0.6 c.c., 2 to 10 minims, B.P.; anthelmintic dose, 12 to 15 c.c., 1 to 4 drams, B.P.

Lin. Tereb., U.S.P.; Turpentine Liniment.—Cerat. Res., 1; Ol. Tereb., 1

Lin. Tereb., B.P.—Ol. Tereb., 65 per cent.; Camphor, 5 per cent.; Sup. Moll. and water.

"Ol. Pin. Pavilionum" (Ol. Pin. Pavill.), U.S.P., Oil of Dwarf Pine Needles; "Oleum Abietis" (Ol. Abiet.), B.P., Oil of Siberian Fir.—Colorless or faintly yellowish volatile oil, of pine-noodle odor, distilled with steam from the fresh leaves of Pinus montana, U.S.P.; of Abies sibirica, B.P. Contains l-pinen, other hydrocarbons, and enters. Resembles oil of turpentine, but has more agreeable odor, and is employed as inhalant in bronchial affections.

Terpenesina Canadiensis (Tereb. Canad.). B. P.; Canada Turpentine.—An oleoresin obtained from Abies balsamensis.

TERPIN HYDRATE

This is used to diminish cough and expectoration in phthisis and in chronic bronchitis, acting similarly to oil of turpentine, and being less irritable, less disagreeable and less toxic. It is also sometimes employed as diuretic and urinary antiseptic, but is not very effective.

Lagne, 1885, claimed a diuretic effect from 0.3 to 0.4 Gm. Matzel, 1905, took 4 Gm. daily without any effect; the urine was not albuminuric. It was excreted as paired glycuronic acid.

PREPARATIONS—TURPENTINE DERIVATIVES

freely sol. in alc. (1:12.5). *Dosage*: 0.25 Gm., 4 gr., U.S.P., 0.1 to 1 Gm., 1/4 to 15 gr., in powders or capsules. *The N.F. Eliorit contains 1 gr. to the drachm, in a vehicle of alcohol and glycerin.*

_Terebenum (Terebene)_, B.P.; Terebene.—Dipentene and other hydrocarbons, obtained by the action of concentrated sulphuric acid on oil of turpentine. Colorless, thin liquid; rather agreeable odor; aromatic, somewhat terpine-like taste. Slightly sol. in water, freely sol. in alc. (1:3). *Dosage*: 0.25 c.c., 4 minims, U.S.P.; 0.3 to 1 c.c., 5 to 15 minims, B.P., on sugar; or by inhalation.

**EUCALYPTOL**

Eucalyptol (Cineol, Cajeputol), C₁₀H₁₆O₂, is obtained chiefly from oil of eucalyptus, but occurs also in other volatile oils, such as cajuput. It is a mild local irritant, used especially in bronchitis, as inhalation (teaspoonful in hot water), or internally (5 to 10 drops on sugar); and in coryza (spraying with 3 to 5 per cent. solution in liquid petrolatum). The oil of eucalyptus may be substituted.

Eucalyptol imparts to the urine the same violet odor as does oil of turpentine, which it closely resembles in action. It has been used in malaria but is greatly inferior to quinin.

_Tercolity._—Large doses of eucalyptol or the related Myrtol produce fatal collapse. Death occurred in about 1/5 of the human subjects who had taken between 10 and 30 cc. Idiosyncrasy toward small doses is manifested by skin eruptions (L. F. Barker and Rowntree, 1918; experimental and clinical bibliography).

**PREPARATIONS—EUCALYPTUS AND CAJUPUT**

_Eucalyptus_, U.S.P. (Blue Gum Leaves).—The dried leaves of Eucalyptus Globulus. *Dosage*: 2 Gm., 30 gr., U.S.P.

_Peedr. Eucalypti_. U.S.P.—_Dosage_: 2 c.c., 30 minims, U.S.P.

*Oil, Eucalypti_, U.S.P., B.P.—A volatile oil distilled from the fresh leaves of Eucalyptus species, yielding not less than 70 per cent. of eucalyptol. Colorless or pale yellow liquid. *Dosage*: 0.5 c.c., 8 minims, U.S.P.; 0.03 to 0.18 c.c., 34 to 3 minims, B.P.

_Ung. Eucalypti_, B.P.—10 per cent. of the oil.

*Eucalyptol_, U.S.P.; Eucalyptol (Cineol), C₁₀H₁₆O₂.—An organic compound obtained from the volatile oil of Eucalyptus Globulus and from other sources. A colorless liquid; characteristic, aromatic and distinctly camphoraceous odor; a pungent spicy taste, and producing a cooling sensation in the mouth. Very sol. in alc. or oils practically insol. in water. *Dosage*: 0.3 c.c., 5 minims, U.S.P.

_Oleum Cajuputi_ (Ol. Cajup.), U.S.P., B.P.—A volatile oil distilled from the fresh leaves and twigs of several varieties of Melaleuca Leucadendron. Used mainly as counterirritant. *Dosage*: 0.5 c.c., 8 minims, U.S.P.; 0.03 to 0.18 c.c., 34 to 3 minims, B.P.

_Sp. Cajup_. B.P.—10 per cent. *Dosage*: 0.3 to 1.2 c.c., 5 to 20 minims, B.P.

**RUBEFACIENT VOLATILE OILS**

A large number of drugs containing volatile oils have been used as ingredients of liniments. With some of the tinctures (arnica, witch hazel) used in domestic medicine, the alcohol is perhaps the main active ingredient. Thymol, menthol, and camphor, and some of the volatile oils that are discussed in other connections could be classed with the rubefacients.

The oils of cloves, cinnamon, and creosote are employed in dentistry to destroy the nerves and to disinfect the cavities of carious teeth.

**PREPARATIONS**

VOLATILE OILS

Tr. Arnica, U.S.P.—20 per cent. in 50 per cent. alcohol. Dose, 1 c.c., 15 minims, U.S.P.

Tr. Arnica Flor., B.P.—10 per cent. Dose, 2 to 4 c.c., ¼ to 1 dram, B.P.

Corydalis, U.S.P., B.P.; Cloves.—The dried flowerbud of Eugenia aromaticus. Dose, 0.03 Gm., 4 gr., U.S.P.

Inf. Corydalis, B.P.—2.5 per cent. Dose, ½ to 1 ounce, B.P.

* Oil. Corydalis, U.S.P., B.P.; Oil of Clove.—The volatile oil, consisting mainly (90 per cent.) of eugenol. Dose, 0.2 c.c., 3 minims, U.S.P.; 0.03 to 0.18 c.c., ¼ to 3 minims, B.P.

Eugenol, U.S.P.—An unsaturated, aromatic phenol (C₉H₆(C₅H₅OCH₃OH) obtained from oil of cloves and from other sources. Dose, 0.2 c.c., 3 minims, U.S.P.

O. Cedre—Cedarwood Oil.

Aquæ Hamamelisæ (Aq. Hamam.), U.S.P.; Liq. Hamam.; B.P.; Hamamelis Water, Solution of Hamamelis (Witch Hazel, Extract of Witch Hazel).—A saturated aqueous distillate obtained by distilling with steam or water the bark, twigs and smaller stems of Hamamelis virginiana and adding about 15 per cent. of alcohol, U.S.P. Clear or colorless or slightly yellowish liquid having a characteristic aroma and taste.

O. Origani.—Originum oil.

O. Pimenta, U.S.P. (Oil of Allspice).—A volatile oil distilled from the nearly ripe fruit of Pimenta officinalis yielding not less than 65 per cent. of eugenol. Dose, 0.2 c.c., 3 minims, U.S.P.

O. Rosmarini (Oil, Rosmar.)., U.S.P., B.P.; Oil of Rosemary.—Distilled from the fresh flowers of Rosmarinus officinalis. Dose, 0.2 c.c., 3 minims, U.S.P.

Sy. Rosmarini, B.P.—10 per cent.

O. Succini.—Oil of Amber.

O. Thymi, U.S.P.; Oil of Thyme.—Distilled from the flowering plant of Thymus vulgaris. Dose, 0.2 c.c., 3 minims, U.S.P.

LINIMENTS

Cutaneous irritants are usually employed in the form of liniments; i.e., in solution or suspension in oil or alcohol. The proportions in which they are used are about the following:

Ammonia Water
Tr. Aconite, Belladonna, Iodin or Opium. 1 : 5
Spirits Camphor, Chloroform of Ether
Tr. Cardamomum or Capsicum 1 : 10
Turpentine
Sp. Sinae
Essential Oils
Croton Oil 1 : 50
Cresote

JUNIPER OIL

This is closely allied to turpentine (containing pines, C₁₀H₂₀, and cadinens, C₁₅H₂₆); but it has a more agreeable flavor. It is distilled from the "berries," the fruit of the conifer, Juniperus communis. In the form of "Holland Gin" or its official substitute, the Spirit Juniperus Comp., it is an old-fashioned diuretic (Cow., 1912) in cardiac and hepatic dropsy; it is supposed to act by mild irritation of the kidneys. Its use in nephritis therefore requires caution. It also has some reputation as emmenagogue. Overdoses produce poisoning, similar to Savin.

PREPARATIONS—JUNIPER

O. Juniperi (Ol. Junip.), U.S.P., B.P.; Juniper Oil.—Distilled from the ripe fruit of Juniperus communis. Dose, 0.2 c.c., 3 minims, U.S.P., 0.03 to 0.18 c.c., ¼ to 3 minims, B.P.

Sy. Junip., U.S.P.—5 per cent. Dose, 2 c.c., 30 minims, U.S.P.

Sy. Junip., B.P.—10 per cent. Dose, 0.3 to 1.5 c.c., 5 to 20 minims, B.P.

Sy. Junip., Cc., U.S.P.—0.4 per cent. of Juniper oil, with Caraway and Fennel oils, in 70 per cent. alcohol. Similar to "Holland Gin." Dose, 10 c.c., ½ dram, U.S.P.
ECBOLIC AND TOXIC VOLATILE OILS

Actions.—Many volatile oils are popularly employed as emmenagogues and ecbolics: turpentine, juniper, savin, rue, pennyroyal, tansy and apioi. They produce pelvic congestion through intestinal irritation. A mild degree of this action may be useful in delayed and painful menstruation, as after exposure to cold. Abortion occurs only with toxic doses; indeed fatal doses are not always effective. Prochnow, 1911, also finds a slight direct action on the excited uterus. Macht, 1913, finds the contraction inhibited, never stimulated.

Savin (Sabina) and Arbor Vitae (Thuja) contain volatile oils similar to turpen- tine but much more toxic. Savin oil contains pinen, cadinen and sabinol, C_{10}H_{14}OH. Thuja contains plen, fenchen, and thujon (isomers of camphor, and having similar actions (Hildebrandt, 1902; Matzel, 1905). Poisoning has often occurred from their use as abortifacients.

Toxic symptoms from oil of savin are those common to volatile oils: Burning, nausea, vomiting, colic and diarrhea, sometimes bloody; severe congestion of the pelvic organs, increased menstrual flow and sometimes abortion; hematuria and painful micturition; unconsciousness, convulsions and coma. Death may occur in a few hours, but more often after several days. Six drops are said to have produced toxic effects (Lewin).

Fatty degeneration of the liver and of other organs (Heffer, 1845; Lindemann, 1890) is produced by large doses of these oils, especially by pulegon, the active constituent of pennyroyal; and also by the oils of sassafras, rosemary and thyme.

Apioi.—Two drugs are known under this name: "Green Apioi" or Oleoresin of Parsley Seed (Olesores, Apio), a green oily liquid. Dose 0.3 to 1 c.c., 5 to 15 minims; and "Apioi" proper, "Crystallized Apioi," "Parsley Camphor," a crystalline aromatic derivative extracted from the oleoresin, dose, 0.1 to 0.3 Gm., 2 to 5 gr. It has been studied by Heffer 1845. Overdoses (0.6 to 0.8 Gm.) produce arhythmia, incoordina- tion, digestive disturbances and fever. Fatal poisoning, with intestinal symptoms, icterus and uremia, is reported by Brenet, 1916.

The Apios are administered in capsules, as emmenagogues and antipyretics. The actions of the different apios do not seem to be identical (Lutz, 1920). Their usefylness is doubtful.

Petroselinum Fructus, U.S.P.; Parsley Fruit.—The dried ripe fruit of Petroselinum sativum.

Olesores. Petrosel., U.S.P., (Liquid Apioi).—Evaporated ethereal extract of Parsley Seed. Dose, 0.5 c.c., 8 minims, U.S.P.

Tansy.—The leaves and tops of Tanacetum vulgare have been used mainly as an- thetetic; against Ascaris and Oxyurus, internally, 0.5 to 2 Gm. as infusion, twice a day; or as enema of 15 to 200. Half an ounce to an ounce of the oil (which contains thujon) has produced death after two to four hours, with convulsions and unconsciousness.

Pennroyal.—The leaves and tops of Hedeoma pulegioides are used as carminative, 5 to 20 Gm., 1 to 3 ounces, as infusion. Oil of Hedeoma (U.S.P.) 0.2 c.c., 3 minims; a teaspoonful has produced convulsions. Its active constituent, pulegon, C_{10}H_{14}O has been studied by Lindemann, 1890; Falck; and Matzel, 1905.

Absinthe.—The herb Artemisia Absinthum, contains a volatile oil, whose chief constituent is thujon, C_{10}H_{14}O. This produces effects similar to camphor (Hildebrandt, 1901 and 1902; Matzel, 1905). The liqueurs "absinthe" and "vermouth" contains this oil and also anise; funnel, and others; it is doubtful what part each of these and the alco- hol (50 per cent.) plays in the toxic complex.

Absinthe Convulsions.—In mammals, intravenous injection of absinthe oil (1 to 3 drops for a cat) produces unconsciousness and general convulsions, clonic and tonic, of epileptiform type (Maganin, 1871). The clonic spasms are due to stimulation of the motor areas, for they become tonic if the cerebral arteries are clamped (Lecomard Hill). The tonic spasms are medullary.

In man overindulgence causes similar effects and is also said to lead to mania. The symptoms and the literature are discussed by L. L. Meyers, 1916.

Nutmeg Poisoning.—This is by no means rare. In man severe symptoms have occurred from one to one and one-half nutmegs, or from a teaspoonful of powdered mace. The effects appear in one to six hours, and are mainly narcotic, varied by ex- citeinent and delirium, with some motor stimulation and local irritation; they usually end in recovery in twenty-four hours. Nutmeg is also ecbolic. Similar effects occur
in animals. Hepatic necrosis has been demonstrated in cats (Dale, 1900). Cushny and Wallace, 1908, showed that the narcotic effect is produced by "myristicin," the high-bolling portion of the volatile oil. The oil has been investigated chemically by Power and Solway, 1906.

Myristica, U.S.P., B.P. (Nutmeg).—The ripe seeds of Myristis fragrans. Dose, 0.5 Gm., 8 gr., U.S.P.

Oil of Myrist., U.S.P., B.P.—Distilled from the preceding. Dose, 0.2 c.c., 3 minims, U.S.P.; 0.01 to 0.18 c.c., 1.5 to 5 minims, B.P.

Sp. Myrist., B.P.—10 per cent. Dose, 0.3 to 1.5 c.c., 5 to 20 minims, B.P.

Senecio.—The alkaloids (seneciose and senecionine) of S. Jacobea and vulgaris produce in cattle toxic effects resembling those of volatile oils: Hemorrhages in abdominal organs, especially the liver; fatty changes, necrosis, congestion, and hepatic cirrhosis (Cushny, 1918). They have been used as emmenagogue. It has a slight depressant effect on the excised uterus (Pilcher, 1916).

Helenium Autumnale.—This contains a neutral bitter principle (Reeb, 1920), which is strongly irritant to mucous membranes. Systemically, it stimulates respiration and directly paralyzes cardiac and other muscle. It is not hemolytic (Lanson 1915).

Spewing Sickness.—A sheep disease of Utah, is due to the eating of Dugalea hoopesii, a composite plant, allied to Helenium and probably containing similar active principles. It produces also similar gastro-intestinal and cardiac symptoms (D. D. Marsh, 1910).

Eupatorium Urceolatum (Ageratoides).—The feeding on the green plant is said to be the cause of one form of "trembles" or "milking-sickness" of sheep; the symptoms consist in weakness and ataxia, ending in death (Curtis, 1917; Marsh and Clawson, 1917). The toxic principle is extracted by 95 per cent. alcohol (Sackett, 1919).

Other species of Eupatorium (Boneset) are used as diaphoretic tea.

VOLATILE OILS AND OLEORESINS EMPLOYED IN URETHRITIS AND CYSTITIS

Members and Uses.—The oil of Sandalwood and the oleoresins of Copaiba and Cubeb, and Matico are used mainly as urinary antiseptics in subacute and chronic urethritis, as adjuvants to local treatment, to diminish the pain and the discharge, and to hasten healing. Sarsaparilla oil is generally preferred. It is best administered in capsules, on a full stomach, so as to minimize gastric irritation. Buchu is used as a diuretic in catarrhal cystitis, Cubeb is sometimes employed in bronchitis.

Manner of Action.—The oleoresins are natural mixtures of resins and volatile oils rich in terpenes and terpen alcohols. The terpenes are excreted as glycuro nic compounds, which have a slight but distinct antiseptic action on the urine. This is much ameliorated by the presence of hexamethyleneamin; but it has the advantage that it is not affected by the action of the urine (Jordan, 1911); and probably they are specifically more effectual for certain bacteria. The mono- and divalent salts not only increase the excretion but also make the medicament more readily available.

Experimental Pleurisy.—Winteritz, 1901, and Pohl, 1912, found that the oral administration of various balsams, sarsaparilla oil, etc., appeared to have favorable effects on experimental ascitic pleurisy (aetumont, etc.) in rabbits. However, their doses are so much larger than the clinical, that the applicability of the experiments is doubtful.

Side Actions.—The gastro-intestinal tract is also irritated, resulting in anorexia, colic, eruptions, and diarrhea. These unpleasant effects are less pronounced with sarsaparilla oil, which therefore is preferred; and they may be further avoided by the use of the santonol esters, which are only dissolved in the intestines. Skin eruptions, scarlatiniform rash, etc., occur infrequently, either directly or from the digestive disturbance. Exacerbations of the oils produce more pronounced irritation of the enteral alterna-
tract, with kidney pain, albuminuria, and vesical tenesmus. Albuminuria may be simulated by the precipitation of the resin-acids with nitric acid; to be distinguished by the addition of alcohol, which dissolves the resins. Glycosuria may also be simulated by the glycuronic acid.

PREPARATIONS—VOLATILE OILS USED AGAINST GENITO-URINARY INFLAMMATION

_Buchu_, U.S.P. (Buchu Fol., B.P.); _Buchu._—The dried leaves of Barosma betalina (also of _B. serratifolia_, U.S.P.). Contains volatile oil, glucosid, bitter principle, etc. _Dose_, 2 gm., 30 gr., U.S.P.; best as infusion.

_Inf. Buchu_, B.P.—5 per cent. _Dose_, 30 to 60 c.c., 1 to 2 ounces, B.P.

_Fluid._ _Buchu_, U.S.P.—_Dose_, 2 c.c., 30 minims, U.S.P.

_Tr. Buchu_, B.P.—20 per cent. _Dose_, 2 to 4 c.c., 1/2 to 1 dram, B.P.

_Copalina _(Copalini),_ U.S.P., B.P. (Balsam of Copalina).—An oleoresin derived from South American species of Copaifera. Contains volatile oil and resin (copacetic acid). Pale yellow to brownish yellow, more or less viscid liquid, either without fluorescence or with only a slightly greenish fluorescence; having a peculiar aromatic odor, and a persistent, bitter and acidic taste. Insol. in water, partly sol. in alc., freely sol. in oils. _Dose_, 1 c.c., 15 minims, U.S.P.; 2 to 4 c.c., 1/2 to 1 dram, B.P.; in capsules or pills (with magnesium). The various "Laifayette," "Chapman" and similar mixtures are undesirable.

_Oil. Copalina_, B.P.—Distilled from the preceding. _Dose_, 0.3 to 1.2 c.c., 5 to 20 minims, B.P.

_Cubeba_, U.S.P.; Cubeb. Fruct., B.P.; Cubeb._—The dried, full-grown, unripe fruits of _Piper Cubeba_. Contains volatile oil and resin (cubebic acid). _Dose_, 1 gm., 15 gr., U.S.P.; 1 to 4 gm., 30 to 60 gr., B.P.

_Oleoresin._ _Cubeb._, U.S.P.—An evaporated alcoholic extract. _Dose_, 0.5 gm., 8 gr., U.S.P.

_Oil. Cubeb_, U.S.P., B.P.—The distilled oil. _Dose_, 0.5 c.c., 8 minims, U.S.P., 0.3 to 1.2 c.c., 5 to 20 minims, B.P.

_Tr. Cubeb_, B.P.—20 per cent. _Dose_, 2 to 4 c.c., 1/2 to 1 dram, B.P.

_Trock. Cubeb._, U.S.P.—_Dose_, 0.2 gm., 3 gr.

_Kwon Rhiz._, B.P.—From _Piper methysticum_.

_Est. Kowa Liqu._, B.P.—_Dose_, 2 to 4 c.c., 1/2 to 1 dram, B.P.

_M虱co._—The leaves of Piper angustifolium.

_Sabal_, U.S.P. (Saw Palmetto)._—The partially dried, ripe fruit of _Serenoa serrulata_.

Statements as to presence of alkaloids and volatile oils are contradictory. Has been used as nutritive tonic, alternative, in respiratory diseases, digestive disturbances, as aphrodisiac, etc. Of very doubtful value. _Dose_, 1 gm., 15 gr., U.S.P.

_Fidest._ _Sabal._, U.S.P.—_Dose_, 1 c.c., 15 minims, U.S.P.

_Sandal Oil Derivatives._—Sandal oil consists chiefly (90 per cent.) of santalol, C_{18}H_{30}O, a mixture of two sesquiterpen alcohol. This may be used in the form of its carbolic ester (Carbanosal, Santalolis Carbonas, N.N.R.), and of its salicylic ester (Santyl, N.N.R.). These are oily liquids, almost without odor or taste. _Dose_, 0.5 c.c., three times daily.

BALMSAMS

Balsams (Peru, benzoin, tolu, storax) are oleoresins containing cinchonic and benzoic acids. The oils act as antiseptics; the oils and resins are mildly irritant, stimulating repair; and the resins furnish local protection and thus allay inflammation. The balsams are therefore employed in chronic inflammations of mucous membranes (bronchitis) and of the skin (eczema and pruritus); and to promote the healing of ulcers and ulcers. Myrrh acts similarly. The balsams are also used locally against acne, destroing the acarus and their ova. Peru balsam is employed externally as a poultice for tuberculosis (for intravenous use, see "Cinamic end in sec.

172 MANUAL OF PHARMACOLOGY
Acid”). Its internal administration is of doubtful utility, as is also the internal use of other balsams in bronchitis. Even large doses of the balsams do not produce albuminuria (Stockman, 1891).

PREPARATIONS—BALSAMS

**Benzoinum**, U.S.P., B.P.; Benzoin (Gum Benjamin).—A balsamic resin obtained from Styrax Benzoin and other species growing in the East Indies. *Dose*, 1 Gm., 15 gr., U.S.P.

Tr. Benz., U.S.P.—20 per cent. *Dose*, 1 c.c., 15 minims, U.S.P.

* Tinctura Benzoini Composita (Tr. Benz. Co.). U.S.P., B.P.; Compound Tincture of Benzoin (Friar’s Balsam, Burlington’s Balsam).—10 per cent. of Benzoin, with Aloes, Storax, and Tolu, in alcohol. *Dose*, 2 c.c., 30 minims, U.S.P.; 2 to 4 c.c., 1/2 to 1 dram, B.P., as stimulant expectorant; as inhalant, teaspoonful to cup of boiling water; externally, mixed with glycerin or water, as lotion for chapped hands. The original formula was much more complex; and the present formula is still needlessly complicated and expensive. When used as inhalant, the steam contains a trace of oil and benzoic acid (Peacock and Deq, 1910), which would be deposited on the mucous membranes. The same results would probably be secured more simply by substituting the official Tr. Tolu.

* Balsamum Purunum (Bals. Peruvi., U.S.P., B.P.; Balsam of Peru.—A balsam obtained from Toluyera Pereira, Central America (not from Peru); often adulterated. Dark brown, viscid liquid of agreeable vanilla odor and persistent bitter acrid taste. Freely sol. in alc. *Dose*, 0.5 to 1 Gm., 5 to 15 minims, B.P. Externally on lint; in ointment, 2 to 3 Gm., four to six times in the day.

It is used generally diluted with parts of castor oil as a stimulant to indolent ulcers.

It is said to promote healing without stimulating granulation; but it is sometimes irritating.

Styrax, U.S.P.; Styrax Praep., B.P.; Storax.—A balsam obtained from the wood and inner bark of Lpidiumbar orientale. *Dose*, 2 Gm., 15 gr., U.S.P.

Balsamum Toluolnum (Bals. Tolu.,) U.S.P., B.P.; Balsam of Tolu.—A balsam obtained from Toluyera Balsamum. A yellowish-brown or brown, plastic solid, becoming brittle when old, dried, or exposed to cold; pleasing, aromatic odor, resembling that of vanilla; mild, aromatic taste. Sol. in alc. *Dose*, 0.5 to 1 Gm., 5 to 15 gr., B.P.

Tr. Toluol., B.P.—10 per cent. *Dose*, 3 to 4 c.c., 1/2 to 1 dram, B.P.

**Spr. Toluol., U.S.P., B.P. (see Index.)**

PREPARATIONS—AROMATIC RESINS

**Ammoniacum**, B.P.—Gum resin exuded from stem of Dorema species. *Dose*, 0.5 to 1 Gm., 2 to 15 gr., B.P.

**Mist. Ammoniac**, B.P.—1 per cent. *Dose*, 15 to 30 c.c., 1/2 to 1 ounce, B.P.

Gallium.—Gum resin from Ferula galbaniflua. *Dose*, 0.5 to 1 Gm., 4 to 15 gr., B.P.

**Mastic. Mastic.**—Resinous exudation from Pistacia Lenticus. **Mastic Vormittis**. These have been used in surgery to fix the skin-bacteria on the hands and operative area. They are brushed on, and allowed to dry. The skin may be treated with iodin. Various formulae have been published (Merck’s Rep. 27: 343, 36: 279, 1923). Borchardt’s consists of mastic 20 Gm.; benzene 60 Gm., castor oil 20 drops; litter. The basis of Heuberger’s resin, of Diethrich’s dammar.

**Myrrha.** U.S.P., B.P.; Myrhh.—Gum resin from Conmiuphora species. *Dose*, 0.5 Gm., 8 gr., U.S.P.; 0.5 to 1 Gm., 3 to 15 gr., B.P., as carminative. Was used by the ancients as incense in religious ceremonies; and by the Egyptians in embalming, in combination with spices.

**Echynoc.** U.S.P., B.P.—20 per cent. in alcohol. *Dose*, 1 c.c., 15 minims, U.S.P.; 1 to 4 c.c., 1/2 to 1 dram, B.P. Used especially as mouth wash (1 : 25) in stomatitis and pharyngitis; as a lotion, 1 : 5 or 10.

PREPARATIONS—RESINOUS DRUGS

**Echynoc.**—The root of Echynace angustifolia (Purple Cone Flower). It contains resin, and no alkaloids (Heyd and Staley, 1934). Several proprietary preparations have been praised for dialegogue, diaphoretic, antiseptic, stimulant, and general alterna-
tive effects (Lloyd, 1904; Madden, 1905); but no good evidence of its value has been published and the claims appear extravagant (J.A.M.A., Nov. 27, 1909). Dose, 1 to 2 Gm., 15 to 30 gr. U.S.P.

**Grindelia, U.S.P., B.P.**—The dried leaves and flowering tops of Grindelia camporum (also Grindelia squarrosa, U.S.P.). Contains an amorphous resin (probably the active principle), sugars, proteins, tannin, and a very small quantity of volatile oil, no saponin or alkaloid (Power and Tutin, 1925). It is said to relax the muscular coats of the bronchi and diminish the excretion of mucus. It is therefore used in asthma and bronchitis. Dose, 2 Gm., 50 gr. U.S.P.

**Festuca, U.S.P.; Festuca, L., B.P.—Dose, 2 Gm., 2 c.c., 30 minims, U.S.P.; 0.5 to 1.5 c.c., 10 to 20 minims, B.P.** Also employed locally in ivy poisoning.

**Tr. Pyreth.**, U.S.P., B.P.—20 per cent.

### INSECTICIDES

Certain volatile oils, or drugs containing them, as also poisons belonging to other groups, are used to kill or repel noxious insects, such as *Mesquites, Roaches, Flies,* etc. "Insect Powder" (the powdered flowers of Pyrethrum species—Peruvian Powder—and of *Chrysanthemum cinerarinifolium*—Dalmatian Powder); *Eucalyptus, Menthol, Erigeron, Cedar,* and Lavender may be cited. (Roach powders commonly contain sod. fluorid or borax; arsenic is efficient, but dangerous; White Hellebore is also poisonous.) Naphthalin and Camphor are used against moths.

The physical properties, volatility, spreading power, etc. are important, as well as the chemical toxicity (W. Moore and Graham, 1918; bibliography).

**Pediculosis.**—The experiences of the war have greatly revied the interest in insecticides against these parasites. Mercury, staphisagria, phenol, etc., are effective against limited infections; but they are too toxic and irritant for extensive application. Naphthalin and volatile oils stupefy and paralyze the parasites, but they are likely to recover subsequently. Acids are definitely fatal. Sulphur dioxide is effective (Knafl-Lens, 1915).

Oiling of underwear destroys the lice mechanically (1 c.c. of oil per 4 square inches of medium weight underwear).

Of chemical substances, the most promising appear to be cresote and especially heliotropin (piperonal). The latter must be applied in thecromoa oil solution (W. Moore, 1918).

**House-fly.**—The toxicity of organic compounds is generally proportional to their volatility (W. Moore, 1917).

**Mosquitos.**—Nearly all volatile oils when mixed with fat tend to protect up to 2 hours. Presumably they obscure the human odor (Bacet and Talbot, 1919).

### MUSTARD OIL

**Actions and Uses.**—The volatile oil which is developed from black mustard on contact with water, produces a more prompt, more violent, and more penetrating irritation than the other volatile oils. Mustard preparations are extensively used for counterirritation, but care must be taken to stop the application when marked tingling is felt, or there may be vesication and even ulceration. Internally, mustard is used as a condiment; larger doses to 4 3 in a tumbler of warm water) produce vomiting; still larger doses cause violent gastro-intestinal irritation. Boiling water prevents the development of the oil by destroying the ferment.

**Composition.**—Volatile oil of mustard (allyl isothiocyanate, CH,NC,CS, is derived from *black mustard* by the action of a ferment, myrosin, on the glucosid sinigrin (potassium myrosmate). The latter itself is not irritant. Mustard seed also contains about 25 per cent. of bland fixed oil.

**White mustard** contains a similar ferment and glucosid, sinibrin, which yields an analogous oil, acryl isothiocyanate. Much less volatile oil is liberated than with black mustard. White mustard seeds have a cathartic action, due to the liberation of H,SO, on contact with water. Large doses may produce sulphid poisoning, with cyanosis, etc. (van Leeuwm, 1916).
DICHLOL-DIETHYL-SULPHID

Similar sulphur-containing oils are formed in other cruciferous plants, such as horseradish, radish, cress; and in onion, garlic, etc.

Plants containing mustard oil (Bursa pastoris) stimulate the contractions of the excised uterus (Grobier, 1915).

PREPARATIONS—MUSTARD

Armoracia Raŭs, B.P.—Fresh Horseradish Root.
Sp. Armor. Co., B.P.—Dose, 4 to 8 c.c., 1 to 2 drams, B.P.
Sinapis Alba (Sinap. Alb.), U.S.P.; White Mustard.—The ripe seeds of Sinapis alba. 
Dose, as emetic, 10 Gm., 2½ drams, U.S.P., of the powder, in tepid water.
* Sinapis Negra (Sinap. Neg.), U.S.P.; Black Mustard.—The ripe seeds of Brassica nigra. 
Dose, as emetic, 10 Gm., 2½ drams, U.S.P., of the powder, in tepid water. 
Powdered mustard is applied as a poultice, mixed with 2 to 10 parts of flour and enough water to make a paste; it may also be sprinkled on the surface of the ordinary lined poultice. It is used in foetubátores for preventing colds (1 to 2 ounces to a gallon); and in general baths for infantile coxa (large tablespoonful to small bath).

* Emplastrum Sinapis (Emp. Sinap.), U.S.P.; Mustard Plaster (Charla Sinapis, Mustard Paper).—A mixture of de-fatted black mustard and rubber, uniformly mixed and spread on paper, cotton cloth or other fabric. Mustard plaster is moistened thoroughly with warm (not hot) water, and applied to the skin for fifteen to thirty minutes.

* Oleum Sinapis Volatile (Ol. Sinap. Vol.), U.S.P., B.P.; Oil of Mustard.—A volatile oil produced synthetically or obtained from the seed of Brassica nigra, consisting chiefly of allyl isothiocyanate (CGLSCN). Colorless or pale yellow, strongly refractive liquid, having a very pungent and acrid odor and taste. 
Dose, 0.0008 c.c., ¼ minim, U.S.P. 
It may be used as counterirritant in ½ to 2 per cent. solution in 50 per cent. alcohol (Herfield, 1906).

Mustard oil is more irritating in aqueous than in oily vehicles (Sollmann). A 2 per cent. suspension is 3 per cent. tragacanth paste represents an effective counterirritant, equal to a 3 per cent. ointment (Ewe, 1970).

* Lim. Sinap., B.P.—3.5 per cent. of Ol. sinap., 3.5 per cent. of Camphor.

DICHLOL-DIETHYL-SULPHID, "MUSTARD-GAS"

General Statement.—This substance acquired great importance as the "blistering-gas" of the war. It was also known as "Yperite," "Yellowcorsh shells" and as thioglycol chlorid. It has the formula

\[ \text{C}_2\text{H}_5\text{Cl} \]

It is an oily fluid of sharp odor, but not related to "mustard oil."

Contact with the fluid or its vapor does not produce any immediate effect whatever; but after a latent period of some hours, intense inflammation develops at the site of contact, even after minute traces. This leads to vesication, followed by local necrosis with very slow healing. The lesions, however, are superficial and extend but little beyond the actual contact. Secondary Infections are common, as the resistance is lowered.

The local phenomena have been attributed to the intracellular hydrolysis of the substance, with liberation of hydrochloric acid. The toxic effect would thus be due to intracellular acidosis.

The intoxication is usually strictly local, involving the skin, the eyes, the respiratory and sometimes the alimentary mucouses, according to the method of application. Systemic intoxication usually occurs only by intravenous injection.

The treatment of the local lesions is mainly by cleanliness and emollients, similar to that of burns. Oils also protect the skin, but only very
slightly. If the patient is seen immediately after exposure, the poison may be partly removed by scrubbing with kerosene; but the penetration is so rapid that this treatment is not successful if delayed for 15 or 30 minutes.

Historical.—The substance and its toxic effects were discovered by Victor Meyer in 1880 (Ber. deut. chem. Gesell., 1886, v. 19, p. 3250, v. 20, p. 1720).

Military Use.—"Mustard Gas" was first used on a large scale by the Germans at Ypres, July 32 and 14, 1917. At first it scored heavily, since its peculiar properties were not at once appreciated. It differs from the other gases in two essential respects: (1) its effects are delayed several hours, so that effective protection is apt to be neglected; and (2) it is very persistent, so that areas that have been shelled with it are infective for several days.

This persistence is due to the limited volatility of the liquid at ordinary temperatures. When atomized by the explosion of the shell, it spreads as a mist, which condenses as a liquid film on any solid substance, leaves, canoes, the ground, etc.; and thus forms deposits that are dangerous both by direct contact, and because their slow evaporation keeps up a prolonged saturation of the air with the poison. This holds especially for valleys, trenches, etc., where the air is stagnant.

When occupying an area which has been heavily shelled with mustard, respirators must be worn almost continuously; this and the insidious course of the poisoning are a severe test of morale. However, since its dangers have been fully recognized, they are greatly diminished.

Physical Properties.—Dichloroethyl sulphide is a colorless or pale yellow, heavy, oily liquid of neutral reaction.

When pure, it has a faint but penetrating odor, reminiscent of stale ether and of mustard oil. This is the source of its popular name, "Mustard Gas," for it is not derived from true mustard oil. The odor of the crude product is more pronounced and similar to garlic. It is due mainly to contamination with ethyl sulphide.

Toxic concentrations of mustard gas can generally be smelled in the air. However, there is considerable difference in individual sensitiveness. Further, the odor is sometimes disguised by adding other substances.

Solubility.—Dichloroethyl sulphide is generally soluble in fats and fat-solvents and alcohol, but is only very slightly soluble in water (0.02 per cent. at 10°C, E. F. Hopkins). Its solubility increases with the temperature, but it is rapidly hydrolyzed.

Chemical Properties.—The toxic action of dichloroethyl sulphide is intimately connected with its combustion, particularly with the presence of the two chlorine atoms. If these are either diminished or increased, the activity is destroyed. This may be accomplished, and the "mustard gas" may be "killed" by hydrolysis, chlorination, and by reducing agents evolving nascent hydrogen; less efficiently by oxidizing substances.

Hydrolysis.—Dichloroethyl sulphide is hydrolyzed by water, probably mainly according to the equation:

\[ (\text{C}_2\text{H}_4\text{Cl}_2 + 2\text{H}_2\text{O} \rightarrow 2\text{C}_2\text{H}_4\text{OH} + 2\text{HCl} \]

The hydrolysis starts promptly and proceeds fairly rapidly for the dissolved substance. The undissolved substance is not hydrolyzed, of course. For this reason, and because of the limited solubility of the substance, the hydrolysis of any excess of dichloroethyl sulphide proceeds very slowly.

Hydrolysis Theory of Toxic Action.—It has been suggested that the dichloroethyl sulphide penetrates as such into the cells, and is there slowly hydrolyzed, resulting in a liberation of free acid within the cells; and that this free acid is really the toxic agent (Lynch, Smith and Marshall, 1918, J. Pharmacol., 12: 265).

The plausible assumption would explain the delayed effects, and is in consonance with most the facts so far as known. It is established that the substance is hydrolyzed before it is excreted; and, there is proof that this hydrolysis may occur within the cells at the place of application, at least in the cells that have been examined.

Evidence for Hydrolysis Theory.—This is summarized by Lynch, Smith and Marshall, loc. cit. The most direct evidence is furnished by invertebrates, especially star-fish ova (Lillie, Cleaves et al., 1918, 1919):
The toxicity of a saturated watery solution decreases rapidly and parallel to the hydrolysis; i.e., the toxicity depends on the penetration of the undecomposed substance into the cells.

Latency.—When ova are exposed for say 8 minutes to the solution and then washed, cleavage progresses normally for 2 hours, when changes start. This coincides with the appearance of free ac d; i.e., the effect appears only when enough acid is developed to neutralize all buffer substances.

The latent period is therefore much prolonged if hydrolysis is slowed by low temperature.

Further proof is furnished by intracellular injection: Eggs injected with water are not materially injured. Those injected with fresh dichlorethylsulphid solution show no immediate effects, but are killed later. Those injected with hydrolyzed dichlorethylsulphid solution are injured immediately about to the same degree as eggs injected with hydrochloric acid of the same acidity.

Destruction of "Mustard Gas."—This may be accomplished by chlorination or dechlorination; or less efficiently by other chemical changes.

Chlorination.—Free chlorin, as gas or dissolved in carbon tetrachlorid, introduces a third chlorin atom somewhere into the dichlorethylsulphid, forming "monochloromustard gas" which is nonirritating. Sulphur dichlorid, pure or dissolved in carbon tetrachlorid, is also highly effective, and is used to "kill" the gas. It is, however, corrosive to organic matter.

Dry hypochlorites chlorinate and destroy the substance readily, with evolution of heat. "Bleaching powder" is very useful as a "kill."* Chloramin T and dichloramin T also react vigorously with "mustard." With these, the reaction appears to be more complicated; but the irritative qualities are destroyed.

All chlorinating agents must be applied as concentrated and especially as dry as possible; else the immiscibility of "mustard" with water prevents intimate access of the chemicals.

TOXIC EFFECTS OF MUSTARD GAS

"Mustard gas" differs from the older war "gases" in that its serious effects are not confined to the respiratory tract. Pulmonary lesions, when they occur, are indeed the most fatal manifestations; but there are also very important actions on the eyes and skin; and sometimes fairly severe gastric disturbances. Even direct systemic effects occur (Lynch, et al., 1918) although these are only faintly indicated in field or factory intoxications.

Slow Course.—The delayed start of the action has been attributed to gradual hydrolysis. This could scarcely explain the delay of over a day. More likely, it is simply the expression of the sluggish character of the inflammation.

Precipitation of proteins by dichlorethylsulphid is also very slow. Excised skin, muscle and mucous membrane are not grossly altered.

Development of Symptoms.—The variations introduced by differences in concentration and other conditions will be discussed later. The following represents the usual stage of the phæo-omena as they occur under field conditions without protection:

No effects are felt immediately on exposure, except in high concentrations, when there may be tendency to sneeze, with or without smarting of the eyes. Hemorrhage, especially from the nose, is a common early symptom (Berghoff, 1919).

The first definite symptoms are generally from the eye, starting 2 or 3 hours after exposure, with the smarting and watering; proceeding to reddening, pain, edema and all the phenomena of acute conjunctivitis. The nose also reacts early with increased secretion and sneezing. The throat likewise becomes sore.

In 4 to 6 hours after exposure, these symptoms have become much more marked and disturbing. The eyes are discharging and very painful; the nasal discharge is more pendent; the voice is husky or suppressed.

Nausea, retching and vomiting, associated with epigastric pains, occur in a large proportion of cases and may recur at frequent intervals for several hours. In severe
cases, they may become very intense and prolonged. Diarrhea may set in, but is rather exceptional.

Skin-rashes also show in this period, as a dusky erythema of the exposed parts of the body, and in the axilla, crotch and genitals. At the end of 24 hours, the eye-symptoms have assumed a very characteristic form in the severer cases. They are very painful, with the lids swollen almost shut, and oozing tears. There is photophobia and blepharospasm, and generally frontal headache.

The exposed skin is further reddened, and swollen and may be itching. The nose discharges freely. The throat feels raw and burning. Aphonia may be complete. A dry harsh cough may develop. The respiration is fairly normal.

Death practically never occurs during the first day. During the second day, the skin erythema may have developed into blisters, sometimes of large size, with the scrotum and penis especially painfully swollen. (The further course of the skin lesions will be discussed later.) The eyes become somewhat less painful, although the acute inflammation may persist for several days.

This is also the time when the inflammation of the respiratory tract becomes conspicuous in severe cases. The expectoration becomes abundant, mucous-purulent, sometimes with large sloughs of tracheal mucosa. This is complicated by secondary infection of the necrotic respiratory membranes. Fever sets in, with rapid pulse and respiration. The infection may terminate in broncho-pneumonia, with death anywhere between the second day to the fourth week.

Most cases, fortunately, are of a milder type; especially as the troops acquire familiarity with the gas and apply the protective measure more stringently. In the opening of the 1918 campaign, the mustard mortality was slight. There were very few actual blisters, although minor rashes were common. The conjunctivites were less severe; the laryngites fairly mild, but almost universal. Most mustard field cases have only slight respiratory catarrh. Only about $0.2$ per cent. are burns (Underhill, 1918).

During the hot months, there is an increase of the pulmonary lesions; perhaps because of the greater volatilization. In factory poisoning, most of the burns were of the hands, arms and fingers (Young, 1919).

Relation of Symptoms to Concentrations, for Men.—These may be observed in factories:

1. **Vapor of Very Low Concentration.**—This produces only conjunctivitis. Continued exposure may impair vision. It should therefore be prevented by precautions of ventilation, leakage, etc.

2. **Vapor of Moderate Concentrations.**—This produces severe conjunctivitis, bronchitis and laryngitis (to name a few); and diffuse areas of erythema. These effects are directly dangerous, especially on prolonged exposure.

3. **Vapor of Higher Concentrations.**—This is felt rapidly in the eyes. Burns occur in the skin and mucous from 1 to 5 hours. If inhaled, it is followed by destructive inflammation of the upper air passages and eventually by pneumonia. Exposure may be followed by nausea, vomiting and collapse.

4. **Liquid Mustard.**—This causes severe destructive dermatitis, blisters, ulcers, etc., as will be discussed later.

Symptoms with Dogs Exposed to Dichloethylysulphid Vapors.—The effects of mustard vapor on animals are essentially identical with those on man (Lynch, Smith and Marshall, 1915, J. Pharmacol., 12: 285). They may therefore be utilized to study such problems as the concentration required to produce certain results, and they are especially useful for the study of the symptomatology and pathology of the severer types, such as are fortunately rarely seen in men.

Relation to Concentration and Exposure.—The severity follows very closely the product of the concentration (mg. per liter air) by the time of exposure (minutes). For dogs, this "milligram-minute" factor is a for the fulminating type; 1.5 to 3 for the acute type of poisoning; and less than 1.5 for sublethal type, if the total exposure does not exceed 1 hour. With 2 hour exposure, the factor may be doubled. 0.001 mg. per liter may produce casualties after exposure of 1 hour, and almost certainly with 3 or 4 hours. The effects of the lowest concentrations are confined to conjunctivitis and skin "rash," which may, however, be very uncomfortable. These may occur with concentrations that are not sensible to the nose—there being no definite relation between the sensitivity of the skin, conjunctiva, and smell (Reed, 1918, 1920).

Toxicity for Animals.—This is fairly uniform for different species, there being less variation for species than there is for individuals (Marshall et al., 1918).

Air saturated with dichloethylysulphid at ordinary temperature would hold about 0.5 mg. per liter. This would be fatal if breathed for 7 minutes.
DICHLOR-DIETHYL-SULPHID

Concentrations of 0.01 to 0.02 mg per liter have a 50 per cent. mortality with a 2 hour exposure, and 50 per cent. with 4 hours. Less than 0.001 mg per liter (1:700,000 by volume) is not fatal even with 8 hours exposure, but produces slight symptoms from the mucous (conjunctiva, nose, appetite).

LESIONS IN UPPER RESPIRATORY TRACT

The corrosive effects on the epithelium are identical with the corrosion of other epithelial surfaces. Their intensity diminishes from the mouth and nose toward the lungs. The bronchi are involved only in the severest cases. Sub-epithelial edema is much less than in the skin or conjunctiva (Warthin and Wellier, 1910).

The primary action is followed by local edema of the trachea or diphtheritic lesions from the nose to the bronchi, even in the mildest cases. In the more severe, there is a marked pseudomembrane formation, secondary purulent bronchitis and broncho-pneumonia (Warthin and Wellier).

The rhinitis, laryngitis, tracheitis and bronchitis play a conspicuous part in the minor as well as in the severe intoxications of mustard gas. Their symptomatology has been sufficiently outlined. The anatomic changes consist in intense congestion, often hemorrhage. In the severer grades this passes into necrosis and desquamation of the mucous, often in large masses. These may interfere with respiration; but more commonly the lesions become infected, ending either in pneumonia or in slow healing.

The congestion is visible early in the nose and mouth, the pharynx, epiglottis and larynx, and extends through the trachea into the finest bronchial tubes. Epithelitis is a common early symptom (Berghoff, 1915).

In the trachea and bronchi the necrotic mucous, and the purulent exudate form a continuous thick, pale yellow false membrane, which is easily detached in large strips. This false membrane formation extends into the bronchioles, where it may occlude the lumen. Incomplete occlusion of a bronchial branch results in emphysema of its ramifications. When the occlusion becomes complete, the air is absorbed, and the corresponding lung area collapses. Thus, emphysema and atelectasis may occur in different portions of the same lung.

The lesions are for the most part little affected directly, presumably because most of the substance is bound and absorbed before it can reach them. Consequently there is no acute pulmonary edema, in the early stages, and no fluid or froth in the air tube; although there may be considerable congestion and some epithelial desquamation.

However, the serious cases become infected by bacteria, and then change to an extensive broncho-pneumonia, with its ordinary phenomena, which may bring about a secondary edema.

In case of recovery, the ulcers of the mucous heal slowly. Ulceration of the trachea may be followed by constriction of its lumen.

TREATMENT OF THE RESPIRATORY LESIONS.—The rhinitis is treated along the usual lines: by frequent spraying or instillation of a few drops of 1 per cent. sodium bicarbonate, followed by a liquid petrolatum. When the condition is not too painful, a few drops of 1 per cent. dichloranin T in chloroform may be introduced several times daily. The mouth and throat may be gargarized with a weak Dakin's or 2/3 to 3/4 per cent. chloramin T solution.

For epiglottic and mild bronchitis steam inhalations may be used, with or without compound tincture of benzoin. An ice-bag may be applied to the larynx.

The severe bronchitis and pneumonia are treated as in ordinary practice.

EYE LESIONS FROM “MUSTARD GAS”

The cornea and conjunctiva are highly sensitive to the “mustard” irritation, and present the earliest and often the most serious symptoms after unprotected exposure to the vapor. Identical effects are produced by contact with the liquid poison. A previous eye burn increases the susceptibility.

Light cases may heal in 3 or 4 days. In severe poisoning the inflammation is insidiously painful for several days, and ocular symptoms may persist for several weeks. Fortunately the deeper structures of the eye are not affected, except under extreme conditions. Consequently, nearly all cases recover without permanent injury, except at most some reduction of vision from cicatrization of the cornea. Severe eye injuries limited in only about 1/5 per cent. of the gassed (Tenferen, 1918).

The course and pathology of the lesions has been studied in detail on rabbits and are essentially the same as for skin lesions, the difference being merely quantitative. The healing process is also similar. The following data are taken mainly from Warthin and Wellier, 1918, J. Lab. Clin. Med., 4, No. 1.
Conjunctival Lesions.—With strong doses (exposure for fifteen minutes to 1:20,000 vapor, or 0.002 c.c. of the liquid) conjunctival irritation and lacrimation occur almost immediately. Within half an hour, hyperemia is usually well marked; and edema sets in within an hour and progresses to the twelfth hour. Toward the end of this period, small subconjunctival hemorrhages may occur. In man, there may also be minute vessels.

The edema begins to subside by the end of the third day.

Microscopic examination of the active stage shows less necrosis than exists in the cornea. There is extreme edema of the subconjunctival tissue, usually followed by liquefaction necrosis and leukocytic infiltration.

Corneal Lesions.—The necrotic changes start in the corneal epithelium and extend through the other layers. This special susceptibility of the cornea is perhaps explainable by the absence of circulation, so that the poison is not removed.

Close examination in 6 or 8 hours will show that in 8 hours the cornea may appear like opalescent porcelain. In the milder cases, this gradually disappears after the third week. In severe cases, it is followed by vascularization and cicatrization with permanent impairment of vision.

Exudate.—The sero-purulent exudate sets in early and may be well developed by the 5th or 6th hour, increasing and sealing the eye-lids by the 10th hour, so that the subject is practically blinded. The lids may be opened by soaking, but in severe cases the sealing recurs to about the third week.

Corneal Ulceration.—This is shown by the fluorescein stain. In rabbits, it appears about the second or third day, and lasts to the fourth or sixth day. Infection is rare (Hess and Barba, 1918).

The changes in dogs and goats are about the same as in rabbits.

Interior of Eye.—Leukocyte infiltration and exudation into the anterior chamber is common. The edema may involve the iris and ciliary body. Involvement of the posterior chamber is exceptional and slight. Panophthalmitis does not occur.

Sensitivity of the Eyes.—This is fairly uniform for different species and individuals, if uniform access of the poison is assured; otherwise the results naturally differ according to whether the eyes are kept open or shut during exposure to the gas.

Eye-sensitivity to Vapor in Human Subjects.—Reed, 1920, reports that 1:10,000,000 (0.0006 mg. per liter of air) produced visible ocular reaction with exposure of less than 1 hour. The skin was sometimes affected in highly susceptible individuals. 1:5,000,000 (0.0012 mg. per liter) for 45 minutes caused quite severe reaction of the mucous membranes, and itching and desquamation of the skin.

Eye-sensitivity of Animals.—The following threshold concentrations were found for dichloralin in a vapor chamber (Marshall and others, 1918):

 Conjunctivitis: 0.001 mg. per liter for 2 hours, or 0.003 mg. per liter for 1/2 hour.

 Corneal ulceration: 0.01 mg. per liter for 3/4 hour.

Solutions in liquid petrolatum give the following results on rabbits (Hess and Barba):

 o.06 per cent.: no effect.

 o.1 per cent.: slight congestion in 24 hours.

 o.25 per cent.: moderate congestion and edema in 24 hours.

 o.5 per cent.: effects more marked; slight clouding of the cornea.

Treatment of the Eye Lesions.—The conjunctiva should be kept clean by frequent irrigation with saturated boric acid, or with 1 per cent. sodium bicarbonate, followed by a few drops of oil. Light-weight cold compresses of saturated boric solution should be applied continuously for 12 to 24 hours, or longer if needed, to relieve the pain and discomfort, reduce the congestion and protect the eyes against light pressure. On the eye-lids must be avoided.

This treatment will also tend to prevent adhesion of the eyelids. If they do become glued together, they must be soaked in boric or bicarbonate solution until they can be opened without force. Forceful opening is liable to do harm.

Organic silver protein salts have been used, but are probably undesirable. They might cause permanent staining. Cocain is also advisable since it could only give temporary relief.

Dichloralin T, 0.3 to 1 per cent. in oil, has been recommended, but would probably be quite painful. Dakin's solution is too irritant.

In corneal ulcers produced by vapor in dogs, Hess and Barba, 1918, found that irrigations with the following solutions, every 4 to 24 hours, had no influence whatever on the natural course of healing: Sodium bicarbonate; 1 per cent.; potassium permanganate, 0.1 per cent.; sodium carbonate, 0.25 per cent.; chlorammon T, 0.1 per cent.

In the event that "Liquid Saline" is splashed into the eyes, this should be washed at once with the 1 per cent. dichloralin T solution.
SKIN BURNS

Dichloretyl sulphid penetrates the skin very rapidly. The effects of the liquid or vapor are absolutely identical, differing only in extent and intensity; vapor burns being usually more extensive but less severe. The susceptibility varies considerably in different individuals, and is also influenced by temporary conditions.

The burns range in intensity from simple rubefaction, through edema, vesication and necrosis. Although severe, the inflammation remains confined to the skin, perhaps because the circulation prevents its accumulation in the deeper structures.

Bibliography.—The phenomena are described by Warthin and Weller, 1918; Marshall, Smith and Lynch, 1918; Sollmann, 1919.

Course.—The inflammation has a rather striking course. There is a latent period, of 1½ hours to 2 days, before any sign of inflammation can be seen or felt. Then the inflammation gradually increases, then remains stationary, and slowly heals. The duration of the stages depends on the severity of the exposure. Light burns appear late and heal early; severe lesions appear early and heal late.

The "mustard" burns resemble X-ray and drug dermatites rather than simple heat burns.

In principle, they do not differ from the course of other toxic dermatites; but it differs in detail: (1) in the length of the latent period, and (2) in the absence of all pain until the ulceration stage has set in. That is, not only are mustard burns imperceptible when first received, but they remain so until the blisters break, about the 3d or 4th day. This is not due to anesthesia.

In the mild rashes, the skin edema causes intense itching about the same time.

The very tedious and slow healing of the necrotic lesions is due to injury of their blood vessels. Moreover, they generally become somewhat infected, but only superficially. There is little or no fever. The lymph-nodes, however, are swollen and painful quite early.

Skin Rash.—Erythema occurs as the first stage of all "mustard" lesions. Vapor burns and dilute solutions (f.i., saturated watery solution) do not usually progress beyond this stage. In such cases the entire course is confined to the "rush." Practically everyone who works with or around mustard gas is liable to the frequent occurrence of these rashes; and they are probably the most common form of "burns" in the field.

The rashes present varieties of intensity and duration, according to the dose, location and susceptibility.

Rashes also commonly surround the blister-burns for considerable distances. A patch of liquid mustard on the skin will produce a circumscribed blister of the underlying skin by direct contact; but the excess of the dichloretyl sulphid evaporates from the cloth, and the vapor spreads between the clothing and skin, until it is confined by a belt, garter, gaiter, etc. The axilla and groin are especially affected.

The lightest degree is that of simple reddening, coming on 24 hours or later after exposure, accompanied by some heat and itching. With the severer grades, the reddening is more intense, the skin markedly swollen, and the heat, burning sensation and itching become almost intolerable, interfering materially with sleep. This varies not only with the intensity, but also with the extent and the location of the rash. A given degree of erythema, when confined to a small area, may give so little trouble that it is only discovered accidentally, while a larger area, when affected to the same degree, may be very troublesome. Creases of the skin that are subjected to pressure on movements, f.i., the inner bend of the elbow and the axilla, are especially uncomfortable when the skin becomes swollen. The itching becomes worse on friction, f.i., after washing and drying the hands.

Severe grades may develop minute millary blisters. These may give the skin the appearance and feel of pebbled cellophane. The edema is confined to the epidermis and papillary layer.

The inflammatory phenomena persist for several days, and then gradually subside, within a week or two, leaving generally some pigmentation, and hypersusceptibility to irritation.
Pigmentation.—This may take various forms. It may have the red appearance of weather-exposure; or be more or less “tanned” as by the sun. In severe burns, the pigmentation is sometimes almost black, but confined to the superficial desquamating epidermis.

Erythema Preliminary to Vesication.—Erythema also constitutes the first stage of the blister-burns. In that case it appears much earlier, is more sharply localized, and undergoes vesication after one or two days.

Prognostic Significance.—The time when the erythema first becomes noticeable is of prognostic value.

If the skin shows pink or livid spots within 1½ hours after exposure, the burn will develop into a deep blister, and probably undergo ulceration and scarring. If the pink spots start between 2 or 3 hours after exposure the blisters will be superficial, and will probably heal without ulceration, and without real scarring. If the rash is delayed for 12 to 48 hours, it will not develop into blisters.

Blister Burns.—When strong vapor or especially when liquid dichloroethyldiphenyl comes in contact with the skin, the erythema passes into vesication. The first noticeable change is a silvery appearance of the skin, produced by loosening of the epidermis. This is then raised by the accumulation of fluid; the blister is usually well developed in 12 hours, and reaches its maximum size in about 24 hours.

The blisters at first are very tense, often an inch or more high, and may be up to 1 or 2 inches in diameter. They are filled with a transparent gelatinous material, i.e., practically coagulated plasma. If they are opened at this time, the contents stand up like a jelly, and require to be pushed or scooped away.

Between the second and third day the serum begins to separate from the clot. The “skin” of the blister becomes very thin and wrinkles as the serum is absorbed, and opaque balls or shreds of the fibrin are seen within the blister. Generally the blister breaks, and the serum, as it separates, drips in a continuous slow stream from the wound. This gives the patient a very distressing and uncomfortable appearance, especially if the genitalia are involved. In fact, however, the process is absolutely painless up to this time, and this without any anesthetics.

If the blister is undisturbed, it may be a week before it is fully collapsed. About 3 days after exposure, the blister begins to become painful, especially on exposure to air, or mechanical contact, or when treated with chemicals. This sensitiveness increases rapidly to the fifth or sixth day, and the pain becomes very severe. This hypersensitiveness lasts for 2 or 3 weeks, or even longer if ulceration develops. However, the lesions become painless long before the ulcers are healed.

With relatively small doses, the blisters are confined strictly to the area that was in contact with the gas, and are surrounded by a narrow zone of erythema. In more serious burns the blisters themselves extend somewhat, but not much farther, and the erythematosous area may be extensive, but this is largely due to the evaporation producing a vapor burn, as explained.

The size of the blisters is not an indication of the severity of the lesion: the largest blisters may be healed in 2 or 3 weeks, while another smaller blister, nearby, goes through a tedious ulceration that is healed only by scarring after 6 or 8 weeks. In fact, the severest lesions (the gangrenous form) do not blister at all.

When a simple “mustard” blister collapses or is opened, and the detached skin removed, the exposed stratum mucosum has a clean red appearance, perhaps with some shreds of fibrin. With the deeper burns, it is covered with a greyish-yellow coating, presumably largely necrotic tissue mixed with some pus cells.

The coating may be removed by soaking in saline or Dakin’s solution, thus exposing a raw, granulating surface beneath; but it rapidly forms again. The process, however, remains rather superficial. It apparently involves the corium more or less, although it does not often destroy the epithelium so deeply that it cannot re-cover the wound. Even in severe cases, it does not extend materially below the corium. Statements that it “corrodes to the bone” have no foundation.

For a couple of weeks, this condition of the wound remains practically stationary: Toward the end of 2 to 4 weeks, further necrosis ceases quite noticeably, about the same time that the hypersensitiveness diminishes. A pale pink ring of epithelium starts from the periphery to cover the wound, which meanwhile may form very excrated granulations.

Toward the end of the fifth or sixth week, practically all wounds are essentially healed, with or without cicatization. The new skin over the burned areas appears shiny and often pigmented, as in X-ray burns.

BURNS OF THE GENITALIA DIFFER SOMETIMES FROM THE TYPE. WHEN THE SCROTUM IS INVOLVED, THE TESCICLES BECOME VERY SENSITIVE. HOWEVER, THIS IS PROBABLY NOT AN ORTHOSIS. IT CLEARLY ABOUT THE SAME TIME AS THE SKIN LESIONS.
DICHLOR-DIETHYL-SULPHID

183

Blister's of the penis may come on quite slowly, and turn into tedious ulcers, which heal much more slowly than other lesions. Infection of the meatus may cause a urethral discharge.

The most severe burns (the gangrenous type) differ from the blister type from the start. Smarting and burning are felt within an hour after receiving the burn. The skin at that time is intensely blanched. By the next day, the burn proper is of a livid, cadaveric color. It does not vesiculate but forms a depression, surrounded by a continuous ring of blister. After a week or so, it breaks down into an ulcer, and the entire thickness of the skin may be removed in a mass. The wound remains painful for 3 or 4 weeks. Healing occurs after 5 to 7 weeks, by cicatrization.

Systemic Reactions of Mustard Burns.—Dichlroethylsulphid applied to the skin does not reach the circulation in sufficient amount to produce any systemic lesions; nor are the mustard-burns, even when extensive and deep, accompanied by the acute toxic phenomena of fire-burns. The temperature remains practically normal. However, extensive burns may produce temporary collapse, mainly if not entirely of psychic origin. Later on, the pain is likely to interfere with sleep. The urine should be watched.

Secondary Purpurae.—Burn scars lower the resistance of the skin to infection. The blisters are usually followed by a crop of furuncles or pustules, generally on and around the burned area. Men who work with mustard commonly have this complaint even when they have only had superficial rashes.

Increased Susceptibility of the Skin.—Healed mustard burns are definitely hypersusceptible to the poison, and also to mechanical injury. A light contusion may result in a blister. This hypersensitiveness, however, is confined to the burned areas and does not extend to the remainder of the skin.

Microscopic Changes in Mustard Burns.—These have been described in detail by Warthin and Weller, loc. cit. Briefly, the dichlroethylsulphid produces slow but severe destructive changes in the epidermis and corium, and especially in the endothelium of the blood vessels.

Even minute quantities penetrate rapidly and deeply. The hair follicles, and sebaceous and sweat glands evidently facilitate the penetration.

The epithelium shows hydropic and other degenerative and necrotic changes within 2 hours. The edema in the early stages is confined to the epidermis and papillary layer, and does not extend much more deeply.

Severe burns: the vessels in the affected area are greatly damaged and collapsed. This results in local anemia in the earlier stages, with marked edema and leucocyte migration. The vascular lesions are non-hemorrhagic and non-thermorhoming.

The slowly progressive character of the necrosis is partly explained by contraction and death of the vessels, and the resultant loss of blood-supply.

Skin Lesions in Animals.—Blistering does not usually occur in any of the experimental animals, including monkeys. Otherwise the lesions are essentially the same as in man.

There are some differences in the degree and rapidity of the primary erythema. In dogs, this is visible in 5 to 15 minutes. Most other animals do not show reddening. Monkeys react by blanching.

Protection against secondary infection being more difficult in animals, the sloughing is often much more severe.

When treated by the paraflin oil method, dogs and goats were found to be about as susceptible as man; but there were considerable differences in individuals. With 15 per cent. solution, about 1/4 of the dogs and goats reacted; 1/4 of the rats; 1/4 of the mice; 1/2 of the guinea pigs and monkeys required 1 per cent. solutions (Marshall and Williams, 1918).

Susceptibility to Skin Burns.—The susceptibility of different individuals varies more than a hundred times, i.e., to produce a visible reaction requires in the case of "atonic" individuals a concentration more than a hundred times greater than will produce results in a hypersensitive. Negroes are notably tolerant. The individual susceptibility is easily determined by rapid and convenient methods, and may be of considerable practical importance, since the natural tolerance is much greater than what can be conferred by environmental conditions.

The tolerance, for a given person, does not change greatly with time, if other conditions are uniform. It is also fairly alike for the skin of the entire body, with the exception of a few special regions. The axilla and crotch are hypersusceptible (largely because of their moisture), the thick-skin palmar surface of the hand and fingers is relatively insusceptible. The area of a previous burn is hypersusceptible; but it is doubtful whether the susceptibility of the unburned areas is changed. So far as present observations go, hypersusceptibility appears not to be especially frequent among those
who have worked constantly with "mustard" and who have received severe and ex-
tensive burns (Sollmann, 1919). Moisture of the skin and perspiration very de-
definitely increase the susceptibility—an important hint for prophylaxis.
The presence of moisture also increases the susceptibility to other irritants that are
more soluble in oil than in water; i.e., phenol or true mustard oil. In all these cases,
the insolvibility in water would favor the penetration into the more solvent skin.
Marshall, Lynch and Smith, 1918 (Journal Pharmacology, 12: 201), explain suscepti-
bility along similar lines: They assume that the outer layers of the skin (the stratum
corneum?) have considerable affinity for the poison, and thus delay its passage into the
deeper, living tissues. On this assumption, the solution affinity of the outer skin layer
would be less when this layer is rich in water, and greater when it is rich in fat.
Smith, Clews and Marshall, 1919, believe that the intracellular threshold of toxicity
would probably be the same in all individuals, and that the differences in toxicity are
due entirely to absorption. They believe that the poison is rapidly absorbed by the
skin-surface. A part passes rapidly into the deeper layers and cannot be removed. A
greater part, however, remains in the upper layer and is removable for 10 minutes.
A large part of this in the superficial layer evaporates, in fact, more than passes inward.
A resistant skin absorbs much more than a sensitive, and on contact with
sensitive skin, the resistant takes up the poison.

REMOVAL OF "MUSTARD GAS" FROM THE SKIN

When the dichloresylphosphid has penetrated the cells of the skin, the damage has
been done, and treatment is only palliative. It is therefore imperative to remove the
poison as completely as possible before it has penetrated and combined. Unfortunately,
the penetration is very rapid; if a small drop is placed on the skin, it is absorbed so
rapidly that even the odor has disappeared within 2 minutes. The fixation within the
skin is almost as rapid, so that the efficiency of removal treatment is limited within
5 minutes, and almost nil after 10 to 20 minutes.

This, combined with the fact that most burns are not noticed until several hours
after they were received, emphasizes the desirability of prophylaxis, of protection against
exposure to contact.
The first step in the treatment of a mustard burn is the removal of the contaminated
clothing.
The removal from the skin may be attempted by chemical means or by solvents.
The solvents have given better results, presumably because of their better penetration.
Any convenient solvent may be used with almost equal results: alcohol, acetone, gaso-
line, kerosene, turpentine, oils or grease, petrolatum and somewhat less efficiently soap,
"green soap" being better than soda soaps. For practical reasons, chiefly economical,
kerosene is generally preferred. The solvent treatment is materially more efficient if it is combined with rubbing; presumably because this presses some of the poison out of the gland ducts.

Chemical Removal.—Chlorinated lime and the chlorommins neutralise the poison if
they are applied immediately; but they fail to reach any that has penetrated. This
renders them rather inferior to the kerosene treatment. In any case, they would be
useless 5 or 10 minutes after exposure.

TREATMENT OF MUSTARD BURNS

Principles.—The various treatments that have been proposed involve mainly three
principles:
1. Attempt at Chemical Destruction of the Poison within the Skin.—These have been
uniformly unsuccessful, since the poison is rapidly fixed within the cells and is thus out
of reach of most, if not all, of the chemical antidotes. The outlook in this direction is
unpromising, though perhaps not quite hopeless.
2. Protective Measures.—These at least add considerably to the comfort of the patient,
and may indirectly hasten healing somewhat. This last statement should perhaps be
somewhat modified. It is very doubtful whether the natural course and healing of the
burns can be materially influenced for the better by any treatment so far tried; but it
can be materially influenced for the worse, by irritation. Protective measures eliminate
this additional injury.

As the first step in the protective treatment, the patient should be removed from
all chance of exposure to the poison, even to the dilute vapor, or other irritant vapors,
until the burns are healed. Irritant dressings must also be avoided.
Further details of protective treatment are discussed later.
3. Antiseptics.—The extensive raw surface, the lowered vitality, and the presence of necrotic tissue in the blistered burn offers excellent opportunity for infections. On the other hand, the infection remains superficial and is easily kept in bounds by antiseptics, and given by ordinary cleanliness. Most burns probably heal about the same whether antiseptics are used or not.

However, the antiseptic should be given the benefit of the doubt. Antiseptic of the chlortetracaine has been found most serviceable, and should be used whenever possible (Warthin et al., 1918). They are especially useful toward the end of the necrotic stage. Perhaps their benefit here may be referred partly to the solution of the necrotic tissue.

The comparison of different methods of treating the burns is not easy, partly because it is difficult to judge the severity of a burn, and its presumptive course, especially if it was not followed through all its stages. Several adjacent blisters that look practically alike at the height of vesication may really be of a different depth; one may heal smoothly within two weeks, the other may undergo necrosis and require four weeks.

Another source of error is the rather abrupt turning point when spontaneous improvement sets in. Without any treatment a necrotic surface that has been practically stationary for a week or more, starts to improve over night, almost visibly. If a treatment has been instituted within a few days of this turning point, it would very naturally, but very erroneously receive the credit (Sollmann, 1919).

Treatment of the Blastos.—This is directed mainly against the burning and itching. Gentle relief is obtained by cold baths and the continuous application of compresses saturated with cold lotions. The ingredients of the lotions are rather immaterial, since their action is mainly physical. Alum or aluminum acetate, 1 per cent., are largely used.

Benzy1 alcohol has been suggested (Hess, 1918; Read, 1918); either a 10 per cent. solution or a lotion containing equal volumes of benzy1 alcohol, alcohol and water, with the addition of 4 per cent. of glycerin.

Friction of the skin should be avoided; also the application of irritant drugs, such as peric acid or mercuric chloride solutions. They are not needed and may increase the dermatitis.

In this and in other stages, it is advisable to give bromid, 1 gm. or 15 grains in water, four times a day, if insomnia. The use of stronger narcotics and especially opiates is to be avoided. They are not necessary in the milder forms; and the more painful burns are too persistent.

Treatment of Small Blister.—Although small burns may be deep and destructive, they are, of course, less dangerous than extensive burns. They must be treated with equal attention to aspesis; but irritants may be used more freely, if desired.

The simplest and perhaps the best treatment is to protect the blister by a cotton and gauze dressing until it breaks spontaneously. It may then be dressed daily either with a dusting powder, especially bismuth subnitrate; or with album lodos; or with petrolatum. Any loose skin is trimmed away.

If ulceration sets in, the burn is painted daily with 2 per cent. dichloramin T in chloroform, and covered with a white petrolatum dressing.

Opinions vary somewhat as to whether the blisters should be opened early or left alone. Apparently there is no difference as to healing; and the discomfort is distinctly greater when the epidermis is removed.

Dusting powders are useful on superficial burns, but not with deep burns. Bismuth subnitrate may be used only on small areas. For larger burns, one may use talcum, skin ointment or a paste of chalk, magnesium, or kaolin.

Excessive pain from ulcers may be relieved by dusting with 10 per cent. of orthoform in talcum. The relief, however, does not last, and is scarcely worth while.

Treatment of Extensive Blister—burns. Preliminary Cleaning.—The clothing should be removed to the skin as soon as possible after exposure; and of course should not be worn again until it has been disinfected.

The skin (and the hair, if it has been stained) should then be scrubbed with kerosene, soap and hot water, as previously described.

Chlorinated Bath.—This is advised by Warthin. It may follow as soon as possible after the kerosene scrub; or may be applied at once, if the patient does not come under treatment within an hour after exposure.

The exposed part should be immersed for one or two hours in Dakin's solution of chlorinated soda. This may be applied as a local bath, a sitz-bath or a full bath, according to the location of the burn. If immersion is not feasible, the solution (0.1 percent. wattery Chloramin T) may be applied on compresses, but this is less effective than immersion.

The chlorinated bath has the purpose of disinfecting the epidermis, thus diminishing
the tendency to secondary infections. It would also neutralize any of the poison that is still unabsorbed; but this would be very exceptional.

Aspasia.—From this point on, the burn should be carefully guarded against bacterial infection. If the blisters are opened, the burns may be protected by dry dressings, or by compresses moistened with 1 per cent. alum or aluminum acetate, repeating the soaking in Dakin’s solution two or three times a day.

Opening of the Blisters.—For the ultimate results, it is apparently immaterial whether the blisters are opened early and freely, or merely punctured, or whether they are protected until they rupture spontaneously. Each plan has its advantages and drawbacks. When the blister is opened, it is more painful; but it is also more accessible to antiseptic treatment. If it is decided to open the blisters, this should be done under aseptic precautions, by puncturing with a sterile needle at one side. The point of entrance may first be touched with iodin solution. If this is done before the contents coagulate, evacuation may be complete. Generally, however, the contents are gelatinous, and the fluid seeps away slowly and must be absorbed by the dressings. The epithelium is not removed at once, but can soon be peeled off in shreds.

Treatment of the Opened Blister.—It is desirable to treat these as open and lightly infected wounds. This is done most effectively by antiseptic and cleansing baths and moist dressings. During the sensitive stage, however, it is often necessary to substitute protection against the chemical irritation of the air and the mechanical irritation of the dressings. The principle of cleanliness and aspasia must be kept in mind and secured as fully as possible.

Rigid Bath Treatment.—This consists in a practically continuous rotation of baths, immersion or packs, at body temperature if necessary, as follows:

Dakin’s solution, 1 to 2 hours.
Sodium chlorid, 1 to 10 per cent., 2 hours.
Normal saline, 1 hour.

This method condenses the use of fatty protectives as likely to favor infection. If the pain is excessive, a “colloidal saline bath” is used, made by dissolving a pound of commercial cornstarch and a pound of sodium bicarbonate in 20 to 30 gallons of sterile normal saline solution. If this is warmed to 90 or 95° F., the whole patient may be immersed for 7 or 8 hours if necessary. A set

Modifications. (a) Alum in Place of the Dakin’s Solution.—During the most sensitive stage the Dakin’s solution may be too painful. In this case, 1 per cent. alum or aluminum acetate may be substituted temporarily, without otherwise modifying the routine. Permanganate, 5 per cent. applied every hour, for 3 or 4 hours after exposure, has been used as a prophylactic; but there is no evidence that it is efficient.

The French medical service used as a lotion a mixture of 2 volumes of solution of hydrogen peroxide, and 1 volume 34 per cent. sodium bicarbonate changed 2 or 3 times daily.

(b) Petroleum Dressings.—These add greatly to the comfort at night, and may be almost indispensable. In fact, they must often be used in alternation with the baths. There does not seem to be any adequate objection to them when used in this way, although elaborate and continuous air-tight dressings with paraffin, rubber-dam, adhesive, etc., are undesirable. It suffices to cover the burn with gauze that has been plastered rather thickly with petrolatum. The ordinary yellow petrolatum is suitable, except in connection with dichloramin T, when a mixture of surgical paraffin and liquid petrolatum, 3:7, must be used (Sollmann, 1910).

(c) Dichloramin T Treatment.—This is a convenient simplification of the routine which can be employed when the sensitiveness is diminishing, i.e., when it produces only a temporary smarting. It is too painful during the sensitive stage.

It is employed as a 2 per cent. solution in chloroform. This is painted on the wound every 2 to 4 hours. If the smarting is still severe, a small area may be treated at a time. It is covered with paraffined lace-mesh gauze. However, this protects only incompletely against adhesion of the secretions.

It is therefore advisable to use ordinary gauze covered with a layer of paraffin ointment. The skin around the wound should always be vaselined.

When changing the dressings, the wound should be wiped gently with liquid petrolatum. Twice daily. It should be soaked in 15 per cent. salt solution until it is quite clean.

Granulations.—The burns usually heal slowly but smoothly. Should granulations become too exuberant, they may be painted with 10 per cent. silver nitrate.

Paresthesia.—This develops about the second or third week in many patients. It is due to staphylococcus pyogenes aureus infection, and is said to have been treated successfully by autogenous vaccine (Warthin).
TREATMENT OF THE GASTRIC SYMPTOMS.—Nausea and vomiting are seen in a proportion of the intoxications by inhalation. Recovery generally follows without other treatment than a light diet. Occasionally, however, the vomiting is very severe and prolonged. Such cases should be treated with alkalies and blimeth and a milk diet, essentially like gastric ulcer.

There seems to be a general lowering of the resistance after mustard gas poisoning; and therefore increased susceptibility to infections, influenza, bronchitis, pneumonia and tuberculosis (Warthin and Weller, 1919).

DIRECT SYSTEMIC ACTIONS

The local actions of dichloroethylsulphid are so conspicuous that they rather obscure the systemic actions. These have been studied by direct injection. They affect mainly the heart and nervous system. Heart-block is particularly characteristic.

Fairly small doses are fatal in dogs, less than 6 mg. per kg. (Lynch, Smith & Marshall, 1918).

**Effect of Subcutaneous and Intravenous Injections.**—There is latent period of 10 to 30 minutes, during which no effects of any kind are disclosed. At the end of this period, salivation sets in, followed by increased nervous irritability, excitement, diarrhoea, and sometimes convulsions. The excitement soon gives place to coma.

The pulse becomes slow and irregular, with 2 or 3 auricular beats for each ventricular contraction. Toward death the heart becomes very rapid, but does not respond to vagus stimulation. Finally, heart-failure is the apparent cause of death.

Warthin and Weller, 1919, studied the effects of fatal doses on rabbits (0.06 c.c. per kg.) and dogs (0.03 c.c. per kg.). If death occurs quickly, the symptoms are referable to the central nervous system and are probably direct. When death is slower, there is severe diarrhoea (catarrhal enteritis).

The nervous symptoms consist in extreme restlessness, incoordinated movements, etc., but no definite paralysis or convulsions (Pappenheimer, 1919). Rabbits, 3 to 10 mg. per kg. is M.F.D."

**Lesions.**—Thermocopy fails to show either gross or microscopic changes in the heart. The only consistent lesion is an intense congestion, sometimes hemorrhagic, of the intestinal mucous membrane, particularly in the duodenum.

**Intestinal Changes.**—They consist of severe mucoid, desquamative and necrotic enteritis. They suggest that excretion of the substance or irritant derivatives occurs partly by the intestines (Lynch et al., 1918). These results have been confirmed by Warthin and Weller, 1919, for hypodermic injection. They also found similar degenerative inflammatory changes in the intrahepatic bile ducts and gall-bladder, so that the excretion may occur partly by the liver. There is no direct evidence that the poison is excreted by these channels.

**Direct Gastro-intestinal Lesions.**—These occur by the ingestion of the substance with the food or saliva. Animals that survive several days after being "gassed" in chambers generally have acute gastro-intestinal catarrh. The lesions are similar to those produced by local contact in other locations: superficial necrosis, followed by ulceration of the mucosa (Warthin and Weller, 1919). The gastro-intestinal symptoms in man are probably chiefly reflex, from respiratory irritation and shock.

**Necrosis.**—These do not show direct changes, even with intravenous injection.

**Secondary involvement (cloudy swelling and hyaline casts)** may occur during infection or extensive necrosis in severe local lesions (Warthin and Weller, 1919).

Such cases may show diminished urine output, increased concentration, diminished urea and chlorid. The condition improves on forced liquid regimen. Mild skin burns have no changes in the urine or blood (Hermann, 1918).

**Blood.**—Human inhalation casualties show initial leukocytosis, followed by more or less extreme leucopenia (Gienas, 1918) associated with severe lesions in the bone-marrow (Krumbbhaar, 1919; Pappenheimer and Yance, 1919). This usually persists even during the broncho-pneumonia, and probably contributes to the high mortality of the complication. The formation of red cells and of the platelets is also diminished. The coagulability time is decreased in the earlier stage, lengthened in the later stages of severe cases (Krummbhaar, 1919). J.A.M.A., 72:390. Hermann, 1918, noted that the maximum of the blood change coincides with the height of the secondary infections,
and believes these responsible, rather than direct action. Pappenheimer and Vance, however, found the same changes after intravenous injections.

**Systemic Symptoms from Inhalation.**—The characteristic effects on the pulse and the nervous system are also seen in animals poisoned by inhalation, and indeed even after the application of large amounts to the skin. The substance must therefore be absorbed fairly readily (Lynch et al., 1c).

**Note.**—Dichlorehthythylphosph is evidently rapidly hydrolyzed for the urine contains products of hydrolysis, probably dihydroxyethylphosph, with all methods of administration. This is not irritant but by artificial chlorination it can be re-converted into the toxic substances (Lynch et al., 1c).

**PROTECTION AGAINST MUSTARD GAS**

The very limited success of treatment makes prophylaxis especially important. Protective measures apply to the surroundings; to the clothing; and to the skin.

**Factory Protection.**—This involves ventilation, installation of neutralizing agents, and thorough instruction and discipline.

**Protective Clothing.**—Ordinary clothing furnishes no protection. Leather is also practically ineffective. Thick rubber furnishes a short protection, but quickly becomes impregnated and then conveys the infection. Ordinary "oil cloth" is quite resistant, but too stiff. Practically, the best results are obtained with cloth painted with linseed oil, so that the pores are entirely closed. The protection is adequate, although not perfect. Certain waxes, gums and proteins are highly resistant.

Attempts have been made to treat porous fabrics so as to neutralize the poison, but it seems improbable that these would be successful.

**Removal from Clothing.**—Clothing that has been contaminated should be promptly disinfected, with the minimum of handling.

Hanging it in the sun and wind for a day or longer does some good, but is not reliable. Bolling with water for an hour destroys the poison by hydrolysis and evaporation. The process is hastened by the addition of washing soda or chalk. These also protect against the acid that is formed. Certain solvents or catalysts may be added. Vacuum steam distillation has been found satisfactory (Marlow, 1918).

**Treatment with dilute solution of chlorinated lime has been tried, but is of doubtful value.**

Superheated steam (170°C for 1½ hours, 120°C for 40 min.) removes the poison partly by evaporation and partly by hydrolysis.

Objects that would be injured by these methods can be disinfected by solvents such as kerosene or gasoline.

**Protection of the Skin.**—The poison, like other fat-soluble irritants, is more injurious when the skin is moist; whilst oiling of the skin confers a certain degree of protection. Unfortunately, this protection is quite limited. It may be fairly complete for short exposure to low concentrations; and with high concentrations it at least increases the efficiency of removal-treatment. For long exposures, however, there is practically no protection by oils.

Extensive experiments with different oils, ointments and admixtures have revealed quantitative differences; but they are not sufficiently great to affect the practical results materially (Sollmann, 1910).

**Other Skin Irritants.**—Hanzlik et al., 1919, give a survey of the results from a large number of substances.

**NON-VOLATILE ORGANIC IRRITANTS**

A number of fixed organic drugs act as local irritants. The most important of these is cantharidin. Capsicum, euphorbia, poison ivy, and croton oil, the "acid principles" of certain fresh plants, especially of the family of Rusculeae, etc., may be counted in this group. They owe their activity to neutral, resinous, or oily principles. Some benzol derivatives—chrysophanic acid, resorcin, pyrogallol, etc.—have a similar action, so also do some of the toxins and the poison of bees (Faust, 1910).
CANTHARIDIN

Actions and Uses.—Cantharides (Spanish Flies) are used for vesication and for prolonged counterirritation in pleurisy, neuralgic and rheumatic pains, etc. The irritation is active, but the penetration slow, so that the effects are gradual, with only moderate pain, and without involvement of the deeper layers of the skin. The blisters therefore heal readily and without scar. On mucous membranes and open wounds, the effects are more severe, leading to local necrosis, and slowly healing, suppurating ulcers. Internally, cantharis is highly toxic by gastroenteritis and nephritis; even the absorption from a large blister may cause severe irritation of the kidneys and urinary passages. It is therefore contraindicated in nephritis, and should never be used internally, although it was formerly employed as a diuretic.

Origin of Cantharidin.—Cantharidin is a crystalline principle, the anhydride of canthic acid. It combines readily with alkalies, forming soluble salts. These produce the same local and systemic actions. Cantharidin is contained in a number of insects, especially beetles. A similar substance exists also in some caterpillars. It is present in varying amount, even in the same species. It was isolated by Robiquet in 1814 from the Spanish "fly" (a beetle—Cantharis or Lytta vesicatoria). It is contained in the soft parts, particularly the blood.

Cantharis was recommended by Hippocrates in dropsy and amenorrhea; it was very popular in the days of heroic medication.

Absorption and Excretion.—Cantharidin is readily absorbed from all surfaces even from the skin. It is excreted mainly by the kidneys (Ellis, 1882); but since it irritates the gastro-intestinal tract when injected hypodermically, some must be excreted by this channel.

Symptoms of Poisoning.—When cantharis is taken by mouth, it produces successively: burning in the mouth, thirst, difficulty in swallowing, swelling and blistering of the tongue, salivation, nausea, vomiting, colic, and sometimes bloody diarrhoea and tenesmus. The gastro-intestinal symptoms may be less pronounced in rapid poisoning. Kidney pain, burning in urethra, frequent micturition, albuminuria, casts, hematuria, painful erections, abortion. Weak and slow pulse, chill, syncope and collapse. Recovery may occur in about five days, the urine returning to normal. Toxic effects have been produced by 0.6 gm.; death by 1.5 to 3.0 Gm., but recovery has also occurred from much larger doses. Of cantharidin, 10 mg. is said to be fatal.

Central Actions.—When injected into the circulation, cantharidin affects the central nervous system, producing short stimulation, excitement, and increased reflexes, followed by paralytic symptoms, coma, etc.

This central action is not often seen, being obscured by gastroenteritis or nephritis.

The Treatment of Poisoning.—This consists of gastric lavage, demulcents, quinine, alkalies and plenty of fluid, heat to the gastric and renal region, and warm baths. No oils or fats should be given.

Cantharidin Nephritis.—The kidneys are highly sensitive to cantharidin. Small doses act entirely on the glomeruli, which are greatly dilated; numerous leucocytes are found in Bowman's capsule. The urine becomes albuminous within half an hour after subcutaneous injection. The smaller doses increase its amount, while larger doses diminish it. The epithelium of the convoluted tubules is only affected by large doses, and rather late in the course of the poisoning. The interstitial tissue escapes entirely in the acute intoxication, and is but slightly changed even in the subacute form (Müntz, 1868; Lyon, 1904; Richter and Roth; Schlayer and Hedinger, 1907; Pearce, 1913). The excretion of phthaldehyde is delayed (Elsdén, 1913); the non-protein nitrogen of the blood is increased (Folin, Kanner and Denkis, 1912).

Hepatic Changes and Edema.—These are seen in dogs, with fatal doses. Opie, 1915, found fibrous clots in the lymph nodes of the hepatic region, around the injured cell, and considers their obstruction responsible for the edema. In their absence, the lymph flow is increased independent of the renal changes.

Thrombosis.—This occurs after acute clinical or experimental poisoning. It sets in slowly and is rather persistent (Lépizé and Cross, 1917; Morgulis and Mulhead, 1918).

Racial Tolerance.—The hedgehog, chicken, and duck are remarkably tolerant to the nephritic action (Ellingor, 1900). This is not due to differences in the absorption,
nor to destruction of the poison, for the cantharidin is found in the urine, just as it is in susceptible animals. Nor are those animals immune to other nephritic poisons. The immunity to cantharides is also only partial; even a single injection of a large dose causes chronic nephritis. But taking the fatal dose for man (30 mg. by stomach) as the unit, that for the same weight of hedgehog lies about 7,000. For the dog and cat it is about 2.5 (1 mg. per kilo); for the rabbit, about 45.

This immunity to the nephritic action does not confer immunity to the local action on the skin. In this respect, the hedgehog is even more susceptible than the rabbit, which latter animal is almost immune to the cutaneous action. The nephritic action is lessened by rendering the urine alkaline (Ellinger, 1909). In the rooster, cantharidin causes changes in the comb, analogous to those produced by ergot. Frogs are not susceptible.

*Vesication in Animals.*—Animals respond to irritation of the skin by cutaneous edema, rather than by vesication. This is probably due to anatomic differences. Of the experimental animals, the horse alone seems suited to test the action of vesicants (Ewe, 1920).

Other Vesicants.—When cantharis is contraindicated—e.g., in cases of inflammation of the urinary passages—it is usually replaced by ammonia water or chloroform, which vesicate if their evaporation is prevented, as by covering the point of application by a thimble. These are rather more rapid in action, but much more painful than fly blister, and are, therefore, avoided, if possible. Iodin, croton oil, and mustard have also been used, but act too deeply.

Contraindications to Vesication.—Blisters in general are contraindicated in people of feeble condition, since they may then lead to ulceration. When they are employed for counterirritation, they should not be applied directly over the inflamed part, but at some distance from it. They might otherwise render the inflammation more violent.

*Alopecia.*—Cantharis is used in the treatment of baldness, in the form of tincture, very greatly diluted with alcohol.

*Treatment of Impotence.*—Many drugs have been employed for this purpose, but with questionable results. *Cantharis* produces erection through reflex irritation from the urethral mucous membrane. It is, however, quite dangerous, since effective doses may set up nephritis. Many *essential oil* act in the same manner, and are at once less dangerous and less active. Here belong, e.g., *daminum*, *ginger*, *mint*, *garlic*, etc., and possibly *cantharid*. *Strychnin* was thought to be effective by raising the tone of the spinal centers, but is probably useless; as also *phosphorus* and *arsenic*. *Alcohol*, *morphin*, *cannabis*, and other narcotics may act as aphrodisiacs by stimulating the imagination. *Yohimbin* has a special action on the blood vessels. The best treatment for impotence consists, of course, in the removal of the cause and improving the general health of the patient by appropriate hygiene.

**Preparations—Cantharides**

*Cantharis* (Canthar.), U.S.P.; Cantharides (Spanish Flies, Russian Flies).—The dried beetle, Cantharis vesicatoria. Contains cantharidin, 0.4 to 1 per cent. (not less than 0.6 per cent., U.S.P.) volatile and fixed oil, etc. Maximal dose; 0.05 Gm., 1 gr.

*Coral Canthar.,* U.S.P. (Blistering Cerate).—35 per cent. of Cantharides.

*Emplastrum Cantharid* (Emp. Canthar.,) U.S.P.; Cantharides Plaster. Preparad by spreading cantharides cerate upon rosin plaster, leaving a margin around the edges. Each square centimeter of spread plaster should contain 0.1 Gm. of cantharides cerate. It requires from six to ten hours to raise a blister, according to the thickness of the skin, its content in fat, and probably also individual susceptibility. The plaster adheres very poorly, and must usually be fixed with adhesive plaster. When the blister has appeared, the plaster should be carefully removed without rupturing the vesicle. The latter is then pierced and dressed with an ointment. This prevents further pain, irritation, or infection. By a "flying blister" is meant a series of small blisters raised along the course of a nerve by the application of successive plasters.

Tr. Canthar., U.S.P.—10 per cent. *Dose, 0.1 c.c., 1/2 minims. Maximal, 0.5 c.c. 8 minims. May be added to liniments to prolong their local action; in hair lotions, 1:50. *Cantharidinum, B.P.; C₄H₄NO₆.—Obtained from various species of Cantharis and of Mysabris. Colorless, glistening crystals; no odor. Very slightly sol. in water or alc., more sol. in chlor., ether or oils. *Cantharidin, 0.05 to 0.2 mg. in a drop of oil, and covered with simple plaster, may be employed as a blister.

The cantharidal preparations of the B.P. are now made of Cantharidin. The proportions are adjusted on the basis that 1 part of Cantharidin is equivalent to about 200 parts of Cantharis; so that the activity of the new preparations is about the same as that of the old.

Acet. Cantharidinum, B.P.—0.05 per cent. (equiv. to 10 per cent. of Cantharis). Collid. Vescic., B.P.—0.4 per cent. (equiv. to 50 per cent. of Cantharis).

Emuls. Cantharidinum (Emp. Cantharidin), B.P.—0.2 per cent. (equiv. to 25 per cent. of Cantharis). See "Emp. Cantharis." *Emuls. Cantharidinum (Emp. Calefac.), B.P.; Warming Plaster.—0.02 per cent. (equiv. to 4 per cent. of Cantharis). *Liquor Epispasticus (Liq. Epispast.), B.P.; Blistering Liquid.—0.4 per cent. (equiv. to 20 per cent. of Cantharis), in acetone menstruum.

Tr. Cantharidinum, B.P.—0.01 per cent., equiv. to 1/4 per cent. of Cantharis (1/4 of U.S.P.). *Dose, 0.05 to 0.2 c.c., 2 to 5 minims, B.P.

Ung. Cantharidinum, B.P.—0.015 per cent., equiv. to 7 per cent. Cantharis (% of the old preparation).

PREPARATIONS—CAPSICUM AND SIMILAR IRITANTS

**Capsicum**, U.S.P.; Capsic. Fruct., B.P.; Capsicum (Cayenne Pepper, African Pepper). The dried ripe fruits of Capsicum fastigiatum, U.S.P.; Capsicum minimum, B.P.

The action is due to about 0.02 per cent. of a crystalline neutral principle, capsaicin (1:10,000 produces lasting burning of the tongue, Nelson, 1910). Capsicum is used externally as a condiment and carminative, and externally to produce prolonged counterirritation for rheumatism, etc. (20 per cent. ointment; or equal parts of tincture and of eup-liniment). *Dose, 0.06 Gm. 1 gr., U.S.P.

Emp. Capsic., U.S.P.; Capsicum Plaster.—Prepared by brushing oleoresin of capsicum upon the surface of rosin plaster so as to form a thin coating, leaving a margin around the edges.

*Oleum Capsic.* U.S.P.—Evaporated ethereal extract. *Dose, 0.03 Gm., 1/2 gr., B.P.*

Tr. Capsic., U.S.P.—10 per cent. *Dose, 0.05 c.c., 8 minims, U.S.P., diluted.

Tr. Capsic., B.P.—5 per cent. *Dose, 0.03 to 0.05 c.c., 5 to 15 minims, B.P.

Ung. Capsic., B.P.—25 per cent.

*Euphorbium.*—The dried juice of Euphorbia resinifera, consists of a gum-resin. The active constituent is the resinous euphorbin which resembles the active resin of castor oil (Boehm, 1915). The drug is rarely used (liniments, 10 per cent.; plasters, 5 per cent).

*Minervum, U.S.P.—The dried bark of Daphne species. The active constituent is the subhydrate of mezeric acid. There is also a glucosid daphnin. The fluid extract is used as an addition to liniments or plasters; also in Fledext. Sarap. Co.

*Piper, U.S.P.—Black Pepper.*—The dried unripe fruit of Piper nigrum. (White paper is the ripe fruit, deprived of its outer pericarp.) Contains the crystalline alkaloid piperin, a volatile oil, and a pungent resin. *Dose, 0.05 Gm., 8 gr., U.S.P.*

*Garii Piper, U.S.P.—Evaporated ethereal extract. *Dose, 0.03 Gm., 1/2 gr., U.S.P.*

Piperis (piperyl-piperidin).—Has been used as an antipyretic and carminative, 0.005 to 0.01 Gm., 1/10 to 1/5 gr., in capsules.

Pulvulilla.—The herb of Anemone Pulsatilla and A. liratensis; Europe. Should not be kept over one year. Active ingredient, anemonin. The drug is very iritant, and is almost obsolete, but has been used against asthma, hemicrania, etc., in doses of 0.1 to 0.2 Gm. It has a depressant action on the excited uterus (Pilcher, 1910).

Anemonin.—This is the active irritant constituent of fresh plants of the buttercup family, for instance, the marsh-marigold, Caltha palustris (Kober, 1917). It exists in Aconitum sceleratus mainly as a mother substance, proto-anemonin, which is volatile with steam. The structure of this and of anemonin have been determined and confirmed by synthesis (Aashina and Fujita, 1920).
Chrysarobin

This is strongly irritant to the skin and mucous membranes. It is employed as ointment (5 to 25 per cent. daily) against psoriasis and parasitic skin diseases, ringworm, etc. It stains the skin (keratin) and linen a brownish-violet color. This can be removed by chlorinated lime or benzol (Mankiewicz, 1916). Caution must be used lest it reach the eyes and produce violent conjunctivitis (or rather keratitis; Igersheimer, 1912) and corneal opacity. It is absorbed from the skin, and excreted partly as chrysophanic acid, which is easily formed by its oxidation, especially in alkaline solutions. The urine is, therefore, colored red by alkalies. A part is excreted unchanged, and causes renal irritation, casts and albuminuria. By mouth, it produces (0.18 Gm.) vomiting, diarrhea, renal pain and hematuria.

Chrysarobin has a strong affinity for oxygen, abstracting it from the tissues. This has been suggested as the basis of its action, the oxidation product, chrysophanic acid, being relatively inactive. The oxidation occurs only in water suspensions in the presence of alkali. Fats, therefore, diminish its activity (Schemberg, Raison and Kolmer, 1915).

PREPARATIONS—CHYRSAROBIN

Aroehis, B.P. (Goa Powder, Crude Chrysarobin).—A substance found in cavities of the trunk of Andira (Youcacone) Araroba.

Chysarobinum (Chrysarobin), U.S.P., B.P.; Chrysarobin.—A mixture of neutral principles extracted from Goa powder; chiefly chrysophanolanthranol, C_{15}H_{16}O_{3}. An orange-yellow, microcrystalline powder, tasteless, odorless, and irritating to the mucous membrane. Very slightly sol. in water, slightly sol. in alc. (1:383); partially sol. in fats. A saturated ethereal solution of chrysarobin is used in the treatment of ulcers. It is painted on daily, the dead tissue being pared off. Dose, 0.05 Gm., 1/4 gr. U.S.P.

Ung. Chrysarobin, B.P.—4 per cent. in Soft Paraffin.

Scotris Rot, Medicinal, N.N.R. (Rubrum Scarlatinum, toluylazo-naphthol).—This is used as 2 to 8 per cent. ointment, to stimulate the growth of epithelium, on clean granulating wounds, especially burns, and on clean ulcers. (Schmiede, 1908; Morswetz, 1909; Dobrowolskaya, 1917, report the results as no better than without the dye.) The application is described in N.N.R. Its use is in the experimental stage. The 2 per cent. ointment often produces irritation and even erosion and sometimes systemic effects (violent gastroenteritis; Lyle, 1912). O. Sachs, 1914, claims that a number of other anilin dyes also stimulate epithelial growth. The property is especially prominent in the compounds allied to amidazo-benzene (Martinetti, 1914). A midlozotanol is being advocated as less staining (Huyward; Beck, 1913). It is used in the same strength.

POISON IVY

Actions.—Contact with certain species of Rhus, common along roadsides, on fences, in woods and swamps, etc., produces typical dermatitis, passing through the successive stages of hyperemia and itching, to violent vesication, edema, and suppuration, according to the specific sensibility of the individual; many persons are practically immune, although a sufficient quantity of the isolated toxicsedendrol has never failed to produce the dermatitis.

The active ingredients of all the species is a resin toxicsedendrol contained in the sticky sap of the plants. It is identical or very similar in all the toxic Rhus species (McNair, 1916). It is so highly active that 1/1,000
FIXED ORGANIC IRRITANTS

mg. has caused severe vesication (Piaff). These small amounts may easily be conveyed in the smoke of burning plants, and perhaps by insects (E. D. Brown) or dust, to some distance, although toxocodendrol itself is nonvolatile. Warren, 1913, and McNair could not find the irritant in the pollen, as has been claimed. Similarly, it may be conveyed by the hands or clothing from one person to another, as if it were contagious.

The dermatitis has a latent period of one to nine, usually four to five days, apparently independent of the dose. There is also some systemic reaction: severe leucocytosis, febrile symptoms, and slight renal irritation (McNair, 1916). The attack generally subsides in four to six days. Internally and hypodermically it produces local irritation and nephritis, but the systemic toxicity is relatively low (critical bibliography, Ford, 1913).

Toxic Species.—The most important are: Rhus vernix, syn. venenata (Poison Sumach, the most powerful); Rhus Toxocodendron (Poison Oak); Rhus radicans and divaricoba (Poison Ivy); Rhus pumila (a Southern species)—all common in North America; the Japanese lacquer tree (Rhus vernicifera). Other toxic species are mentioned by L. E. Warren, 1909 and by McNair, 1916. The common sumach, Rhus radicans, does not have this action.

Nature of the Toxocodendrol.—Piaff, 1897, showed that the toxicity is not due to a volatile alkaloid, as claimed by Khittle, 1884; nor to a volatile acid (Maisch, 1866); but that it is caused by a fixed oily substance. Acree and Syme, 1907, isolated this as a tar or wax, and showed it to be a glucosid, dissociable into rhamnose, gallic acid and starch. It is soluble in alcohol and oils and is precipitated by lead acetate, from which it is dissolved by ether. It is not destroyed by heating an hour at 100°C. (v. Adelung, 1913, 1914). The toxocodendrol occurs in the leachates of plants, which terminate in fine hairs (Schwalbe, 1902). However, McNair, 1916, did not find it in the plant hairs; it also doubts the glucosidal nature (reply by Acree, 1916). Further investigation is evidently necessary.

Artificial Immunity.—Warren, 1910, who reviews the literature of the subject, mentions that immunization by the chewing of leaves was claimed by Davison in 1895. Ford, 1907, found that repeated hypodermic injections of increasing doses of the leaf-extract induced resistance to the local necrosis and to the nephritis; and that the wound of these animals conferred passive immunity on others. v. Adelung, 1913, was not successful in producing immunity to the isolated toxocodendrol.

Congenital Tolerance.—The congenital variations in susceptibility are very marked, many individuals being immune to ordinary contact, although the immunity is probably never absolute. The tolerance is sometimes lost, and one attack seems to leave the skin more sensitive to others; but Ford mentions that Syme gradually acquired tolerance. Perspiration seems to facilitate infection.

Treatment of Ivy Poisoning.—This is best accomplished by thorough scrubbing with mild soap, then thoroughly rubbing in a hot solution of potassium permanganate (1 per cent. for ordinary skin; 1 per cent. if the skin is delicate or broken); and applying a paste of castile soap. The permanganate stain may be removed by 1 per cent. oxalic acid or by sulphuric acid; but these must be used cautiously. Salves or oils must not be used since, by dissolving the toxocodendrol, they would spread the infection. They become indicated only in the later stages, when the poison has become completely removed. Rubber gloves protect against infection.

Lead acetate (saturated alcoholic solution) precipitates the toxocodendrol; but the compound dissociates easily, so that the applications, to be effective, must be made frequently. Other popular remedies are: copper or iron salts; the expressed juice of "touch-me-not" (Impatiens fulva); and fluid extract of Grindelia Robusta (diluted with 1 to 8 vol. of water and used as a lotion).

Other Plants Producing Dermatitis.—These comprise a number of tropical fruits belonging to the same family—Lithea caustica; Anacardium (active principle, cardol, an oily substance); Semecarpus. Primula, chrysanthemum, arbor vitae, and many other plants (Vanilla beans, Claveric, 1908); the fruit of the ornamental Ginko tree (Starr, 1913), affect sensitive persons in the same manner.

Female-male juice has apparently produced mild dermatitis in susceptible individuals (Lisk, 1918).

Primula Dermatitis.—This is caused by direct contact with the common Chinese primrose plant, Pr. obconica, and a few other species. Nester describes toxic crystals in the reddish secretion of the leaves. The treatment consists in cleansing with alcohol.
or other, and the application of Zinc Ointment (O. H. Foerster, 1910; Rost, 1914). Primrose dermatitis has also been studied by Simpson, 1917.

Hypericum.—Ray, 1914, stated that cattle feeding on a Tunisian species (H. cris- sam) develop dermatitis of non-pigmented portions of the skin, and inflammation of the mucous membrane exposed to light. The phenomena are due to a fluorescent substance. Rogers, 1914, claims analogous effects for the common St. John’s wort, Hypericum perforatum. Similar symptoms are also said to be sometimes produced by buckwheat.

The action of fluorescent dyes on plants is discussed by Gickhorn, 1914.

PHYSICAL COUNTERIRRITANTS

Irritation of the skin is easily produced by physical agencies, which are often preferred to the chemical irritants. The effects and indications are similar. They can only be enumerated here: heat and cold, in the form of applications, baths, heated air, or caustery. Friction, generally combined with massage. Electricity, radiotherapy and phototherapy.

Antiquated are: Acupuncture (pushing needles through the skin to the underlying organs, said to be popular with the Chinese); scarification (small incisions with knife or needle); stones (a string carried through a fold of skin and left to suppurate). Venesection, cupping and leeches also act by altering the distribution of the blood.

DRUGS EMPLOYED FOR THEIR LOCAL EFFECTS ON THE ALIMENTARY CANAL

STOMACHICS

Bitter, aromatic and “sharp” drugs have been used since ancient times as “tonics,” and in functional dyspepsias. They were supposed to increase the appetite and improve digestion, and thus favor nutrition.

Classification.—Simple bitters generally contain some “bitter principle” —neutral substances, often crystalline, non-nitrogenous, sometimes glucosidal, and without pronounced systemic actions. In aromatic bitters these are mixed with volatile oils. The astrignent bitters contain tannin. Condiments, which also contain aromatic oils or other sharp principles, form the transition to carminatives. These are employed to secure the expulsion of gas from the alimentary canal.

Efficiency in Health and Disease.—About a tenth of the medicines mentioned by Hippocrates belong to this class, and they have always played a prominent rôle in folk medicine.

Modern scientific investigations (Moorhead, 1913) have confirmed that the bitters may improve deficient appetite, and the flow and quality (acidity) of the gastric juice, in conditions of poor health (anemia); although they have no effect on normal individuals (Carlson and co-workers, 1914 and 1915).

Bastedo, 1920, states that bitters increase the appetite in achylia gastrica, although they have no effect on the secretion. He considers them especially valuable in convalescence after acute illness.

The aromatics and condiments probably act by mild direct irritation of the gastric mucosa, the beneficial effects being due to the hyperemia and motor stimulation.

Effect in Experimental Cachexia.—In dogs provided with a Pavlov gastric pouch, and rendered cachecbic by repeated large hemorrhages, Moorhead, 1913, found that the administration of bitters improved the appetite and the gastric deficiency, although not quite to normal. The animals consumed more food and the gastric juice became more abundant and more acid. The increase of appetite occurred whether the bitters were
The use of stomachics is a common practice to aid digestion and improve overall health. The use of stomachics can be divided into different categories based on their nature and purpose. For instance, antispasmodics and emetics are used to treat specific conditions, while astringents are used to reduce inflammation and swelling.

**Antispasmodics**

Antispasmodics are used to treat conditions that cause muscle spasms or cramps. They work by relaxing the muscles and reducing pain and discomfort. Examples of antispasmodics include belladonna, antimony, andatohn, nux vomica, and picrotoxin. These substances are often used for their sedative and soothing properties.

**Emetics**

Emetics are used to induce vomiting in cases where the body needs to be cleared of harmful substances or toxins. They work by stimulating the gag reflex and causing the stomach to empty its contents. Examples of emetics include apomorphine, ipecac, and other substances that are known to provoke vomiting.

**Astringents**

Astringents are used to reduce inflammation and swelling by constricting blood vessels and reducing blood flow. They work by tightening the skin and mucous membranes, which helps to reduce swelling and inflammation. Examples of astringents include tannins, quassia, and other substances that are known to have astringent properties.

**Antisepatics**

Antisepatics are used to destroy harmful microorganisms and reduce the risk of infection. They work by disrupting the metabolic processes of bacteria and other microorganisms, making them unable to survive and replicate. Examples of antisepatics include bichromates, trichloracetic acid, and other substances that are known to have antisepatic properties.

**Therapeutic Uses of Stomachics**

- To increase appetite, from whatever cause this be deficient.
- To improve digestion in all kinds of "atomic" dyspepsias, with nausea or secretory deficiency. They tend to remove the anorexia, oppression, constipation, hypochondria, etc. In subacute or chronic maladies, the astringent latters may be more useful, otherwise they are either objectionable. Tannin must be especially avoided when the latter is to be prescribed with iron, since this makes an unsightly mixture. Tannin-free are the simple latters and the majority of the aromatic latters.
- As tonics in anemia, convalescence, phthisis, etc., to hasten recovery.
- As antitolics.
- To modify or improve the taste of food or medicines; also to obscure a "bad taste in the mouth."

**Administration**

It is believed that stomachics should be administered half an hour, preferable 5 or 10 minutes, before meals. They are generally more pleasant, and therefore more effective, if they are judi-
ciously blended, as in the aromatic and compound bitters (Tr. Gent Co.; Tr. Cardamomi Co.). Overdoses produce nausea and so defeat object.

Since the effects of bitters depend on the taste, it is useless to admit them in the form of pills and tablets, although this is often done.

**SIMPLE BITTERS**

These are practically free from aromatic oils or tannin, and therefore be mixed with water. The tintures are strongly alcol.

Certain pure alkaloids, such as Quinín or Strychnin, may be used simple bitters.

**PREPARATIONS**

Berberis, B.P.—The dried stem of Berberis aristata. The rhizome and roots aquililium were formerly official in the U.S.P. The pharmacology has been st by Hildebrandt, 1907.

Tr. Berber., B.P.—10 per cent. **Dose**, 2 to 4 c.c., ½ to 1 dram, B.P.

Calumba, U.S.P.—Calumbre Rueda, B.P.; Calumba (Colombo)—The dried n Jateorhiza palmata, U.S.P.; Jateorhiza Columba, B.P. Resembles gentian be mixed with iron. Contains several alkaloids (Calumbacin, jateorhizin, an matic), related to berberin. Biberfeld, 1908, found that these differ only quinina in action, paralyzing the central nervous system, especially the respiratory center: lowering the blood pressure through cardiac and vasomotor depression. **Dose**, 2 to 30 gr., U.S.P.

Inf. Calumb., B.P.—5 per cent. **Dose**, 15 to 30 c.c., ½ to 1 ounce, B.P.

Tr. Calumb., U.S.P.—20 per cent. in 60 per cent. alcohol. **Dose**, 4 c.c. to 1 U.S.P.

Tr. Calumb. B.P.—10 per cent. **Dose**, 2 to 4 c.c., ½ to 1 dram, B.P.

Chirata, B.P.—The dried root of Sveria Chirata.

Inf. Chirat., B.P.—5 per cent. **Dose**, 15 to 30 c.c., ½ to 1 ounce, B.P.

Tr. Chirat., B.P.—10 per cent. **Dose**, 2 to 4 c.c., ½ to 1 dram, B.P.

Gentiana, U.S.P.; Gentiana Radix, B.P.; Gentian.—The dried rhizome and ro Gentiana lutea, Switzerland. One of the most useful of the bitters; mention- Pliny. The bitter principles are the crystalline glucosid gentiin, and the amor gentianarin. There is also a small amount of tannin, not enough to be astrin but sufficient to be incompatible with iron. **Dose**, 2 gr., 15 gr., U.S.P.

* Extractum Gentianae (Ext. Gent.), U.S.P., B.P.—A watery ptilar extract, largely as pill excipient. **Dose**, 0.25 Gr., 4 gr., U.S.P.; 0.12 to 0.5 Gr., to 2 gr.

Inf. Gent., C., B.P.—1.25 per cent., with Bitter Orange and Lemon peels. 15 to 30 c.c., ½ to 1 ounce, B.P.

* Tinctura Gentianae Compansa (Tr. Gent. Co.), U.S.P., B.P.—10 per cent Gentian, with Bitter Orange Peel and Cardamom, in 45 per cent. alcohol. **Dose** 1 dram, U.S.P.; 2 to 4 c.c., ½ to 1 dram, B.P.

Pareira—The root of Chondodendron tomentosum. Contains beeberein, beerin, and other alkaloids (studied by Fallis, 1912; Scholtz, 1913). Comm “Beebeeni sulphate crys,” is isobeebein. It is isomeric with codein, and like has narcotic actions (Scholtz and Koch, 1915). **Dose** of Pareira, 2 Gr., 20 gr. Picrohiza, B.P.—The rhizome of Picrohiza kurroa. **Dose** 0.6 to 1.25 Gr., 20 gr.; antiperiodic dose, 2 to 4 Gr., 45 to 60 gr., B.P.

Ext. Picrok. Lip., B.P.—**Dose**, 1 to 4 c.c., 15 to 60 minims, B.P.

Tr. Picrok., B.P.—25 per cent. **Dose**, 2 to 4 c.c., ½ to 1 dram, B.P.

Quassia, U.S.P.; Quassi Lignum, B.P., Quassia.—The wood of Picaena e (also of Quassia amara, U.S.P.). **Dose**, 0.5 Gr., 5 gr., U.S.P.

A to 5 per cent. aqueous infusion is used by enema (to ½ pint, retained as possible) against oxyuris.

Inf. Quass., B.P.—1 per cent. **Dose**, 15 to 30 c.c., ½ to 1 ounce, B.P.

Tr. Quass., U.S.P.—20 per cent. **Dose**, 2 c.c., 30 minims, U.S.P.

Tr. Quass., B.P.—10 per cent. **Dose**, 2 to 4 c.c., ½ to 1 dram, B.P.

STOMACHICS

Succ. Tarax., B.P.—The juice, preserved with 25 per cent. of alcohol. Dose, 4 to 8 c.c., 1 to 2 drams, B.P.

Xanthoxylum, U.S.P. (Prickly Ash).—The dried bark of Xanthoxyllum americanum or X. Clava-Herculis. Contains berberin. Dose, 3 Gm., 30 gr., U.S.P.

Fidest. Xanthoc., U.S.P.—Dose, 2 c.c., 30 minims, U.S.P.

ARSTRINGENT BITTERS

With these, tannin is a prominent ingredient, whilst volatile oils are present only in small quantity, if at all. The preparations can be mixed with water.

PREPARATIONS

(*Tr. Cinchona Co., U.S.P., B.P., see Index.)

Cascarilla, B.P.—The dried bark of Croton Eluteria. Inf. Cascarilla, B.P.—3 per cent. Dose, 15 to 30 c.c., ½ to 1 ounce, B.P.

Tr. Cascarilla, B.P.—20 per cent. Dose, 3 to 6 c.c., 15 to 1 dram, B.P.

Cimicifuga, U.S.P. (Black Cohosh, Black Snakeroot; Macrotys).—The dried rhizome and roots of Cimicifuga racemosa (Constituents, Flinnemore, 1910). Dose 1 Gm., 4 Gm., U.S.P.

Est. Cimicif., U.S.P.—A powdered extract, 1 Gm. representing 4 Gm. of the drug. Dos. 0.25 Gm., 1 Gm. U.S.P.

Condurango.—The bark of Marsdenia Condurango. Used as astringent bitter especially in gastric ulcer and carcinosacs.

Fidest. Condur.—Dose, 1 to 3 c.c., 15 to 45 minims.

Cusparia (Angostura Bark).—The bark of Cusparia febrifuga. Contains alkaloids, chiefly cusparin (Troeger and Mueller, 1911). Dose, 0.6 to 2.5 Gm., 10 to 40 gr.

Serpenaria, U.S.P.; Serpent. Rhiz., B.P.; Serpentaria (Virginia Snakeroot).—The dried rhizome and roots of Aristolochia Serpentaria or reticulata. Dose, 1 Gm., 15 gr., 4 Gm., U.S.P.

Tr. Serpent., B.P.—20 per cent. Dose, 2 to 4 c.c., ½ to 1 dram, B.P.

AROMATIC BITTERS

These contain both aromatic oils and bitter principles, but no tannin. Their alcoholic preparations can not be mixed with water without turbidity.

PREPARATIONS

(Ausretii Amari, Cortex, see Index.)

Atumnicae Flores, B.P. (English or Roman) Chamomile Flowers.—The dried flower-heads of Anthemis nobilis.

O. Anthem., B.P.—The distilled oil. Dose, 0.03 to 0.18 c.c., ½ to 3 minims. B.P.

Bud, B.P.—The dried leaves of Piper Betle.

Calamus (Sweet Flag).—The rhizome of Acorus Calamus.

Narcissus, U.S.P. (German Chamomile).—The dried flower-heads of Matricaria Chamomilla. Volatile oil and bitter principles. Used as infusion, internally as domestic, carminative, and diaphoretic; externally as counterirritant. Dose, 15 Gm., 4 Gm., 4 Gm., U.S.P.

Fors., Ginseng.—The root of Panax quinquefolium, very highly valued by the Chinese, belongs to this series. So do other species of Parax and Aralia.

Numerous other bitters are used in domestic medicine, but are not worth mentioning.

CARMINATIVES

This class comprises certain aromatic oils and drugs that are used in flatulence and colic, to expel gas from the stomach and intestines and to diminish the colic pains. They have a “warm” or pungent taste and act as a mild irritant action on the digestive tract. The mechanism of their action in colic is not clear; it may involve motor stimulation, sensory reflexes, and antiseptic action.
They are often added to irritant cathartics, for the purpose of diminishing "gripping."

The most useful carminatives are the mints, fennel and anise; ginger; and capsicum.

**PREPARATIONS—CARMINATIVES**

*MENTHA PIPERITIS*. U.S.P.; Peppermint.—The dried leaves and flowering tops of Mentha piperita. *Dose*, 4 Gm., 60 gr., U.S.P.

*Ag. Mentha Pip. see Index.*

*OL. MENTH. PIP.* U.S.P.; B.P.—The distilled oil, containing at least 50 per cent. of menthol. Colorless liquid, characteristic odor, pungent aromatic taste. *Dose*, 0.1 c.c. to 0.3 minims, U.S.P.; 0.03 to 0.18 c.c. to 0.3 minims, B.P.

*SPIRITUS MENTHA PIPERITIS* (Sp. Menth. Pip.), U.S.P.; B.P.; Spirit (Esence) of Peppermint—to 10 per cent. of the Oil; the U.S.P. is tinged green by maceration with Peppermint. *Dose*, 2 c.c. to 0.3 minims, U.S.P.; 0.3 to 1.2 c.c. to 5 to 20 minims, B.P. in water.

*MENTHA VIRIDIS*. U.S.P.; Spearmint.—The dried leaves and the flowering tops of Mentha spicata. *Dose*, 4 Gm., 60 gr., U.S.P.

(Aq. Menth. Vir., see Index.)

*OL. MENTH. VIR.* U.S.P.; B.P.—The distilled oil, containing at least 40 per cent. of carvone. *Dose*, 0.2 c.c. to 0.3 minims, U.S.P.; 0.05 to 0.18 c.c. to 0.3 minims, B.P.

*SP. MENTH. VIR.* U.S.P.—10 per cent. of oil, colored by maceration with spearmint herb. *Dose*, 2 c.c. to 0.30 minims, U.S.P.; diluted Zingiber, U.S.P.; B.P.; Ginger.—The dried rhizome of Zingiber officinale. The chief active ingredient is a volatile oil. It also contains capsaicin (Nelson, 1930). *Dose*, 1 Gm., 15 gr., U.S.P., as powder or in water. Similar to Ginger are: *Galanga, Zedoaria, and Asarum.*

*Oleores. Zingib.* U.S.P.—An evaporated ethereal extract. *Dose*, 0.05 Gm., 1/4 gr. U.S.P.

*Syr. Zingib.* U.S.P.; B.P.—1 per cent., U.S.P.; 2.5 per cent., B.P. *Dose*, 15 c.c. 4 drams, U.S.P.; 2 to 4 c.c. to 1 dram, B.P.

*Funtura Zingiberis* (Tr. Zingib.), U.S.P., Tincture of Ginger.—20 per cent. tincture alcohol. *Dose*, 2 c.c. to 0.30 minims, U.S.P.

*Tr. Zingib.—B.P.—10 per cent. *Dose*, 2 to 4 c.c. to 1 dram, B.P.

**VEGETABLE CATHARTICS**

**MANNER OF ACTION.**—Cathartics or evacuants are drugs which induce defaecation. They may do so by simply increasing the bulk of the intestinal contents (petrolatum, agar, etc.) or by preventing the absorption of water (salines); or by irritating the small or large intestine, as most of the vegetable cathartics. The cathartics differ from other irritant in that their irritation is relatively mild and is confined more specifically to the intestines. This may be explained by selective action, or more simply by the alkaline reaction or bile of the intestines favoring their solution or decomposition. This solution must not be too rapid or the drug will be largely absorbed or decomposed before reaching the lower intestine. The isolated principles are therefore less useful, and sometimes less effective than the galenic preparations in which they are masked as compounds or by the extractives, gums, etc., of the drug.

**LIBERATION AND SOLUTION OF THE CATHARTIC CONSTITUENTS.**—Castor oil and croton oil become active only when their fatty acids are liberated; croton oil contains some free acid and is, therefore, pungent also on the skin. The emodin cathartics often contain glucosidal compounds, which must be split before the action occurs. The group of "resins" are insoluble in water, but are decomposed and dissolved by alkalis and bile.

**INFLUENCE OF THE BILE ON CATHARTICS.**—The bile seems to be necessary for the activation of many of the resinous cathartics, the following being relatively or quite ineffective in its absence: gamboge, podophyllum, convolvulin, jalap, and scammonium (Buchheim and Stadtmann). The bile acts presumably by increasing the solubility.
CATHARTICS

senna and calomel are active in the absence of bile (Valeri, 1910). Also seems to act quite well without bile in animal experiments; but clinically it has been claimed that it is ineffective in biliary obstruction.

Efficiency on Hypodermic Administration.—The anthracene and resinous cathartics also increase peristalsis if they are injected subcutaneously or intravenously; the resin group is even more active by this channel. The action, however, is even then a local one, the constituents being excreted into the intestine. The cathartics are not administered in this manner; in practice, since the injection would be painfully irritant; the effects are also more easily controlled when the drugs are given by mouth.

Absence of Toxic Effects.—Only very excessive doses of the drastic cathartics produce serious effects through gastroenteritis. A relatively mild irritation suffices for active catharsis. None of the vegetable cathartics are at all corrosive; and even toxic doses cause necrotic changes only as the result of excessive inflammation. The irritation is confined to the intestinal tract; the stronger cathartics escaping absorption, shift the milder laxatives would scarcely be irritant even if absorbed. There is consequently no danger of nephritis.

Location of Action.—This is of practical as well as scientific interest, because it often determines the choice of the cathartic. The older investigators have only a limited value, because they generally involve operative procedures which are apt to render the intestinal movements abnormal or to arrest them altogether. Cannon's method of observing these movements in intact animals by means of the Roentgen-rays has opened the way for more reliable observations. This method has been applied to pharmacologic problems especially by Magnus, 1909 and by his pupils. Their results have been confirmed in man (J. H. Meinlschmidt and Gebhardt, 1912). They have shown in this way that Senna acts mainly on the large intestine, increasing the defecation-reflex. Castor oil stimulates peristalsis in the small intestine. Colocynth stimulates the movements of the small intestine and leads to intestinal effusion. Magnesium sulphate quickens the passage through the small intestine, and prevents the absorption of fluid and the concentration of the contents of the large intestine. Calomel increases peristalsis both in the small and large intestine.

The Normal Course of the Food through the Alimentary Canal.—The following description (Magenes) applies specifically to cats fed with 25 c. c. of potato mash, mixed with 5 Gm. of gumnaphate (to render it opaque to the Roentgen-rays) and observed with the fluoroscope. The phenomena are similar with other food and in other animals, including man (Cannon, 1913).

Passage through the Stomach.—Immediately after feeding, the stomach is entirely filled, with the fundus dilated and resting. In the pyloric antrum, regular powerful peristaltic waves are observed, sweeping the contents against the pyloric sphincter. In a quarter of an hour, the food begins to be expelled into the duodenum, small portions of it being expelled in completed in two or three hours; meals and especially fats are discharged more slowly.

Passage through the Small Intestine.—This exhibits three motor processes: (1) The pendulum movements, which produce an alternating "pythian segmentation" of the contents; kneading and mixing the chyme, and exposing it to a large absorbing surface. (2) True peristaltic waves, appearing from time to time, and propelling the entire contents of the loop slowly for a few centimeters in a descending direction. (3) Peristaltic "rush," sudden waves of contraction sweeping the contents swiftly through long segments. This is seen especially under pathologic conditions, such as poisoning.

In cats the passage of food into the cecum begins in two and one-half to three hours and is completed in seven to eight hours after the feeding. The passage is hastened by colchicine, delayed by fats, and especially by meats (some two hours). In man the small intestine appears in the colon is four to six hours. The chyme as it reaches the colon is still semisolid.

Passage through the Large Intestine.—The colon is divided functionally into two portions. The proximal portion effects the concentration of the chyme by a churning process; groups of powerful ascending (antiperistaltic) waves sweeping the contents upon the ileo-cecal valve. Extensive absorption of fluid occurs during this process, and as the contents become solidified, fragments are separated from the lower portion.
by annular contractions of the intestinal muscle. These masses then wander very slowly toward the rectum. The passage through the large intestine occupies about the same time as that of the small intestine, in man about six hours.

Defecation Reflux.—This is started by the arrival of the mass in the rectum. It is greatly influenced, however, by the sensitiveness of the rectum and by the habits of the patient. It is here that the delay in constipation mainly occurs.

Total Time for the Passage of Food.—In man the journey from the mouth to the rectum is made in about nine hours; the further delay in the rectum depends on the habits of the individual.

Cathartics on Excised Intestines.—The effects are not related to those produced in life. For instance, the addition of aloin to the bath is inactive; cascara and castor-oil inhibit the contractions; saponified croton-oil stimulates (Meissner, 1916).

Alvarez and Taylor, 1917, obtained more positive results by giving cathartics of all the groups to living rabbits, then exciting the intestines. The segments showed irregular irritability; they contracted poorly and fatigued quickly. They employed very large doses, and the significance of their results is therefore doubtful.

Contraction of Intestine at Different Levels.—These exhibit some peculiarities (Alvarez, 1916).

Peculiarities of the Cathartics.—These are largely explained by the mechanism, the location and the severity of the action.

Time of Action.—A cathartic which acts on the large intestine cannot produce any effect until it reaches this place. Even then the response will depend on the habits of the patient. These become less important with the more irritant cathartics. The usual time of response, for the more important cathartics, is as follows:

- Salines, one-half to one hour on empty stomach; two to four hours if in bed.
- Castor oil, one to two hours on empty stomach.
- Jalap, three hours or less.
- Senna, four to five hours.
- Rhubarb or Phenolphthalein, four to eight hours.
- Cascara or Aloes, eight to twelve hours.
- Podophyllum, ten to sixteen hours.

Colic and "Gripping" is proportional to the severity of the irritation. It is due partly to increased peristalsis, partly to direct irritation, as evidenced by abdominal tenderness. It may be mitigated by belladonna and carminatives.

Consistency of the Stools and Elimination of Fluid.—The consistency varies from the soft but formed stools of the milder laxatives, to the watery stools of the "hydragogue" cathartics, the salines and drastics. The more rapid passage of the intestinal contents leaves less time for the absorption of fluid, so that the stools always contain more water. Some of the cathartics also prevent the absorption of fluid by osmosis (salines); or by imbibition (agar); and some perhaps by inhibiting the absorbing power of the epithelium (castor oil, calomel). The fluid in these cases comes really from the food rather than from the body. Even large doses of the anthracen cathartics (senna, cascara, etc.) do not increase the secretion of intestinal fluid (Thiry, Brieger, Flemming). On the other hand, the irritant cathartics (colocynth, jalap, etc.) actually produce effusion into the small intestine. The practical results, as concerns the water supply of the tissues, is the same in either case; whether these are deprived of fluid by effusion or by non-absorption.

Effects on the Local Circulation.—All catharsis must be accompanied by some hyperemia, were it only by the increased intestinal movement.
The irritant cathartics produce a more violent intestinal congestion, which extends also to the pelvic organs, and thus increases the menstrual flow.

**The Systemic Circulation.**—This is affected indirectly by the splanchic dilatation; and by the withdrawal of fluid from the blood. Both factors tend to lower the blood pressure moderately. The heart rate is slowed reflexly.

C. H. Nelson and Hyland, 1913, made a clinical study of these effects after full doses of salts and compound jalap powder. The latter gave somewhat greater results. The average decrease of the systolic pressure was 17 per cent.; of the diastolic pressure, 8 per cent.; of the pulse pressure, 24 per cent.; of the heart rate, 14 per cent. The conditions generally returned to almost normal within a day. Individual cases, especially in arteriosclerosis, gave much greater falls (from 150 to 100 mm.), sometimes with the appearance of arrhythmias and increased heart rate.

**Influence on Dropsies.**—Cathartics favor the absorption of dropsies by carrying off liquid from the body; in ascites, the emptying of the intestines also removes some of the pressure from the veins, and thus tends to the removal of the edema by improving the general circulation and the urine flow.

**Elimination of Waste Products.**—Cathartics are employed in nephritis to relieve the kidneys of a part of their work, by eliminating fluid, and presumably some of the metabolic products, through the stools.

**Uric Acid.**—Abl, 1913, claimed that cathartics increase the elimination of endogenous uric acid. Stehle, 1915, found no change with laxatives, but only with drugs that stimulate the digestive glands.

**Effects of Cathartics on Bile; Cholagogues.**—The stools, with moderate catharsis, have usually a darker color, suggesting an increased bile content. This is not due to increased secretion of bile, as was supposed by the older therapists; but to the more rapid passage of the intestines, leaving less time for the reabsorption and decomposition of the bile. The dark color of the stools is due partly to mercurous sulphid. The only really effective stimulant of bile formation is the administration of bile or bile salts; salicylates (5 Gm. per day) and olive oil are perhaps also very slightly effective.

**Experimental Investigations of Cholagogues.**—The older experiments on animals with biliary fistulas, gave contradictory results, because they did not extend over sufficient time to discount the natural variations in bile flow. Reliable experiments on human patients were made by Pfaff and Balch, 1867; Van Hengel, 1913; and Ignatowski and Monossohn, 1914. The last-named found the bile secretion increased by feeding animal protein, and especially fat. Sodium salicylate was less effective and bile-acids less. Weinberg, 1911, experimented in Pawlow's laboratory with dogs provided with gastric and biliary fistulas. He found the order of efficiency to be: bile > soap > albuminous > hydrochloric acid > olive oil. No effect was obtained with glycine, egg albumen, saccharose, dextrose, water, normal saline or sodium carbonate. Okada, 1915, found marked increase with salicylate, chloral, salol, potas. bitart., bile salts, wine, and large doses of alcohol. A slight diminution was caused by atropine; no effect by calomel or sod. bicarb. Food increased the secretion, but the nature of the diet was generally unimportant; fats, egg white, albuminous and meat extracts produced some increase; starch and sugar were indifferent. Volberth, 1915, reports diminished bbling of the gall-bladder after milk or oil; increased filling after acid or bile.

Downs, A. W. and Eddy, 1910, and Downs, 1920, report increased secretion of bile after injection of epinephrin, secretin and various gland substances (not after thyroid).

**Excitation of Gall-bladder.**—Klee and Kniepfl, 1914, found that this is stimulated in animals; by eating, entrance of the chyme into the intestine, injection of Witte's serum; and especially by the administration of olive oil. No effect was produced by 0.2 per cent. hydrochloric acid. Weinberg, 1911, also observed this effect of oil.
Autonomic Drugs on Gall-bladder.—Lieb and McWhorter, 1915, found that the muscles of the gall-bladder receive augmentor impulses from the parasymphathetic inhibitory from the sympathetic. The autonomic drugs act correspondingly: pilocarpin, barium and strychnin stimulate; atropin, epinephrin, nitrates and bile salt relax. The rhythmic movements are increased during digestion, or by the introduction of acid into the duodenum (Okada, 1915).

Therapeutic Indications.—Cathartics are used chiefly for the following indications:

To relieve constipation—cascara, rhubarb, phenolphthalein, small doses of salts.
To soften the stools, in hemorrhoidal and other rectal diseases; and to prevent straining in aneurism, hernia, and apoplexy—petrolatum, cascara podophyllum, sulphur.
To cleanse the intestines in digestive disturbances, diarrheas and other intestinal putrefactions—calomel, castor oil, rhubarb, cascara, aloe.
To facilitate the absorption of dropies; to relieve the kidneys in nephritis; to lower the temperature in fevers; to relieve internal congestions, especially of the brain—calomel, large doses of salines, compound jalap powder; in emengendes, croton oil or elaterin.

Cathartics are perhaps the most ancient method of internal medication, and were for a long time practically the only method. The Greeks used the same word Φασαμενος, both for internal medication in general and for the use of cathartics in particular. The present English word physic is similarly applied.

Contraindications.—All inflammatory conditions of the abdomin organs (peritonitis, gastroenteritis, etc.) contraindicate the administration of intestinal irritants. Pregnancy and menstruation are contraindication to the use of the stronger cathartics, since the hyperemia may lead to abortion or excessive menstrual flow. General debility, tendency to collapse, threatened intestinal hemorrhage, and toxic spasm of the intes tine, are further contraindications. Cathartics should not be used in intestinal obstruction or intussusception.

Habitual Constipation.—In this condition ("chronic intestinal stasis"), cathartics should be used as little as possible; the condition being treated most effectively by the removal of the cause and the cultivation of proper hygienic and dietetic habits; aided by the mechanical laxatives, petrolatum, agar or enemis. Small doses of salts, cascara or similar aperients may be needed. The irritant cathartics should be avoided.

In using cathartics against habitual constipation, one should always employ the mildest remedy which will accomplish the result. One reason for this is that soft, non liquid, stools are desired; but, further, a "habit" is quite readily acquired so that the intestines will require stronger and stronger stimuli, and the usual cathartics gradually lose their efficiency. If the treatment has been begun with mild measures, stronger ones are left for later use if necessary. The habitual use of very irritant cathartic is also apt to engender chronic enteritis.

Therapeutic Classification.—The cathartics may be classified according to their clinical characters, i.e., mainly by the degree of their effects. This can not be done rigidly, because the effect varies with the dose; moreover, the names are defined somewhat differently by individuals authors.

The following table gives a useful clinical classification. The more important agents are in italics.
1. Laxatives or Aperients.—Increase peristalsis only moderately, producing somewhat more frequent stools, of almost normal consistency, and this without causing notable irritation. They are active in doses of 10 Gm. or over.

- Fruits, Manna, Agar, etc.; mechanical means (massage, enemas, etc.);
- Sulphur, Magnesia, Carminatives, Bile, Bland Oils (Olive, Cottonseed, Liquid Petrolatum, etc.).

(Small doses of Cascara, Senna, Castor Oil, Rhubarb, and Ipecac are also laxative.)

2. Purgatives.—Increase peristalsis actively, causing more frequent soft or semifluid stools.

   (A) Simple Purgatives.—Active in doses of 0.2 to 1 Gm. Full doses may cause more or less colic and irritation:
   - Aloe, Rhubarb, Senna, Cascara, Phenolphthalein, Castor Oil, Calomel, small doses of drastics.

   (B) Saline Purgatives.—Active in doses of about 10 Gm. Rather profuse, watery stools, with practically no irritation or gripping:
   - Sulphate of Magnesium or Sodium, Sodium Phosphate, Magnesium Citrate, Potassium Bichromate, Rochelle Salt, etc.

3. Drastics.—Produce watery stools, with much irritation. Large doses are apt to set up an enteritis:

   - Elaterium, Colocynthis, Jalap, Scammony, Gamboge, Podophyllum, Croton Oil, the stronger Mercurials, and Antimony Sulphid.

4. Hydragogues.—All which produce watery stools, i.e., the salines and drastics.

5. Cholagogues.—Were supposed to increase the bile flow:

   - Aloe, Rhubarb, Mercurials, Podophyllum, Euonymus, Sod. Salicylate or Phosphate, Acid, Nitrohydrochlor. Dilut., Bile.

Pharmacologic Classification.—The cathartics may also be divided into the following groups:

1. Those which act mainly on the colon and rectum, inhibiting colon antiperistalsis, and provoking the defecation reflex. This includes the drugs containing emodin and other anthraquinon derivatives: Senna, Cascara, Rhubarb, Aloe, and perhaps also Phenolphthalein and Bile.

2. Those which stimulate the peristalsis of the small intestine and inhibit the antiperistalsis of the colon, but without producing much irritation or effusion. This includes Castor Oil and probably Calomel and Sulphur.

3. Those which, in addition to these actions, cause marked intestinal dilution and irritation. This comprises Colocynthis, Jalap, and presumably the other drastic resinous cathartics, Podophyllum, Elaterium, Gamboge, Croton Oil, etc.

4. The saline cathartics, which retain water by osmosis.

5. The colloid cathartics, which retain water by imbibition: Agar, Fruits, Manna, etc.

6. Emollient cathartics, such as Petrolatum or Olive Oil.

7. Enemas and similar local measures.

THE ANTIRAQUINON OR EMODIN CATHARTICS

Active Constituents.—Senna, Rhubarb, Cascara, Aloe and related drugs contain glucosidal compounds which are themselves inactive. In the alkaline intestine they are hydrolyzed or oxidized, yielding various
oxymethyl-anthraquinons (Buchheim; Tschirch and pupils, 1899), which produce the cathartic action. The pure substances would be too irritating, but their action is graded by their slow liberation, and by the presence of colloid extractives. The most common of these substances are emodin and chrysophanic acid. Numerous isomers of these are possible (15 for emodin alone). The special characters of the different drugs is probably due to differences in these isomers; in the stability of their glucosidal combination; and to the presence of other associated substances (tannin in rhubarb). The action of these drugs does not progress to inflammation. They are often more effective when given in divided doses (three times daily), than when given in a single dose.

Emodin is partly absorbed and is excreted into the urine and milk (laxative effects on sucklings).

The structure of these anthraquinons is shown by the following formulas:

\[
\begin{align*}

\]

Emodin is probably the most important of these principles. It is present in the amount of 0.8 to 1 per cent. in senna; 2.6 per cent. in frangula; 0.6 per cent. in cascara; 0.8 per cent. in Cape aloe; and 1.5 per cent. in rhubarb (Tschirch and Hiepe).

Coloration of Urine.—The drugs containing emodin color the urine yellowish-brown when it is acid, reddish or violet when alkaline. It may be advisable to acquaint the patient with this fact.

Other drugs which change the color of the urine are: Laxwood (Hematoxylin) does not color acid urine, but produces a reddish or violet color in alkaline urine. Sanguinaria gives a yellow color to acid urine, with a yellow foam; if the urine is made alkaline it gives a very pronounced pink. Picric acid gives reddish-brown color in both acid and alkaline urine. The various coal-tar products give a brownish-black color. Methyl blue imparts a green color.

Manner of Action.—The older work (Buchheim; Tappeiner and Brandl, 1880) showed that the action of the emodin group is mainly on the large intestine, which reacts by increased movement also to intravenous injection; and that there is no increase of intestinal secretion. The X-ray experiments of Magnus with senna show that the effects consist chiefly in increase of the local defecation reflex, and inhibition of the colon antiperistalsis.

Experiments of Magnus (1900)—Senna does not affect the course of the chyme through the stomach and small intestine. The first effect occurs when the senna reaches the colon, so that its action must be strictly local. Here it inhibits antiperistalsis and thus prevents the concentration of the feces. At the same time, it starts the defecation reflex. It thus leads to the expulsion, first of the solid contents already present in the rectum, and then of the more fluid contents of the upper colon.
CASCARA SAGRADA

Cascara is used chiefly in habitual constipation. It softens the stools without noticeable irritation. The susceptibility is not lost with use; on the contrary, the establishment of regular habits usually permits it to be gradually withdrawn. By its bitter taste, it acts also as a stomachic. It may be given as the fluidextract, 15 drops three times daily; or in a single dose, a half teaspoonful, in the evening. This causes a single soft stool in the morning. In the Aromatic Fluidextract, which is much more pleasant, some of the bitter and cathartic principles have been destroyed (Wenzell, 1886) by an alkali (magnesia). It may be given in twice the dose.

It is generally stated that the fresh bark is emetic, through the presence of a ferment, which gradually disappears as the bark is aged. R. H. True, and Kingh, 1905, did not find any emetic effect from the unaged bark.

In the excised intestine, cascara increases the rate, but lessens the intensity of the contractions (Flury, 1912). The tone is increased by small, and lowered by large doses, also intravenously (Ott and Scott, 1908).

When cascara is administered hypodermically (as with the proprietary "Peritain"), its constituents are rapidly absorbed and excreted by the kidneys, producing mild irritation, but not catharsis (Chistoni, 1914).

Cascara sagrada ("Sacred Bark") was used by the early settlers, but was little known to the profession till introduced by Bundy, 1873. Johnson and Hindman, 1914, reviewed its history, composition and bibliography.

PREPARATIONS—CASCARA

Cascara Sagrada (Casc. Sagr.), U.S.P., B.P.; Cascara Sagrada (Cascara; Rhamnus Purshiana).—The dried bark of the trunk and branches of the shrub Rhamnus Purshiana, stored at least one year. The active principles are: Cascarin, which is a cathartic or emodin principle; isoelemid, bitter resins, etc.; no chrysarobin or chrysophanic acid (Sweett, 1904. This author claims that emodin is not the main active constituent).

Dose: 1 Gm., 75 gr., U.S.P.

Fluid. Cascr. Sagr. Arom., U.S.P. (Aromatic Cascara).—A watery extract, with the bitter principles partly destroyed by maceration with magnesia; preserved with 45 per cent. of alcohol, flavored with glycyrrhiza, aromatics and saccharin. Dose: 1/2 c.c. to 1 c.c., 30 minutes, U.S.P.

Syr. Casc. Arom., B.P.—40 per cent. of Liquid Extract, flavored with orange, cinnamon and syrups. Dose: 3 to 6 c.c., 1/2 to 1 dram, B.P.

Frangula, U.S.P. (Buckthorn Bark).—The dried bark of Rhamnus Frangula. Dose: 1 Gm., 15 gr., U.S.P.

Romea Crispae.—Dock root is said to contain chrysophanic acid about 0.1 per cent. of an emodin identical with that of cascara (Beal and Okey, 1910).

SENNA

The effects are more extensive and more irritant than with the other drugs of the group, so that it is better suited for acute than for chronic constipation. There is considerable griping, which may be corrected by carminatives, or by the previous extraction of the resins with alcohol (as in the Fluidextract).

PREPARATIONS—SENNA

Senne (Senn.), U.S.P.; Senne Folia (Senn. Fol.), B.P.; Senna.—The dried leaflets of Sesamum indicum or angustifolia. Introduced by the Arabsians. Constituents: senna-emodin, senna-isoeudrin, senna-chrysophanic acid, and other anthraquinone derivatives (bixin, aloem-odonin), free and in glucicosidal combinations; also some sali-
cyclic acid (Tutin, 1913, 1914; Tambach, 1913). *Dose,* 4 Gm., 1 dram, U.S.P., as cathartic; as laxative, 1 to 2 Gm., 15 to 30 gr., infused in a cup of hot water. Many of the laxative nostrums ("Castoria," "Fig Syrup," "various "Teas") owe their activity mainly to senna.

A preparation for hypodermic use is marketed as "Sennatin." Betke, 1914, claims good effects in postoperative ileus.

*Conj. Senn.,* B.P.—10 per cent. of powdered Senna. *Dose,* 4 to 8 Gm., 2 to 2 drams, B.P.

*Inf. Senn.,* B.P.—10 per cent., with Ginger. *Dose,* 15 to 30 c.c., ½ to 1 ounce, repeated; single, 60 c.c., 3 ounces, B.P.

*Inf. Senn. Co.,* U.S.P. (Black Draught).—Average *dose,* 120 c.c., 4 ounces, U.S.P., contains about 7 Gm. of Senna; 15 Gm. of Magnes. Sulph., with Mannia and Fennel.

*Fistex. Senn.,* U.S.P.—*Dose,* 6 c.c., 30 minims, U.S.P.

*Mist. Senn. Co.,* B.P.—25 per cent. of Magnes. Sulph. in Inf. Senn., with aromatics. *Dose,* 30 to 60 c.c., 1 to 2 ounces, B.P.

*Syn. Senn.,* B.P.—30 per cent. Flavored with coriander.

*Inf. Senn.,* B.P.—4 c.c., 1 dram, U.S.P.

*Syn. Senn.,* B.P.—About 40 per cent., with coriander. *Dose,* 2 to 8 c.c., ½ to 2 drams, B.P.

*Tr. Senn. Co.,* B.P.—20 per cent., with caraway and coriander. *Dose,* 2 to 4 c.c., ½ to 1 dram, repeated; single, 8 to 12 c.c., 2 to 4 drams, B.P.

*Pulvis Glycerici Compositus* (Pulv. Glycyrrh. Co.,) B.P., U.S.P. (Compound Licorice Powder).—Greenish-yellow to greenish-brown powder; odor of fennel. Average *dose,* 4 Gm., 1 dram, U.S.P.; contains about 0.7 Gm. of Senna, 0.5 Gm. of Sulphur and a little Fennel oil. *Dose,* 4 to 8 Gm.; 1 to 2 drams, B.P.

*Senna Fructus* (Senn. Fruct.), B.P.; Senna pods.—The dried ripe fruits of Cassia acutifolia or angustifolia.

*Cassia Fructus* (Cassia Fruct.), B.P.—The ripe fruits of _Cassia Fistula._

*Cassia Pulpa* (Cassia Pulpa.), B.P.; _Cassia Pulpa._—An evaporated watery extract of the preceding.

**RHUBARB**

This contains a considerable quantity of tannin as well as cathartic principles. The astringent action predominates with smaller doses (0.05 to 0.5 Gm.) and these are used as astringent bitter in gastric caarthur, and in diarrhea. Larger doses (1 to 5 Gm.) are laxative with little colic. They may be employed in chronic constipation, but the astringent action makes it inferior to cascara.

It may cause skin eruptions.

*Constituents* (Tutin and Clewer, 1911). The cathartic principles are mainly _resin_, non-glaucosidal, but yielding on hydrolysis various anthraquinone derivatives, which also exist partly free: rhein, emodin, aloe-emodin, chrysophanic acid, etc. The astringent principles are glucosidal compounds of tannin (rheotannic acid), and gallic acid. There is also a large amount of calcium oxalate.

**PREPARATIONS—RHUBARB**

*Rheum,* U.S.P.; *Rhei Rhei,* B.P.; Rhubarb.—From _Rheum_ officinale and probably other species growing in China and Tibet. (The species of Rhubarb cultivated in this country are devoid of cathartic properties.) Rhubarb has been used since antiquity in China, and by the Roman physicians. *Dose,* 1 Gm., ½ gr., U.S.P.; 0.3 to 0.6 Gm., 3 to 10 gr., repeated; single, 1 to 2 Gm., 15 to 30 gr., B.P.

*Ext. Rhei,* B.P.—A powdered extract, 1 Gm. representing 2 Gm. of drug, U.S.P.

*Dose,* 0.25 Gm., 0.4 gr., U.S.P.; 0.12 to 0.5 Gm., 2 to 8 gr., B.P.

*Fistex. Rhei,* U.S.P.—*Dose,* 1 c.c., 15 minims, U.S.P.

*Inf. Rhei,* B.P.—1 per cent. *Dose,* 15 to 30 c.c., ½ to 1 ounce, B.P.

*Mist. Rhei et Sodae,* N.F.—Sod. bicarb., 3 per cent. *Fluidext. Rhubarb,* 1 per cent.; *Fluidext. Ipecac,* 0.3 per cent.; *Sp. Peppermint, Glycerin,* and *Water,* *Dose,* 4 c.c., 4 dram.

*Pill. Rhei Co.,* U.S.P.—*Each pill contains* 0.13 Gm. of Rhubarb, 0.10 Gm. of Aloe.

*Dosage,* two pills, U.S.P.

*Pill. Rhei Co.,* B.P.—Pill-mass containing 25 per cent. of Rhubarb, 20 per cent. of Aloe, 14 per cent. of Myrrh. *Dose,* 0.25 to 0.5 Gm., 0.4 to 8 gr., B.P.
CATHARTICS

dose 10 cc., 25 drops, U.S.P.

Symp. Rhei. B.P.—7 per cent., with Coriander. Dose, 2 to 8 c.c., 5 to 2 drams, B.P.

Symp. Rhei Aromaticus (Symp. Rhei Arom.), U.S.P.; Aromatic Syrup of Rhiarb, 15 per cent. of Tr. Rhei Arom. 0.1 per cent. Pot. Carb. Dose, 10 c.c., 25 drops, U.S.P.

Tr. Rhei, U.S.P.—20 per cent.; flavored with Cardamon. Dose, 4 c.c., 1 dram, U.S.P.

* Tinctura Rhei Aromatic (Tr. Rhei Arom.), U.S.P.—20 per cent. flavored with Cinamon, Clove and Nutmeg. Dose, 2 c.c., 20 min., U.S.P.

*Tinctura Rhei Composita (Tr. Rhei Co.), B.P.—10 per cent.; flavored with Cardamon and Coriander. Dose, 2 to 4 c.c., 15 to 1 dram, repeated; single, 8 to 16 c.c., 2 to 4 drams, B.P.

A_LOES

General Statement.—The inspissated juice of the leaves of various species of Aloe from the West Indies, Africa, etc., furnishes the commercial varieties of aloe, which differ somewhat in composition and action. They contain anthraquinone derivatives, especially aloins (10 to 16 per cent.). These are glucosides which are probably inactive themselves; but which yield emodin and other active anthraquinone derivatives on cleavage. This cleavage occurs in the intestine; it is favored by alkalis and perhaps also by bile and by iron salts. Aloe may be used as such. Aloes is intensely bitter, so that it must be administered in pills. Very small doses may be used as stomachic. Moderate doses are simply laxative, but somewhat apt to gripe, and are therefore commonly combined with belladonna or carminatives (myrrh, etc.). They do not lose their efficacy or opiate-like character by being used and would be suited to habitual constipation, but have no advantage over cascara. Aloe suposes is to produce considerable congestion of the pelvic organs and are therefore contraindicated in hemorrhoids, menstruation and pregnancy. On the other hand, they may be used as emmenagogues. They are especially prescribed for correcting the constipative action of iron medication.

Hydromederc Administration.—Aloes is also effective subcutaneously, being excreted into the large intestine; but this method is too painful (H. Meyer, 1890). Aloes Nephritis.—In rabbits, hydromederc injection (3 c.c. per kilogram of 5 per cent., repeated on two or three successive days) produces a tubular nephritis. The anatomic lesions have been investigated especially by Mirrér (1885); they are practically the same as acute and chronic poisoning, and consist mainly in degeneration of the epithelium of the convoluted tubules. This loses its striations and staining qualities, and the nuclei disappear. The glomerular epithelium is but slightly altered, and the glomerular vessels show no lesions. The urine may be increased or diminished and contains protein, leukocytes, casts, crystals, and blood.

Metabolism.—There is also an increased protein metabolism, resulting in rise of ura in mammals, of uric acid in birds. The latter may therefore develop gout. Dogs show some fever (Berrir, 1913).

PREPARATIONS—ALOE

Aloe, U.S.P., B.P.; Aloe.—The dried juice of the leaves of Aloe species: Aloe Perly, yielding Soocotine Aloe; Aloe vera, yielding Curcufl Aloe; Aloe ferox, yielding Cap Aloe (Natural history of the commercial aloe, Wilbert, 1905). Aloe was used by the Greeks and probably by the Egyptians. Brown, opaque, glossy masses; aromatic odor; nauseous bitter taste. Partly sol. in water; completely sol. in alc. Dose, 2.5 gm., 4 dr., U.S.P.; 0.12 to 0.5 Grm., 2 to 5 gr., B.P.; best as pills.

Per. Aloes Com. B.P.—1 per cent. of Ext. Aloe, with Myrrh, Aromatics and Euphoric. Dose, 15 to 60 c.c., 1/2 to 3 ounces.

Lit. Aloe, B.P.—A powdered watery extract. Dose, 0.06 to 0.25 Grm., 1 to 4 gr., B.P.
PHENOLPHTHALEIN

This is a mild tasteless purgative, normally acting even on the large intestine.
It is but little absorbed from the alimentary canal, and is ordinarily non-toxic even in large doses. It may be used in habitual constipation, and has been exploited under several proprietary names (purgen, laxams, etc.). *Phenoltrachlorphthalein, 0.4 Gm. dissolved in 20 C.C. of neutral olive oil, has been suggested as a subscutaneous purgative (Abel and Rowntree, 1905; Rowntree, 1910). Phenolsulphonphthalein is used to test the excretory efficiency of the kidneys (Abel and Rowntree, 1905; Rowntree and Geraghty, 1910; Chesney, Marshall and Rowntree, 1914).

Action.—The purgative effect of this familiar indicator was discovered by V. Vamosy in 1900. It appears to be connected with the quinone structure. It has been investigated experimentally by V. Vamosy, 1902; Tunacliff, 1902; Fleig, 1905; Abel and Rowntree, 1906, etc.; and clinically by Dornbluth, 1905, and many others. Animals are rather less susceptible than man. Ott and Scott, 1908, found evidence that it acts directly on the muscle of the excised intestine. Fleig and others attribute the action to increased intestinal secretion, but the evidence is not satisfactory. It acts also upon hypodermic or intravenous administration, reaching the intestine through the blood. The blood pressure is scarcely affected, even when large doses are injected into a vein (Tunacliff, Abel and Rowntree, etc., the kidneys are not irritated, nor are there any other systemic effects. Phenolphthalein itself does not produce local irritation, but its soluble salts are highly irritant. It is not bactericidal (Abel and Rowntree).

Absorption, Fate and Excretion.—Phenolphthalein is insoluble in acids, but gives a pink solution with alkalies. It passes the stomach unchanged. It is partially dissolved in the alkaline intestine, but very little is absorbed, almost the entire quantity (over 85 per cent.) appearing unchanged in the feces (Vamosy). After large doses, traces are found in the urine (Fleig; Elmer, 1909), which is then colored violet-red by alkalies (Gruenbild, 1906).

After hypodermic administration, it is excreted by the urine, feces, saliva, tears, etc. The excretion is very rapid, beginning within fifteen minutes and ending in twelve to eighteen hours. In the urine it exists partly free, partly conjugated. The body content is excreted more rapidly than ever (Fleig). It is excreted into the intestine mainly by the bile, and to some extent reabsorbed in the large intestine (Abel and Rowntree). The fate of the phtaleins is also discussed by Kastle, 1906.

Toxic Effects.—Only a few doubtful cases are on record (Holz, 1905; Best, 1906; Zabel, 1911; Orland, 1913, etc.). These presented phenomena of intestinal irritation, always ending in recovery. Hydrick, 1914, claims that even 0.05 to 0.15 Gm. produces
quite constantly a slight albuminuria, lasting one to three days. On the other hand, very large doses have often been given without bad effects: to man, several grams by mouth, 0.5 Gm. subcutaneously; to dogs, 1.25 Gm. per kilogram.

**Administration.** Phenolphthalein may be taken in the evening, as powder, capsules, or lozenges, in doses of 0.1 to 0.2 Gm., 1.5 to 3 Gm.; for bedridden patients, 0.5 Gm., 5 Gm.; for children, 0.03 Gm., 0.5 Gm. These smaller doses soften and regulate the stools for several days, with little or no colic. Large doses are hydroagogue.

**PREPARATIONS—PHENOLPHTHALEIN**

*Phenolphthaleinum* (Phenolphthal.), U.S.P., B.P.; Phenolphthalein (Dibromo-

phenolphthaleinone), (C₉H₄.Br₂).CO,C₉H₄.CO. White, crystalline powder, odorless and tasteless. Almost insol. in water, sol. in alc. (1:13). Dose, 0.15 Gm., 0.25 Gm., U.S.P.; 0.15 to 0.5 Gm. 2 to 5 Gm., B.P.

**Phenolphthalein, N.N.R.—** The preceding, with CO replaced by SO₂,

Dose, 6 mg., as test of kidney function (for details, see N.N.R.).

**Rate of Excretion.**— In dogs, Arbuthnot et al., 1917, find that with intramuscular injection the excretion varies greatly according to the rate of absorption. With intravenous injection, about 50 per cent. is excreted in an hour, regardless of the amount injected (between 3 and 30 mg.). The amount excreted is practically independent of the quantity of urine (beyond a certain minimum). A part is lost in the body by resorption, so that the recovery is not quantitative (Kendall, 1917).

**Absorption from Subcutaneous Injections.**—McIntosh and West, 1917, report that these are normally followed by the appearance of the drug in the urine within 10 minutes but that it may be considerably delayed in diseases of the central nervous system, especially when the meninges are involved.

**Related Compounds.**—Other compounds related to phenolphthalein are also excreted by the kidneys. These may be somewhat antiseptic (E. J. Davis, 1948).

**BILE**

The administration of bile or bile salts (sodium glycocholate and taurocholate) stimulates the secretion of bile (Pfaff and Balch, 1897), increases peristalsis (Stadelmann, 1896); acts as an indirect antiseptic (Limbourg) by evacuating the intestines, and facilitates the digestion of fat. They have been advocated in obstructive jaundice and in biliary fistulas; but their effects are not very pronounced. Added to enemas, bile is used as a laxative against impacted feces and against ascites, but has little advantage over soap.

The pharmacologic actions of bile-salts are similar to those of saponins. Like these, they lower surface tension, hemolyze blood, dissolve fats and proteins, etc.

**Relative Choliagogic Effects of Bile Constituents.**—By oral administration to dogs with biliary fistula, the following results were obtained (C. W. Hooper, 1927; Hooper and Whipple, 1927):

<table>
<thead>
<tr>
<th>Vitamin</th>
<th>Volume of Bile</th>
<th>Output of Bile Pigment</th>
</tr>
</thead>
<tbody>
<tr>
<td>Taurine Acid</td>
<td>Great increase</td>
<td>Little effect</td>
</tr>
<tr>
<td>Glycocholic Acid</td>
<td>Moderate</td>
<td>Marked diminution</td>
</tr>
<tr>
<td>Cholic Acid</td>
<td>Little</td>
<td>Slight</td>
</tr>
<tr>
<td>Bile Fat</td>
<td>No</td>
<td>Strong</td>
</tr>
<tr>
<td>Entire Bile</td>
<td>Marked</td>
<td>Diminished *</td>
</tr>
</tbody>
</table>

*This indicates that the bile pigment is not absorbed as such.

**Peristalsis.**—On excised small or large intestines, bile or bile salts produce mainly spasm (Ott and Scott, 1909; d’Enrico, 1910); but the large intestines may be stimulated (Schuepbach, 1910). In man, evacuation is assured especially by enemas, but also by oral administration (Glassner and Singer, 1910).

**Excised Uterus.**—Bile and bile salts, in moderate concentrations, increase the contractions of the pregnant, not of the virgin uterus. High concentrations inhibit (Cautron, 1914).
Clotting of Blood.—This is delayed by the addition of bile, apparently by interference with the reaction between fibrinogen and thrombin (Hoessler and Stebbins, 1910).

Autolysis.—Bile salts and whole bile activate autolytic processes, and are thus cytolytic (Tatum, 1916).

Toxic Actions.—Bile is non-toxic by mouth, but when injected into the circulation (Melzer and Salant, 1905; 1906; Bunting and Brown, 1912) it produces severe nervous and cardiac depression (Brandenburg, 1903; Glur, 1909) and hemolysis. It is also directly toxic to muscle and nerve.

J. H. King and H. A. Stewart claim that the pigments are mainly responsible for the circulatory effects. High toxicity of the bile pigments has been affirmed and denied (bibliography, Merck's Report, 1914, 25:12).

Bile acids are highly toxic. Small doses stimulate the vagus center; larger doses depress the heart directly, with slow irregular pulse and low blood pressure. They also produce depression of the medullary centers, coma and paralysis; and hemolysis and cell destruction. They have a local vasoconstrictor action (Samelson).

Toxic Symptoms of Biliary Retention (Obstruction).—These consist in dulness, delirium, convulsions, fever, generally fatal in a few days. It is not at all certain that the effects are due entirely to bile acids or pigments; possibly more complex poisons are concerned.

Bile Salts in Gonorrhea.—Loechlen, 1909, introduced the local injection of bile salts in the acute stage for destroying the gonococci. V. Hofmann, 1912, found that 1 to 2 per cent. had little effect; 5 to 10 per cent. gave better but only temporary results. They were improved by following with silver injections, or by using a soluble siberlic acid compound.

Bibliography.—An extensive bibliography on bile is contained in Merck's Report, 1914, 25:1.

PREPARATIONS—BILE

Fetal Bovis, U.S.P.; Ox Gall.—The fresh bile of Bos taurus.

Fetal Bovinum Purificatum (Fet Bov. Pur.), B.P.; Purified Ox Bile.—An evaporated alcoholic extract. Dose, 0.5 to 5 Gm., or 5 to 15 grs., B.P.; as emema, 1 to 50.

Extractum Felli Bovis (Ext. Fet. Bov.) U.S.P.; Extract of Ox Gall (Purified Ox Gall). An alcoholic extract of bile, evaporated and mixed with starch; 1 Gm. represents 8 Gm. of Ox Gall. Very bitter yellow powder. Dose, 0.1 Gm., 1/2 Gm., U.S.P., in pills or in sugar-coated capsules. As emema 2 per cent.

Bile Salts, N.N.R.—The various commercial preparations are used as pills, generally 0.05 to 0.5 Gm., 1/2 to 1 gr.; or as suppositories, in the same dosage.

Sodium Cholate (not to be confused with sodium cholate) is a misnomer for "Platter's Bile," a preparation of impure bile salts. Laxative dose 0.3 Gm.; or by enema, 0.2 to 0.5 Gm.

CASTOR OIL

This consists mainly of the triglycerid of an unsaturated fatty acid, ricinoleic acid. The neutral fat is not active, but becomes so when it is saponified in the intestine. The cathartic effect is due mainly to motor stimulation of the small intestine. The intestinal secretion is not increased, the fluid character of the stools being due to the quicker passage of the feces.

With the usual dose, 1/2 to 1 ounce, the response is certain and complete, resulting in a few hours in one or two extensive semifluid stools with but slight hyperemia or irritation, there being little or no colic. The evacuation is so complete that there may be some after-constipation. It is especially suited to the treatment of acute constipation or acute diarrhea from dietetic errors, ptomain and other poisoning, etc. It does not use continuously, since this may produce gastric disturbance. There is some pelvic congestion, so that it is avoided during menstruation and pregnancy.

Mechanism of Action.—This has been studied by x-ray by Magnus, 1908, and his observations have been confirmed on man. The pure oil delays slightly the passage through the stomach (as do other neutral oils). Rancid oil hastens the gastric expulsion.
In the small intestine, the segmenting movements and peristalsis are greatly increased, so that the expulsion may be completed in 1 to 2 hours instead of the normal 12 hours in the colon, the normal antiperistalsis is allayed, so that the feces escape concentration. The populsive movements of the colon are not much increased, but the passage of the fecal material is hastened by its thinner consistency.

In China it is used as an article of diet. The properties of Castor Oil were known to Herodotus; but Croton Seeds were first described in the middle of the sixteenth century.

Castor oil is said to be an active poison for flies (Boyes and Garjot, 1919).

**Administration.**—It is best given on an empty stomach an hour before breakfast. The taste may be somewhat disguised by wetting the mouth with hot coffee or milk and giving the oil floating in these liquids, so that it will not be so adherent. The after-taste may be mitigated by peppermint or bread. It is sometimes preferred in emulsion: N.F., 33 per cent.; B.P. (Mistura), 40 per cent. flavored with orange flower and cinnamon. The soft gelatin capsules are the only tasteless method; but since the ordinary size contains only 1 c.c., it is difficult to administer an effective dose. (For other methods, see J.A.M.A., 60:1174.)

**PREPARATIONS—CASTOR OIL.**

*Oleum Ricini* (Oliv. Ricinum), U.S.P.; Castor Oil.—A fixed oil expressed from the seed of Ricinus communis. An almost colorless viscous oil, of faint but characteristic odor and extremely disagreeable taste. Sol. in an equal volume of alc. *Dose,* 15 c.c.; 1 drams. U.S.P.; 4 to 30 c.c., 2 to 8 drams, B.P.; for infants, a teaspoonful. Also used as hair tonic, diluted with 1 to 10 vol. of alcohol.

*Eflud. Ric. Oil.* B.P.—A 37.5 per cent. emulsion. *Dose,* 30 to 60 c.c., 1 to 2 ounces, B.P.

**Ricin**

**Occurrence, Clinical Symptoms and Treatment.**—This toxin is contained in the castor seeds, but does not pass into the oil. Similar sub-toxin has been obtained in croton oil (Croton); and in jequirity seeds (Abrin); in the bark of the locust tree, Robinia pseudoacacia (Robinia); and in the seeds of some leguminous plants (Phasian). The last is far less toxic (Mistura of Literature, Ford, 1913). The ricin is responsible for the toxic effects on eating the castor seeds; five or six of these are fatal to a child, twenty to thirty, three or four seeds may cause violent gastroenteritis, with nausea, headache, persistent vomiting, colic, sometimes bloody diarrhea, thirst, emaciation, and great delirium. The symptoms usually do not set in until after several days. More severe infections cause small frequent pulse, cold sweat, ileus, and convulsions. Death occurs in six to eight days, from the convulsions or from exhaustion. The fatality is about 6 per cent. This small fatality is due to the destruction of the poison in the alimentary canal. The treatment would be innocuous and symptomatic. Three to ten days are required to complete recovery (Critical Review and Bibliography, Ford, 1912).

**Effects on Animals.**—The actions can be best studied on rabbits, by hypodermic or intravenous injections. Even with the latter, there is an incubation period of at least twelve to eighteen hours before symptoms appear. These correspond to those described for man. They are partly local—gastroenteritis; and partly central—paralysis of the respiratory and vasomotor centers. The local inflammation also occurs on other mucous membranes to which the poison may be applied, especially the conjunctiva.

The autopsy findings are very characteristic. They consist in swelling and reddening of Peyer's patches and mesenteric lymph glands, internal hemorrhages and diffuse sequelae. Cruz, Flexner, Mueller and others have shown that these lesions are not due to thrombosis, but to direct action on the tissues. The site of the injection is boggy.

Frogs have a much higher resistance than mammals. The phytotoxins have no direct effect on muscle or nerve.

**Action on Blood.**—In vitro, ricin hemolyzes and agglutinates the corpuscles of nearly all warm-blooded animals (Stollmark, 1888). The agglutination does not seem to occur in the body, but is of great importance as an immunity phenomenon. Leucocytes, lymphoid, and other cells (except those with thick membranes, as yeast) are also agglutinated; as likewise the stroma of laked corpuscles (Ellstrand). The presence of serum is inactive.

The agglutination has been referred to precipitation of the nucleoalbumins (Statson) or other proteins, such as those of serum (Krons, 1903). All kinds of cooled precipitates carry down ricin, and it is adsorbed by solid proteins and lipoids.
Nature of Ricin.—This appears to be a true protein; for a preparation of ricin has been obtained, which is a typical albumin, and which is so active that 0.0005 mg. is fatal to a kilogram of rabbit; i.e., 1 part of the ricin is fatal to 2,000,000 parts of rabbit; the fatal dose for man would therefore be about 0.035 mg., or 1/30,000 grain (Osborne, Mendel and Harris, 1905; Osborne, 1906). The agglutinating action is also very powerful.

The attempt has been made to separate the agglutinin (which is adsorbed by blood corpuscles) from the cytoxin, which is destroyed by pepsic digestion. Jacoby, 1902, believes that they have certain groups in common.

Antiricin.—Injections of the phytotoxins produce typical antitoxins, so that an immunized animal can survive 5,000 ordinary fatal doses of ricin. Some of the basic work of Ehrlich was done with ricin and abrin. He showed (1893) that the immunity starts in five to six days, and lasts six or seven months. The resistance of the corpuscles is unaltered; the antiricin being contained in the pseudoglobulin fraction of the serum (Jacoby, 1902). It contains antitoxin, antiagglutinin (probably identical) and precipitin. Maden and Walbun found that this combination obeys the same laws as diphtheria antitoxin. The toxicity of ricin is modified rather completely by lecithin (Lawrow, 1913).

ABRIN AND JEQUIRITY

Abrin, a toxalbumin from Jequirity bean (abrus precatorius), resembles ricin so closely in its action that the difference was established only when it was noticed that immunity against one did not constitute immunity against the other. Hausmann, 1902, has studied it by the methods of Jacoby. The literature was reviewed by Ford, 1917.

Poisoning.—When the whole beans are swallowed, no toxic effects result, since the shell is so hard that the poison does not dissolve. But if the powder is taken, it produces effects similar to ricin. Its toxicity is greatly increased by heating the animal (Leane and Dreyfus, 1913).

Use in Ophthalmology.—The action on the eye is much stronger than with ricin, producing ophthalmitis. It has been used therapeutically (Weker, 1885), to clear corneal opacities. This is dangerous, unless standardized preparations are used, and excessive effects checked by an antiserum.

CATHARTIC RESINS

General Statement.—Jalap, Colocynth, Podophyllum, Elaterin and similar drugs contain active principles which are for the most part resinous (i.e., soluble in alcohol, but slightly soluble in water), often glucosides. On chemical manipulation (probably hydration) these yield resinous acids which are much less active.

The effects of these resins are highly irritating, producing considerable colic (sometimes vomiting), and several watery stools, in one or two hours with jalap and most of the others; but with podophyllum only after twelve to twenty-four hours. They are used especially in dropsie (Compound Jalap Powder); small doses of podophyllum also act laxative in habitual constipation. The others tend ultimately to produce constipation. Colocynth, and presumably the others, stimulate peristalsis in the small intestine, inhibit antiperistalsis in the colon, and lead to the effusion of fluid from the whole intestinal canal.

The resins require the presence of bile, which renders them soluble. They are therefore less active in obstructive jaundice. They produce gripping, and are therefore often prescribed with belladonna and aromatics. If they are not removed by catharsis, they may cause severe enteritis.

The principles are not as effective when given pure as when they are mixed with extracting, as in the crude drugs and "resins" (alcoholic extracts precipitated by water) or as preparations of the crude drug. This is due, in some cases, to their being some what soluble, and therefore absorbed in the stomach.

Subcutaneous Administration.—This produces diarrhea with podophyllum and colocynthin, but is not available because it also produces nephritis, local irritation and abscesses.
Mechanism of Action.—This has been studied on colchicine by the x-ray method by Falck, 1909, under Magnus. Similar observations have been made with jalap or manna. The gastric movements may be slightly increased but often remain normal. In the small intestine the peristalsis is so much quickened that the contents may be completely expelled in half an hour instead of the normal eight hours. This is accompanied by the effusion of considerable fluid into the lumen. In the large intestine the propulsion is only slightly increased; but the stools are rendered still more liquid by the inhibition of antiperistalsis, and by the secretion of additional mucus. Falck, 1911, found that the colchicine peristalsis and effusion are arrested by morphin and opium, although these do not ordinarily act directly on the intestine, but on the stomach.

Other Actions.—Conevalolin and jalapin appear related to saponin and agaricin. They are hemolytically in neutral solution. This has been suggested as an index of the intestinal action, but the relation requires confirmation (G. Heinrich, 1918). They are destroyed by alkalies, not by acids.

Jalap
This is perhaps the mildest member of the group. It produces watery stools within three or four hours, with little intestinal irritation, without gastric disturbance or much prostration. It has little taste and is therefore easily administered. It is used in ascites, cerebral congestion, hypotension; and as adjuvant to antihelmintics. Scammonia is closely related to jalap.

Continents.—These have been studied by Power and Rognerson, 1909 and 1912. The “resin” is a complex substance, which can be separated by solvents into several theoretical portions: Jalapin (conevalolin, jalapurin) and Scammonin (orisabin).

PREPARATIONS—JALAP GROUP
Jalap, U.S.P., B.P.; Jalap.—The dried tuberous root of Eoxononim purga. At least 7% per cent. of resin. U.S.P.; 10 per cent., B.P. Dose, 1 Gm., 15 gr., U.S.P.; 0.3 to 1.2 Gm., 5 to 20 gr., B.P.

Tr. Jalap. Co., B.P.—10 per cent. of resin. Dose, 1 to 4 c.c., 1/4 to 1 dram, B.P.

Tr. Jalap. Co., B.P.—8 per cent. of Jalap, 0.5 per cent. Scammon Res., 1 per cent. Tinct. Dose, 2 to 4 c.c., 1/4 to 1 dram, B.P.

Resina Jalapae (Res. Jalap.). U.S.P.; Jalap. Res., B.P.—Prepared by precipitating the alcoholic extract of Jalap with water. Dose, 0.125 Gm., 2 gr., U.S.P.; 0.12 to 0.5 Gm., 1 to 5 gr., B.P. Maximum dose, 1 Gm., 15 gr.

Scammonia Resinoid (Scam. Resid.). U.S.P.; Scammon. Rad., B.P.; Scammon Root.—The dried root of Conevolus Scammonia, yielding not less than 85% of resin. Used by the ancients. The constituents are similar to Jalap. They have been investigated by Power and Rognerson, 1912. Dose, 0.25 Gm., 4 gr., U.S.P.

Res. Scam., U.S.P., Scammon. Res., B.P.—Prepared by precipitating an alcoholic solution with water. Dose, 0.5 Gm., 5 gr., U.S.P.; 0.35 to 0.6 Gm., 4 to 8 gr., B.P.

Ipomeae Radici (Ipom. Rad.). B.P.; Grrizahn Jalap Root (McLean Scammon Root).—The dried root of Ipomeae orizabensis.

Kalcedona, B.P. (Pharbitis Seeds).—The dried seeds of Ipomea hederacea. Dose, 2 to 0.5 Gm., 10 to 45 gr., B.P.

Pulv. Kalated. Co., B.P.—Similar to Pulv. Jalap. Co. Dose, 0.6 to 4 Gm., 10 to 60 gr., B.P.

Tr. Kalated. B.P.—20 per cent. Dose, 2 to 4 c.c., 1/4 to 1 dram, B.P.

Kalated Res., B.P.—Dose, 0.12 to 0.5 Gm., 2 to 8 gr., B.P.

Ipomeae Turpetum. B.P.; Turpetum.—The dried root and stem of Ipomea Turpetum. Dose, 0.3 to 1.2 Gm., 5 to 20 gr., B.P.

RESIN OF PODOPHYLLUM
This acts very slowly, generally only after twelve to twenty-four hours or longer, producing several soft stools. Larger doses (20 mg., 1/2 gr. or more) act as a hydragogue cathartic; but it is chiefly employed in small
214  MANUAL OF PHARMACOLOGY

doses (5 to 10 mg, ½ to ¾ gr.) as a laxative in chronic constipation often combined with aloe or calomel. 0.3 to 0.5 Gm. has been found effective.

PREPARATIONS—PODOPHYLLUM

Podophyllum, U.S.P., Podoph. Rhiz., B.P.; Podophyllum (Mandrake, Madder).—The dried rhizome and roots of Podophyllum peltatum (yielding not less than 3 per cent. of resin, U.S.P.). Active constituents, resin and a crystalline podophyllum tocin. Podophyllum was used by the Indians.

Ficcat. Podoph., U.S.P.—Dose, 0.5 cc., 8 minims, U.S.P.

T. Podoph. B.P.—3-5 per cent. of resin. Dose, 0.3 to 1 cc., ½ to 15 min.

*Resina Podophylli (Res. Podoph.,) U.S.P.; Podoph. Res., B.P.; Resin of Podophyllum.—Prepared by precipitating an alcoholic extract of Pods with acidulated water. Amorphous greenish-yellow powder, of slight peculiar faintly bitter taste. Very irritating to mucous membranes, especially of the eyes in alcal. A very similar resin is prepared from the East Indian species of Podophyllum (literature, Scoville, 1905). Dose, 10 mg., ½ gr., U.S.P.; 10 to 60 mg., ½ to 1 gr. as pillows. Maximum dose, 0.5 Gm., 1½ gr.

Podoph. Ind. Rhiz., B.P.—The dried rhizome and roots of Podophyllum Corresponds practically to Podophyllum, also in the strength and dose of its preparation.

Podoph. Ind. Res., B.P.

Stillingia, U.S.P. (Queen’s Root).—The dried roots of Stillingia sylvatica, a pungent resin and volatile oil. Used mainly in domestic medicine in purgative, also as a nauseant and emetic. Dose, 2 Gm., ½ gr., U.S.P.

Ficcat. Stillingia, U.S.P.—Dose, 2 cc., 8 minims, U.S.P.

Lepandra (Calver’s Root).—The rhizome and roots of Veronica Virgina tain an amorphous bitter principle, and not a crystalline glucosid, as formerly (Powers and Rogerson, 1910). “Lepandra” is a reservoir. The preparation pharmacologically inert, but were supposed to be cholagogue without producing final irritation. Dose, 1 Gm., 15 gr.

Juglans (Butternut).—The root bark of Juglans cinerea, collected in Used as a mild laxative. Dose of extract, 1 to 2 Gm., 15 to 30 gr.

The fluid extract of the root, 1 to 20 minims, is said to be a gentle and laxative similar to rhubarb, and was used in chronic constipation.

Iris (Blue Flag).—The rhizome and roots of Iris versicolor. Power and 1911, could not find any active principle, although the drug and the resinoid were formerly considered cathartic and diuretic. Dose, 1 Gm., 15 gr.

Iridis Rhizoma (Oris Root).—The rhizome from several cultivated species has a violet odor. It is used in sachets and tooth powders.

COLOCYNTH, ELATERIN AND BRYONIA

A number of plants of the cucurbit family (Cucurbitaceae) yield dangerous drugs. They are of complex composition, each containing active principles, resinous and alkaloidal. They produce con casutery stools, with intense irritation and hyperesthesia (mechanism of above). They are less used than formerly, when they were first employed to reinforce the action of other purgatives as in the Co.

Cathartic Pills. Colocynthis is excreted by the kidneys and m should therefore not be used by nursing women. Elaterin is on powerful cathartics, sometimes used in uremia. Large doses dangerous prostration.

The toxic dose of Colocynthis is 0.6 to 1 Gm.; fatal, 4 Gm. Of the toxic dose is 5 mg.; fatal, 0.6 Gm.

PREPARATIONS—COLOCYNTH, ETC.

Bryonia.—The root of Bryonia alba and dioica. Bryonin and bryonidin exist in mixtures. The purgative action is due to non-glucosidal resins and (Power, 1912). Dose, 0.6 to 4.5 Gm. (10 to 60 grains).

According to Jensen, 1915, the fresh root is much more poisonous than 1
The toxic principles are more abundant in the autumn. At that time the root contains
2 pgm.; 5, gm.; 12 gm.; 25 gm.; B.P.

*Elaeumum (Elaeum), U.S.P.; Elaterum.—A neutral principle obtained from Ela-

Elaerumum, a substance deposited by the juice of the fruit of Echallum Elaterum
(used in antiquity). White, hexagonal scales or prismatic crystals; odorless, and
having a slightly acid, bitter taste. Insol. in water; slightly sol. in alc. (1:125).

These 3 to 6 mg., 1/2 to 1/2 g., repeated in five hours if necessary, but not daily (U.S.P.,
1 mg. 1/4 g.). The dose of elatium is 6 to 10 mg., 1/2 to 1/2 g.

Elaterum consists of two crysta-line substances, the levorotatory α-elaterum, which is
inactive; and 5 to 60 per cent. of the active destrorotatory β-elaterum. Commercial elat-

Elaerumum contains 0.02 per cent. Joll. Resin; 0.02 Gm.; Gamboe; 0.015 Gm.; a total of seven active ingredients. "Doset,
two pills. U.S.P.

Flusis Catharticae Compositae (Phl. Cathart. Co.). U.S.P.; Compound Cathartic Pills.—Each pill contains: Comp. Ext. Colocynth. 0.08 Gm.; Alum. 0.06 Gm.; Jalap Resin. 0.02 Gm.; Gamboe. 0.015 Gm.; a total of seven active ingredients. "Doset,
two pills. U.S.P.

Flusis Catharticae Compositae (Phl. Cathart. Co.). U.S.P.; Compound Cathartic Pills.—Each pill contains: Comp. Ext. Colocynth. 0.08 Gm.; Alum. 0.06 Gm.; Jalap Resin. 0.02 Gm.; Gamboe. 0.015 Gm.; a total of seven active ingredients. "Doset,
two pills. U.S.P.

216 MANUAL OF PHARMACOLOGY

Applied externally, croton oil produces irritation, proceeding to pustulation and even sloughing. When diluted with 2 to 10 parts of olive oil, it may be used as counterirritant, but is dangerous.

PREPARATIONS—CROTONE OIL

* Oleum Tigillii, U.S.P.; Oleum Crotonis (O1. Croton.), B.P.; Croton Oil—A fixed oil expressed from the seeds of Crotog Tigillum. A pale yellow or brownish-yellow, somewhat viscid and slightly fluorescent liquid, having a slight, fatty odor. Slightly sol. in alc. Dose, 0.05 c.c., 1 minim, U.S.P.; 0.01 to 0.06 c.c., 1/4 to 1 minim, B.P.; on a lump of sugar, slice of bread or lemon. With unconscious patients, a small drop may be placed at the back of the tongue, and repeated every hour to three doses. Maximum dose, 0.05 c.c., 1 minim.

COLLOID AND EMOLLIENT LAXATIVES

These act mainly by retaining water in the intestine through inhibition, thus modifying the bulk and consistency of the feces, so that these are more easily expelled. They are useful in habitual constipation, especially if aided by the occasional administration of cascara. Agar is typical of this class. In fruits (prunes, grapes, tamarinds, etc.) this colloid action is supported by the organic acids and sugars. Mannna acts through its difficulty absorbable sugar, the action being largely osmotic. Petrolatum is not absorbed and therefore softens and lubricates the feces. Olive oil, in so far as it escapes digestion and absorption, acts in the same manner.

Agar-agar.—This is prepared from various Japanese marine algae. It consists mainly of the hemicellulose "gelose," which gelatinizes with water. It is tasteless and has been used for culinary jellies, but is not digested (8 to 27 per cent. is utilized in man; Salki, 1906; Swartz, 1911; herbivorous utilize about 20 per cent.; Lohrich, 1908). It was introduced as a laxative by A. Schmidt, 1895. J. L. Morse, 1910, advises the chopped shreds, 1/4 to 1 ounce for adults; 1 or 2 teaspoons for children; part with the breakfast cereal, part with sauce or cream at another meal. For children, it may be boiled with oatmeal, or made into a Pudding (1 to 200 boiled water). O. H. Brown and Swenk, 1917, recommend as daily dose two heaping teaspoonsful, in a quart of water, boiled till dissolved, seasoned and flavored to taste and preferably taken hot.

The effect is usually not noticeable for nearly a week. The efficiency is not very great, and it usually requires the addition of cascara or phenolphthalein (Bastedo, 1914).

PREPARATIONS—AGAR, ETC.

Agar, U.S.P.; Agar-agar.—The dried mucilaginous substance extracted from marine algae growing along the eastern coast of Asia. Thin, translucent, membranous, agglutinated pieces, yellowish-white or brownish-white; odor slight; taste mucilaginous. Dose, 10 Gm., 2 1/2 drams, U.S.P.

Mannna, U.S.P.—The dried saccharine exudation of an Ash-tree, Fraxinus Ornus. Contains mannit, about 90 per cent. Dose, 15 Gm., 4 drams, U.S.P., to 60 Gm., ounces, as infusion.

Tamarindus, B.P.; Tamarind.—The fruit of Tamarindus indicus. It owes its activity to organic acids, especially citric. It is used as a laxative, in doses of 4 to 30 Gm. (1 to 8 drams).

For Petrolatum, see Index.

EVACUANT ENEMAS

Rectal injections or ointments increase the peristalsis of the large as well as the small intestines in response to the mechanical stimulation. The effect is enhanced by the addition of irritants.

Enemata have an advantage over cathartics taken by mouth, in that they may be made absolutely non-irritant, and may therefore be used in
conditions in which the other cathartics are positively contraindicated. If the purpose of the enema be merely to soften hardened scybala, they would be used warm, in copious quantities, preferably with soap; or as decoctions of mucilaginous substances.

To secure the maximum motor effect, the injection must be used cold, and in fairly large quantity: Adults a pint, quart, or more; children according to age (at a year, an ounce, and about ½ ounce more for each year). Water and bland oils are also often used by high injection.

The irritants which are most commonly used in enythers are: Soap; molasses, 1:8; salt, 1:16; turpentine, 1:20 (emulsified with egg-yolk); bile, 1:30.

Enemas also have other uses: For local effects on the rectal mucous membrane (astringents, etc.); for the removal of parasites; and as a method of introducing medicine and nourishment.

Irritant injections into the colon may either inhibit the emptying of the stomach, by pyloric spasm; or on the other hand, they may shorten the gastric sojourn by increased peristalsis (F. W. White, 1917; x-ray method with cats).

ANTHelmINTICS

General Statement.—Anthelmintics (anti, against; helminthos, worm) are remedies used against intestinal parasites.

Active peristalsis tends to remove intestinal parasites, as well as the other intestinal contents. Active cathartics are therefore Vermifuges—i.e., drugs which expel parasites. But these parasites, when in good condition, are endowed with remarkable faculties of maintaining their position in the intestines—by traveling in the direction opposite to peristalsis, or by fixing themselves to the intestinal wall by means of suckers or hooks, or by their serrated vitality, etc. It therefore becomes necessary to lower their vitality. This may be done to some extent by appropriate diet. But this is rarely sufficient, and it is generally necessary to employ drugs which will paralyze them—Vermicides. Since the latter present some danger to the host as well, they should be used in the smallest doses. The vermicides but rarely kill the parasites; these usually recover if they remain in the intestine. It is therefore necessary to follow the vermicide by an active cathartic, a saline, jalap, or calomel. Oily cathartics must be avoided, since they favor the absorption of most anthelmintics.

Preliminary Dietary Measure.—The administration of anthelmintics is usually preceded by a fast, so that the parasites will not be protected by the diluent effect of the intestinal contents. It is very doubtful whether this weakens the parasites by starving them, as has been suggested. It is more likely to weaken the patient and to hasten absorption of the poison. The fast should therefore not be severe. It suffices usually to eat a light supper on the preceding evening, to administer the drug in the early morning, and to delay breakfast for several hours. Should vomiting occur, it is safer to postpone further dosage for a few days.

Adjunct Condiments.—Mustard, pepper or onions are recommended to be used freely in the preparatory supper. These are in fact fairly active vermicides, and whilst not sufficiently powerful alone, they aid materially the medicinal vermicides (Sollmann, 1918).
Vermicides.—Many substances would be poisonous to parasites; but they are generally also poisonous to the patient. A vermicide must have special properties; it must either be specifically toxic to the worms, or it must be poorly absorbable.

Many anthelmintic principles are volatile or chemically unstable, and therefore become ineffective. The pharmacologic extracts or isolated principles share this instability although to a less degree.

It is more than probable that these parasites, as most other forms of life, have peculiar susceptibility to certain poisons. There is some hope that further research will bring forth specific vermicides. At present, the following data have been gathered largely from empirical observations:

Specific Vermicides.—The most efficient for Tapeworms are Male Fern (especially for Bothriocephalus); Pelletierin (especially for Tapeworms); Santonic, Chenopodium and Spigelia. Thread Worms are treated most efficiently from the rectum by enemas. Thymol (see Index) and Chenopodium are used for Hook-worm. Aspidium is also said to be effective against Hook-worm.

Since the vermicides are under no circumstances absolutely safe, they should never be given unless the parasites or their eggs are actually demonstrated in the feces.

Efficiency of Anthelmintics as Tested on Earthworms.—All clinical anthelmintics are markedly toxic to earthworms. These may therefore be used to determine whether any substance has any anthelmintic value, and to compare the relative activity of different samples of a drug. They could not be used, however, to compare the clinical value of different anthelmintics; since this often involves factors other than simple vermicidal efficiency, such as toxicity for the patient, irritation of the intestines, etc.

The following are some of the more important results observed on earthworm (Sollman, 1918).

Highly effective are Aspidium, betanaphthol, carbavel, chenopodium oil, chloroform, dibrom and dichlorobenzol, pelletierin and thymol. Santonic is also highly active in the presence of a suitable solvent (mixture of bile salts and sodium bicarbonates). Fresh pumpkin and squash seeds are quite efficient, the active principles being soluble in water, and injured by boiling.

Fairly efficient are granatum, kamala, kousso. Spigelia is weak.

Combination of Anthelmintics.—Spices and similar “sharp” substances, mustard, onions, pepper, also cantharidin, are quite toxic and seem to potentiate the effects of other anthelmintics. Mixtures of other anthelmintics give simple summation of their effects on the worms; but such mixtures are perhaps useful by decreasing the toxicity for the patient.

Expulsion of Worms.—Most drugs that are toxic to earthworms produce primary irritation or agitation, resulting in withdrawal of the worm from the neighborhood of the poison. This is probably an important factor in the clinical effect of vermilugues.

ASPIDIUM OR MALE FERN

Composition.—The anthelmintic action resides in several closely related substances, complex methane derivatives of phloroglucin and its homologues, with butyric radicles in ketone combination (Boehm, 1897). The most important is probably the amorphous fulvic acid. Analogous compounds occur in several other anthelmintic drugs (Roterin in Kamala; Ascaridol in Chenopodium; Tanacetin in Tanacetum cusso).
ANTHELMINTICS

1904) is perhaps an impure silicic acid (Schmidheen). The inactive constituents are:
the crystalline silicic acid or silicin (CaSiO₄), and aspidinol. The crystalline silicic acid
is the lacton of the active amorphous acid, the two being readily converted into

each other. This probably explains the deterioration on keeping the root. All these
substances are so closely related, and change so readily into each other that our knowl-
edge is very confused; even the elementary formulae are in dispute. Aspidium also
contains volatile and fixed oil, tannin, etc. Silicic acid is decomposed in the body,
yielding trimethylphosphoroglucin. Flicicin acid is an inactive artificial reduction product of
silicic acid or aspidin.

Actions.—Active silicic acid probably paralyses the muscles of the parasites without
affecting the nerves; at least it has this action in rain-worms, (W. Straub, 1902). This
has been utilised for the standardisation of silica preparations (Yagl, 1914). In frogs,
it paralyses the central nervous system, the heart and skeletal muscles. In mammals,
it produces local gastro-intestinal irritation followed by tetanic convulsions with
simultaneous central and cardiac paralyses.

Administration.—Aspidium is used against tapeworms and hook-
worm. Its reputed dates from the ancients. The oleoresin is admin-
istered in capsules of 1/2 to 2 c.c., or emulsions. If a cathartic is given, if
no oil is taken and if the patient is vigorous, the ordinary doses cause little
discomfort. If unsuccessful, several weeks should elapse before another
administration.

Phenomena of Poisoning.—This may occur even with moderate doses
(Sidler Huguenin, 1898); and larger doses are dangerous. Four grams
of the oleoresin have produced severe poisoning, but 20 Gm. have been
given without toxic effects (Drenkhaw, 1911). The milder symptoms
consist in colic, diarrhea, headache, diziness, dyspepsia, yellow vision,
and sometimes temporary blindness. Severe cases showed delirium;
violent muscle-cramps, syncope, tonic convulsions and coma; often glyco-
stria, albuminuria and casts, and icterus; death occurs by respiratory
paralysis.

Recovery is slow, often with permanent blindness (Stuelp, 1904).
This occurs also in animals. It is due to spasm of the retinal vessels, with
subsequent optic atrophy (Harnack, 1912).

The treatment would be evacuant, demulcent and symptomatic.

PREPARATIONS—ASPIDIUM

Aspidium, U.S.P.; Filix Mas, B.P. (Male Fern).—The rhizome and stipes of Dryop-
teris Filix Mas and marginalis; using only such portions as have retained their green
color. Dose, 4 Gm., 60 gr., U.S.P.

Oleoresina Aspidii (Oleores. Aspil)., U.S.P.; Et. Filicis Liqu., B.P. (Oleoresin of
Male Fern).—An evaporated ethereal extract (containing at least 20 per cent. of silicin,
B.P.). Greenish oily liquid, often containing a crystalline sediment which should be
included before dispensing. Disagreeable taste and odor. The oleoresin preserves
the activity indefinately. The crystalline deposit is inert (Sollmann, 1918). Dose,
2 Gm., 30 gr., U.S.P. (Caution; not repeated on same day); 45 to 90 minutes, B.P.; in
capsules or emulsion. Maximum dose, 17 Gm., 4 drams.

Amorphous Silicic Acid, N.N.R.—0.5 to 1 Gm., FimarOil, N.N.R., 10 per cent.,
10 c.c.

Canni, B.P.; Kouso (Bryera).—The pistillate flowers of Bryera antelmiatica.
(The male flowers are powerfully emetic, and, therefore, useless as vermicides.) Con-
tains kaustatic, related to silicic acid (Leichenring, 1894; Lobeck, 1901). Dose, 8 to 16
Gm. to 4 drams, B.P. as infusion.

It is irritant, and apt to be promptly vomited; said to depress the heart; disagreeable
in action; unsuitable unless quite fresh.

Kanola (Rottleria).—The glands and hairs from the fruit-capsules of Mallotus
Philippinensis. Contains Rottelier, related to silicic acid (Telle, 1907; Semper, 1910).
Dose, 10 Gm., 2½ drams.
CHENOPODIUM OIL

The oil distilled from American Worm-seed is a very effective anthelmintic, especially against round worm, hook-worm, and intestinal amebas. Against hook-worms, it is equally or more successful than thymol, and less unpleasant. It does not require a preliminary fast, and does not usually make the patient sick (Coutant, 1916). It is relatively safe, although the full doses are sometimes toxic.

Efficiency.—Brinting, 1906, 1912, found that chenopodium oil has a high toxicity for nematodes and a low toxicity for mammals. Subsequent experience has shown chenopodium oil to be effective against all forms of intestinal parasites, including hook-worms, parasites that infest the large intestines, such as oxyuris and whipworms; and also against intestinal amebas.

Efficiency Against Hookworm.—Schuefner and Verwoort, 1913, found it clinically fully equal to thymol, and superior to beta-naphthol or eucalyptol. Bishop and Brosins, 1915, consider it more efficient than thymol, with the further advantage of easier administration. In the Orient, according to Heiser, 1915, the clinical results have been superior to other hook-worm remedies.

Darling et al, 1918, again found it more efficient than thymol, against anchylostomiasis. Necators are less resistant.

Efficiency against Aciaris.—M. C. Hall and Foster, 1917, found that it surpassed all other drugs. They insist that it should be given with castor oil.

Other Intestinal Worms:—Darling et al, 1918, discuss its efficiency against ascariasis, clonorchiasis, tenia, oxyuris and trichuris.

Mechanism of Action.—The effects on the worms are similar to safranin, viz., peripheral stimulation, followed with large doses by paralysis (Trendelenburg, 1901).

Administration.—Ordinary doses do not kill, but merely paralyze the worms, so that it must be given with a cathartic, usually castor oil. Oils do not increase, but rather diminish, the toxicity (Salant and Bengis, 1915).

Doseage against Aciaris.—For children 10 to 15 drops of the oil are given on agt two or three times a day for two days, and followed by a tablespoon of castor oil [Lett., 1914].

Doseage against Hookworm.—The routine of the Rockefeller Commission (1917) consists in a light evening meal, followed by a purgative dose of magnesium sulphate. In the morning, the patient receives some milk followed by 3 doses of chenopodion oil, each of 0.5 c.c. on a teaspoon of granulated sugar, an hour apart. Two hours after the last dose, magnesium sulphate is again given.

The course is repeated every three to five days, until the parasites have disappeared from the feces. The dosage for children is 1 drop per year, on sugar. The treatment may be contraindicated during fever or acute gastro-intestinal inflammations.

Darling et al, 1918, found such treatment more effective and less toxic than double the dose in one treatment.

Bishop and Brosins, 1915, advise an even more simple technic, requiring no dietary preparation. The oil is used in capsules of 0.5 c.c. For adults, three doses, each of 1 c.c., are given at intervals of two hours. Castor oil, 2 ounces, is administered last hour after the last dose. For convenience in collecting the stools, the treatment is usually started in the evening.

Coutant, 1916, simply gives 10 drops, half an hour before a light breakfast, repeated for three mornings. The other meals are as usual.

Amebic Dysentery:—Chenopodium administered as for hook-worm promptly relieves the clinical symptoms of subacute and chronic amebic dysenteries and causes the disappearance of the amebas from the stools. Chenopodium is often successful in patients and carriers that have resisted emetine, because of the encysted amebas. Relapse may occur, but not so often than with ippecac (E. H. Walker and Emech, 1917, Barnes and Coot, 1918).

Minor Side Effects of Therapeutic Doses.—Nearly a third of the patients react by some degree of dizziness, nausea, vomiting; tingling in hands and feet, temporary deafness, or general depression (D. A. Roht, 1918). Dizziness and nausea are the most frequent. Vomiting, sometimes with streaks of blood, occurs in about 36 of the cases, and is with the nausea (Darling et al, 1918).

Incidence occurs in 20 per cent. It varies in intensity from a disagreeable aftertaste to a bilateral loss of hearing, lasting usually for a week to several months. It will present after 2 years (Roht, Oppikofer, 1919). Thymol does not

MANUAL OF PHARMACOLOGY

220
Severe Human Intoxications.—These are rare, and generally attributable to gross over-dose. However, severe poisoning has been described after 2 doses of 10 minims, 4 hours apart (Constant, 1915); and death has occurred after 2 treatments with 3 c.c. within a week. The symptoms are those of the minor cases, but terminate in coma, tachycardia and convulsions. Death occurs usually after 2 or 3 days of coma (Levy, 1915; Seifert, Nenewirk, 1915, page 142; Darling et al., 1918).

Treatment.—This would consist in purgatives and stimulants (Mottis, 1914).

Toxic Effects on Animals.—These have been studied especially by Salant and his co-workers, 1910-1916. The toxicity varies greatly, even with intravenous injection. It is increased by starvation, diminished by abundant diet. Cumulative effects have also been observed.

Intact animals first show depression of the higher centers, then convulsions. There is a cardiac fall of blood pressure and organ volume, with slowed heart and decreased vaso irritability. Somewhat larger doses also decrease the rate and amplitude of the respiration, independently of the circulation. Peristalsis is diminished, by intravenous injection, as well as in the excised intestine. The depression is antagonized by barium, but not by pilocarpin. Renal irritation is also evidenced. Caffeine antagonizes the respiratory depression; epinephrin and digitalis the cardiac depression (Salant and Livingston, 1916).

Oral and hypodermic administration may cause renal disturbance in rabbits fed on oil, but not in those fed on carrots (Salant and Bengtis, 1917).

Absorption and Excretion.—The oil is absorbed from the ligated stomach and especially from the small intestine. The excretion occurs partly by the lungs (Salant and Livingston, 1916).

Constituents and Relation to Toxic Effects.—Alsborg, 1915, attributed the efficiency of chenopodium oil mainly to "ascaridol." M. C. Hall and Hamilton, 1918, on the other hand, consider this as less efficient and much more irritant than the more abundant factor that distills at lower temperatures. Pittenger, 1920, also claims that the more volatile fraction is less emetic.

PREPARATIONS—CHENOPODIUM

*Oleum Chenopodii* (OIl. Chenopod.), U.S.P.; Oil of Chenopodium (American Form-seed).—A volatile oil distilled from Chenopodium ambrosioides anthelminticum. Den., 0.2 c.c., 3 minims, U.S.P.

PELLETIERIN

This is a mixture of alkaloids obtained from Pomegranate bark. It acts much more powerfully on Tannia than on Ascaris (v. Schroeder, 1884; also effects on higher animals). Decoctions of the bark have been used as aerviorum remedy since the Romans; but the large amount of tannin (20 or 25 per cent.) often causes vomiting, so that the alkaloids are preferred. These are generally given in the form of the tannates to avoid gastric irritation, employing the usual preparation of the patient. The ordinary dose often causes mild toxic symptoms: vertigo, dimmed vision, great weakness, and cramps in the legs, formation, convulsive trembling, etc. Toxic doses produce promptly mydriasis, partial blindness, violent headache, vertigo, vomiting and diarrhea, profound prostration, sometimes convulsions (Landis, 1889).

Active Constituents.—Tannet, 1878, found two active, liquid volatile alkaloids, Punicin and Isopunicin. There are, further, two less active alkaloids, Methylpyrinic and Benzopunicin. More recently, E. Hess and Eichel, 1918, have worked on the separation of the alkaloids and determined their chemical structure.

PREPARATIONS—PELLETIERIN, ETC.

*Pelletierin Tannate* (Pellet. Tann.), U.S.P., B.P.; Pelletierin Tannate.—A mixture of the tannates of alkaloids obtained from the bark of the root and stem of the Pomegranate. Commercial pelletierin tannate is of rather variable composition, containing from 15 to 25 per cent. of alkaloid (L. E. Warren, 1918). The vermicidal efficiency of different samples does not differ greatly.
The official tannate occurs as light yellow, amorphous powder, of astrigent taste. Incompletely soluble in water (1:240), dissolving readily on dilute hydrochloric acid. Soluble in alcohol (1:16). **Dose**, 0.25 Gm., 4 gr., U.S.P.; 0.12 to 0.5 Gm., 1/6 to 1/2 dr., B.P.; suspended in water.

A nostrum sold as "Tanret's pelletierin" is a dilute syrup, without apparent advantage.

**Decoct. Granat.**—25 per cent. **Dose**, 15 to 60 c.c., 1/4 to 2 ounces.

**Fidext. Granat.**— **Dose**, 2 c.c., 30 minutes, U.S.P.

**Arca.**—The fruit of Areca Catechu. Contains vermicidal volatile alkaloid (Arecolin). Areca is used only in veterinary medicine. Arecolin stimulates peristalsis (Parke, 1916). Arecolin hydrobromid has been used locally, 1/4 to 1 per cent., as miotic (smarling).

**Pepo**, U.S.P.; **Cucurbita Semina Preparata** (Cucur. Sem. Prepar., B.P., Pumpkin Seed, Melon Pumpkin Seed).—The dried (fresh, B.P.) ripe seeds of Cucurbita Pepo (maxima). **Dose**, 30 Gm., 1 ounce, U.S.P.; 100 Gm. bruised to a cream with water or milk, B.P.

Pumpkin or Melon Seeds, fresh or at least not over a year old, are eaten in 1/2 ounce doses, on the day preceding the regular treatment. They are not sufficiently active themselves, but serve to support other measures. They were investigated chemically and pharmacologically by Power and Salway, 1912; but none of the constituents had any action on the host or parasites. Weinhblum, 1912, found neither alkaloids nor glucosides, and also considers the action very unreliable. The earthworm test, however, shows that fresh seeds are actively vermicidal (Sollmann).

The fresh "milky" of the **coconut** is also said to be antihelmintic.

**Spigelia, U.S.P.; (Pink Root).**—The dried rhizome and roots of Spigelia marilandica. It is said to stupify round worms, but the earthworm test shows only a feebly active effect (Sollmann, 1916). It contains a bitter acrid resin; a poisonous alkaloid; volatile oil, etc.

Little is known of its action. Toxic effects, which are rare, resemble those of pelletierin.

**Dose**, 4 Gm., 60 gr., U.S.P.

**Fidext. Spigiel.**— **Dose**, 4 c.c., 1 dram, U.S.P.

**Butaca Semina**, B.P.; **Butaca Seeds**.—The seeds of Butaca frondosa. Used in India as antihelmintic.

**Psal. Butaca Sem.**, B.P.— **Dose**, 0.6 to 1.2 Gm., 10 to 20 gr., B.P.

### SANTONIN

**General Statement.**—Santonina has been a favorite remedy against round worms since Dioscorides. It is also used against pinworms if these have ascended beyond the reach of enemas. Santin is insoluble, non-irritant and almost tasteless, and is therefore easily administered to children. It may be mixed with some sugar, and combined with calomel or castor oil, which does not increase its absorption. To children of two to five years, 0.03 Gm., 1/3 gr., may be given every hour for two or three doses, according to age, and then not repeated for at least three days. The adult dose would be three times as much. It should not be given on an empty stomach, since this would favor absorption.

Santonin is the lacton of santonic acid. It is dissolved in the intestine as sodium santoninate, and the greater part is eliminated unchanged in the feces. A small amount is absorbed, oxidized, and the derivatives (especially the crystalline Santogomina, Jaffé, 1890) are excreted by the urine. An unknown derivative imparts a bright yellow color to the urine when acid, changing to pink when alkaline.

Dose, 0.12, but little above the ordinary cause "yellow vision," persisting for some hours, without other bad effects. Overdoses produce serious poisoning. Santonin should therefore only be sold on prescriptions. The Troches, by their resemblance to candy, are especially liable to produce accidental poisoning.
Action on Worms.—It was formerly believed that santonin is not directly toxic to worms, but that they attempt to escape from it, and thus die into the large intestine, from which they are evacuated by the purgative. However, the apparent harmlessness was due to the failure to imitate the solvent action of the intestine. Solutions of santonin in dilute pepsin and sodium bicarbonate mixtures are highly toxic to earthworms. The irritant effect on worms plays a part in securing their expulsion, but this effect does not demonstrate that of other worms.

Mechanism; Relation to Structure.—This has been studied by Trendelenburg, 1915, on rain-worms, leeches and ascaris. It consists in strong stimulation (increased movement and contractions) of the muscle, persisting after removal of the ganglia. The effect is highly specific; since it is not produced in anything like the same degree by other substances (although some alkaloids have a weak action); nor does santonin stimulate vertebrate muscle. It is connected with the lactone structure, as is also a depressant effect on the isolated frog heart. The convulsant effect on mammals, on the other hand, does not depend on the lactone, but on the naphthoquinone nucleus.

The Phenomena of Severe Intoxication.—These are vomiting, colic and diarrhoea, painful micturition, hematuria, headache and vertigo, weakness, somnolence; finally convulsions (which may be unilateral), and fall of temperature (Binz, 1877; Harnack, 1901).

Treatment.—This would consist in evacuation; chloroform inhalation against the convulsions; and stimulants against collapse.

Fatal Dose.—In children, 0.06 Gm., 1 gr., has produced serious poisoning, and two cases have been fatal; in other cases, 0.18 Gm., 3 gr., caused only light symptoms, and recovery has occurred after 0.72 Gm., 11 gr. By adults, 0.5 to 1 Gm. and more have been taken without damage (Lewin).

The Color of the Urine.—This may be confused with that of emoin (rubarb, etc.). The emoind colors can be shaken out with ether, or precipitated by lime or barium extra, while the santonin color can not.

Xanthopsia.—Dozes as small as 0.1 Gm. may cause "yellow vision"—i.e., white light has at first a violet, then a yellowish-green hue, and these colors that the entire field of vision. The power of seeing in dim light is also lessened. It has been demonstrated that these effects are peripheral (Knie, 1894), and the theory is advanced, based on some experimental data, that santonin impairs the reproduction of the visual purple and violet, which are at first used very rapidly. There is no truth in the statement that it discolors the media of the eye (Filehne, 1900).

Calcium vison also occurs, but more rarely with amyl nitrite, picric or chronic acid, and digitalis (de Schweinitz, 1899).

Uric Acid Elimination.—This is increased by Santonin, as by other intestinal irritants (Abb. 1913).

Other Uses.—Santonin has been used in epilepsy and in diabetes, but with little effect.

PREPARATIONS.—SANTONIN

*Santoninum (Santonin.), U.S.P.; B.P.; Santonin, C15H14O6.—The inner anhydride or lactum of santonic acid obtained from Santonica. Colorless crystals (turning yellow in exposure to light); odorless and nearly tasteless when first placed in mouth, but afterward developing a bitter taste. Very slightly sol. in water, sol. in alc. (1:143). Dose, 0.06 Gm., 2 to 3 gr., B.P.; in powder, with a little sugar. Maximum dose, 0.2 Gm., 3 gr.

Santonica, "Levant Worm-seed" (really the unexpanded flowerheads of Artemisia eruca), also contains cined, but this has no action on ascaris (Bruening, 1921).

Trach Santonina, B.P.; Santonin Lozenges.—Each contains 0.06 Gm., 1 grain.

VERMIFUGE FOR THREAD WORMS (OXYURIS)

These are usually treated most efficiently by the rectal injection of various irritants. The rectum is first washed with injections of iron, tannin, or bitters (guassa), to limit the secretion of mucus, and is then irritated with solutions or emulsions of salt (3 ss to pt.), aloes (3 j to pt.), or turpentine (5 j to pt.), etc. Mercury salts are sometimes used as injection or suppository but are dangerous.
CONVULSANT POISONS

Convulsions may be caused by direct stimulation of the muscles (atrin); or of efferent motor nerves (physostigmin, aconitin); or by reflex from strong afferent stimulation; or by stimulation of the motor cortex in the cord, medulla or brain, either directly by the drug, or as a result of asphyxia, etc. These produce different types of convulsions. *St" convulsions*, as typified by strychnin and caffeine, are generally symmetrical and when fully developed, tetanic (i.e., the contractions are maintained); *medullary convulsions* (picrotoxin, camphor, asphyxia) are more irregular, asymmetrical and clonic (rapid intermissions). *Cerebral convulsions* (absinthe) are of the epileptic type, irregular, often involving only limited groups of muscles.

Convulsions are usually the result of extreme stimulation of the motor centers, and as such are mainly of toxicologic interest. Smaller doses of the convulsant drugs, however, may be used for therapeutic stimulus, their action often extending to other nervous centers, and exciting respiratory and vasomotor centers.

STRYCHNIN AND NUX VOMICA

**General Statement.**—Strychnin, the main alkaloid of Nux Vomica, is a powerful excitant and toxicologic importance. It increases reflex excitability of the spinal cord and of the medullary centers. The action is chiefly on the dorsal gray matter of the cord.

Therapeutic doses produce a "bitter" and, therefore, tonic effect on alimentary canal; improved tone and nutrition of muscle; and a limit amount of respiratory and vasomotor stimulation.

Toxic doses cause characteristic tetanus, violent changes in blood pressure, and spasmodic respiration. Death occurs from asphyxia from the paralysis which succeeds the stimulations.

Actions closely resembling those of strychnin are produced by a number of other alkaloids, which have little practical importance. The actions of tetanus toxin also are very similar.

**Description of the Motor Effects.**—The principal symptoms of strychnin poisoning in all vertebrate animals are referable to modified increased reflex excitability of the spinal cord, culminating in symmetrical convulsions and tetanus. The motor reflexes are modified so that small stimuli are effective; and the response even to slight stimulation is maximal, tetanic, and tends to spread to all the muscles. Ordinary reflexes are increased.

The tetanus, however, depends apparently not on this increase of normal reflexes, but on the enormous exaggeration of the special reflex the "start" from a sudden stimulus or fright (Cushman, 1919). It involves contraction of all muscles and therefore reversal of inhibitory reflexes.

The symptoms in man correspond to those in the lower vertebrates. With small doses, there is merely a greater response to stimulation, the muscles feel somewhat more taut. As the dose is increased to 7 mg. in men, 5 or 6 mg. in women (Hartenberg, 1913), this tautness becomes more sensible, especially in the neck and jaws; the movements become rather abrupt; and slight twitchings may appear in the indivi
muscles, often in the little finger. In case of paralysis from a high lesion (apoplexy), the paralyzed muscles may be the first to react since they are removed from the cerebral inhibitory impulses.

**Convulsant Effects.**—With toxic doses, these symptoms are promptly succeeded by sudden convulsions, usually following some stimulation; or the premonitory symptoms may be absent. The attack may start with a loud cry, which is usually caused mechanically, by the convulsive movement of the air, rather than by pain. The convulsions involve all the voluntary muscles of the body, including the diaphragm. The movements are at first rapidly intermittent, but become promptly tonic, resulting in a typical tetanus. Since all the muscles are contracted, the convulsions are symmetrical, and the body assumes the position corresponding to the stronger muscles, which in most situations are the extensors. Accordingly, the body is arched backward (opisthotonos), so that the patient may touch the ground only with the head and heels. The legs are adducted and extended, the feet curved inward. (A frog may be held horizontally by the feet.) The arms are either strongly flexed over the chest, or rigidly extended, with the fists balled. The jaws are fixed, and foam gathers at the mouth. The rigid diaphragm and the tense thoracic and abdominal muscles arrest respiration. The skin and mucous are, therefore, cyanotic and congested; the eyes protruded, evolved; and the pupils dilated. The pulse is small and tense, often imperceptible. The patient remains perfectly conscious, and suffers severe pain from the violent contractions. The asphyxia may be fatal in the first attack. More commonly there is a:

**Remission.**—The tetanus lasts perhaps a minute, then the muscles relax, and the patient passes into a greatly depressed, almost paralytic condition, still perfectly conscious and very anxious and oppressed, with dry throat and thirst, sometimes sweating. This intermission lasts at most ten or fifteen minutes, when there is another attack, usually again following some slight stimulation. If this is not fatal by asphyxia, it is again followed by remission, and so on, the whole sequence being repeated. The remissions, however, become progressively shorter, the spasms become weaker and the paralysis more prominent. Death occurs usually in the interval after the second to fifth attack, from exhaustion and general depression. It may be preceded by asphyxial coma.

**Recrvery** may occur from sublethal doses, or under appropriate treatment, the convulsions and depression disappearing gradually. Animals, however, have been observed to relapse into fatal convulsions several hours after apparently complete recovery (Sollmann), so that patients should be watched.

**Dependence of Convulsions on Reflex Stimulation.**—In the lighter grades of strychnin poisoning, the convulsions occur only on reflex stimulation. In the severe grades, they are often apparently spontaneous, but even here they are really reflex, due to slight and accidental sensory stimulations. This is shown by the fact that convulsions do not occur spontaneously if all sensory impressions are prevented from reaching the spinal cord, as by dividing all the posterior roots in frogs (Hermann Meyer, 1846); together with the medulla (Hering, 1853; Verworn, 1900); or by placing the frog in a very weak cocaine solution (Poulsson, 1880).

1 The opposite position, body bent forward, constitutes "opisthotonos."

15
Different Forms of Stimulation.—Practically all kinds of sudden sensory stimulation may provoke the convulsions. The skin is especially sensitive, even to the slight jars produced by heavy walking. Sudden light and sound are also dangerous. Gradual stimulation is much less effective (as with all reflexes), so that a patient may support considerable but sudden stimulation, as shock, circulating, as well as artificial respiration; when a slight, but abrupt or unexpected touch would cause an attack.

Stimulation of the exposed intestines does not cause convulsions, since these are produced in sensory fibers. Chemical stimulation (the application of dilute acids) not only fails to produce tetanus, but the stimulated intestine is flaccid. (Sclater.) Tetanus of tetaus is easily explained because the slow penetration of the acid leads to a gradual instead of abrupt stimulation. The various explanations of the diminished reaction are mainly hypothetical (Baglioni, 1900 and 1909; Sano, 1908).

Simple and Crossed Reflexes.—The effects of strychnin are relatively greater (i.e., the threshold is lowered more) for the crossed or leg-arm reflexes than for simple crossed reflexes, apparently because the excitability in simple paths is normally already so high that it can not be materially increased by strychnin. Therefore, the strychnin increase of excitability is better marked in the more difficult complex paths where several synapses are interposed; or when the normal threshold has been raised by ether or asphyxia (E. L. Porter, 1914, 1915). The excitability is increased for single induction shocks, as well as for interrupted stimuli (van Leeuwen, 1915).

The Modification of the Short Reaction of Ordinary Reflexes into the Prolonged Contraction of Strychnin Tetanus.—It might be supposed that the strychnin tetanus is due to summation of repeated stimuli; that each muscular contraction, by the movements of tendons and joints, sets up a fresh reflex, these rapidly succeeding stimuli fusing into a tetanic contraction which persists until the nerve centers are exhausted (Baglioni, 1900). However, there is good evidence that this is not necessary, but that the tetanus is in fact a true multiplex response to a single stimulus: For it occurs also if all reflexes are but the original single stimulus is excluded; i.e., tetanus occurs in a leg with a single stimulus of its divided sensory nerves, the remainder of the animal being cutaneous (Vesali, 1915; Buchanan, 1913; Henkel, 1912). The spinal stimuli, in strychnin tetanus, reach the muscles at the rate of 50 per second (Fahrenkamp, 1914).

Eltington, 1914, concludes that the strychnin action consists in greater sensitiveness of the central receptor cells; not in greater spread of the impulses, nor in greater intensity of the afferent impulses.

Normal and "Start" Reflexes.—Cushny, 1910, pointed out that strychnin has two apparently distinct actions on reflexes. A strychninized frog (0.05 mg.) responds to weak and slowly acting stimuli by reflexes of a normal coordinated character, but with lower threshold; whereas stronger and sudden stimuli produce the typical universal tetanus. This differs from normal reflexes not only quantitatively, but in that it causes the contraction of even antagonistic muscles. Cushny considers that this is a distinct reflex, which finds its physiological expression in the "start," for instance on a sudden fright; but which is enormously exaggerated by strychnin, so that it tends to displace the ordinary reflexes.

Reversal of Reciprocal Innervation.—The modification of the reflexes by strychnin is not merely quantitative, but also qualitative. Sherrington (1905 to 1909) showed that in a normal animal, the contraction of a muscle is accompanied by the automatic relaxation of its antagonistic muscles. The reciprocal reflex is destroyed by such substances as strychnin and chloroform. With strychnin, all reflex stimulations result in simultaneous contraction of all the muscles, including the antagonist; while with chloroform, they result in simultaneous relaxation. The vasomotor system presents analogous phenomena (Bayliss). The work of de Barante (quoted under "Localization") shows other qualitative changes in the functions of the sensory cells.

Location of the Tetanizing Action.—The distinction between the possible sites of convulsive action furnishes interesting illustrations of the general methods of experimental pharmacology. Most of these experiments can be carried out more conveniently on frogs; but they can also be demonstrated on mammals.

The Action is Localized in the Spinal Cord.—This can be easily shown by exclusion: (a) The peripheral motor apparatus is excluded by section.
of the nerve trunk, which arrests the convulsions in the corresponding muscles (Johannes Mueller, 1844). Conversely, no convulsions will occur if strychnin is injected directly into a muscle—say the leg; provided that the leg is first ligated so that the poison can not reach the general circulation. (b) If this experiment is modified so that the nerve is not included in the ligation, the absence of convulsions will also prove that strychnin does not affect the peripheral sensory apparatus (Magenide, 1838).

(c) The brain and medulla oblongata are not essential to the convulsions, for these occur in frogs in which these centers have been destroyed. (d) The posterior root ganglia are also not concerned; for typical tetanus can be obtained, by direct stimulation of the cord, when all the posterior roots have been cut in frogs (Hermann, 1846; Verworn, 1903); and in dogs even when the afferent fibers from these ganglia have completely degenerated after section (Sherrington, 1898). Nor does the localized application of strychnin to the exposed posterior root ganglia produce any effects (de Barenne, 1910).

(e) Action on the Spinal Cord.—It is evident, therefore, that the strychnin action is located somewhere within the spinal cord. The next question, whether it acts on the sensory or on the motor tracts, or on both, has not been conclusively answered, although it has been the subject of much ingenious investigation. At present, it appears that both the motor and sensory portions of the cord must be poisoned, to obtain the typical strychnin convulsions.

Methods of Anatomical Isolation.—The basic experiments in this direction were made by Hermann Meyer in 1846: After cutting away the entire posterior columns of the spinal cord, he found that strychnin does not produce tetanus, even if the remaining cord is touched. If the ablation is confined to a part of the cord, the corresponding muscles do not participate in the convulsions. This seems to indicate that the action is located in the posterior and not in the anterior columns. However, as pointed out by Hermann, 1900, the proof is not conclusive, for the operation produces too much shock, and besides, destroys all the physiological relations of the motor cells. Similar objections apply to all anatomical methods, so that these can not furnish conclusive evidence. It was therefore necessary to have recourse to physiological means.

Localized Application of Strychnin to the Spinal Cord.—Houghton and Mairhead, 1895, basing themselves on the earlier and imperfect work of A. J. Spence, 1869, attempted to utilize the fact that impulses go from the sensory cells of the cervical segments of the cord to the motor cells of the caudal segments, and vice versa. By destroying the circulation and applying strychnin locally to the exposed cord it is therefore possible to make impulses pass either through a poisoned sensory cell to an unpoisoned motor cell; or through an unpoisoned sensory to a poisoned motor cell. In Fig. 4, the strychnin is supposed to be restricted to the cervical half of the cord. The path goes through a poisoned sensory to an unpoisoned motor cell; the path, through an unpoisoned sensory to a poisoned motor cell. When the hindleg is stimulated in this frog, the hindleg participates in the convulsions. When the hindleg is stimulated, there is no convulsion. Analogous observations have been made on mammals (Ryan and McGuigan, 1911); on frogs with the sensory paths paralyzed by phenol (Baglioni, 1900); and on the excised nervous system of toads (Baglioni, 1900).

These results were interpreted as proof that strychnin acts essentially on the sensory
mechanism of the cord, and that the motor cells were at best unessential for convulsions appeared when the impulse passed through a poisoned sensory cell, even though the motor cell be unpoisoned; whereas no convulsions appeared when the sensory cells were not poisoned, even though the motor cell was poisoned.

However, these results are obtained only when the cervical cord is poisoned. If the strychnin is applied to the lumbar cord, the convulsions do not spread at all to the cephalic portion than in the cephalic direction. The entire subject is reviewed by Mcguigan, Kekcton, and Sloan, 1916.

Barrence, 1917 to 1915, adduced some new facts. By strictly localized application of strychnin to the exposed spinal cord of frogs and dogs he finds:

1. When the application is restricted to the ventral surface of the cord, no perceptible symptoms are produced.

2. When it is restricted exclusively to the dorsal surface, there is no tetanus; but instead, a characteristic syndrome, comprising sensory disturbances (paresthesias), increased reflexes, and incoordinate asymmetrical twitchings. These “dorsal symptoms” are sharply localized on the skin according to the level and side of application to the cord; the skin areas being identical with the “dermatomata” defined by anatomic-physiologic isolation methods. They occur even after the division and degeneration of the posterior root fibers.

3. Typical tetanus occurs only if both the sensory and motor tracts are poisoned. If, if the strychnin is applied dorsally to the arm region, and ventrally to the leg region, then stimulation of the leg causes only normal reflexes (unpoisoned sensory to poisoned motor); stimulation of the arm causes tetanics of the legs (poisoned sensory to poisoned motor) in which the arms do not participate (poisoned sensory to unpoisoned motor). This experiment (which was confirmed by Bertiott, 1918) indicates that both the sensory and motor nerves must be poisoned, to obtain the typical tetanus.

Kerr's Hypothesis. — The cerebral motor centers react to the direct application of strychnin (and also to picrotoxin) by increased excitability to electric stimulation, and even by rhythmic spontaneous movements, identical with those which would be induced by chemical stimulation. The action is not abolished by deep anesthesia (Bicklea and Zbinden, 1913). It is localized in the gray matter, for it disappears on ablation and no effect is produced by direct application to the white matter (S. S. Maxwell, 1902 and 1907; Baglioni and Maginni, 1900).

Strychnin acts in this respect like creatin and picrotoxin; in contrast to calcium precipitants and barium. These stimulate only the white matter directly, although they may lower the threshold of the gray matter to electric stimulation.

De Barrene claims that local application of strychnin to the cerebral cortex produces sensory excitation of the corresponding zones, but no motor symptoms.

The “silent area” of the brain does not respond to the local application of strychnin (Amanita, 1913).

Psychic Centers. — These are evidently not affected by strychnin, since consciousness is not disturbed until the onset of asphyxial coma.

Practical Significance of the Location of Strychnin Action. — The location of the tetanizing action of strychnin in the spinal cord explains, for instance, why strychnin convulsions are abolished by curare, since curare blocks impulses from the cord to the muscles. Also, that strychnin has a stronger action on a paralyzed limb in those cases of paralysis in which the lesion is above the cord, for cutting off of the spinal cord from the brain always increases its reflex excitability.

The fact that strychnin in small doses increases the tone of muscles is also due to its heightening the reflex excitability of the spinal cord. Not only the convulsive centers, but other spinal centers are put in a condition more favorable to reflexes. It is in this way that strychnin is useful in impotence or in paralysis of the bladder or other sphincters, when these are due to lowered activity of their respective spinal centers.
Indirect Results of the Motor Actions.—The increased activity of the muscles brings about several secondary results, such as pain, asphyxia, increased metabolism, disturbance of temperature, tendency to rise of blood pressure and quickening of pulse; early postmortem rigor. The asphyxia in turn produces its characteristic phenomena.

Pain.—Strychnin convulsions are extremely painful, just as any other form of muscle cramp.

Metabolism.—The increased muscular tone or convulsions result in increased consumption of oxygen and output of carbon dioxide, and increased use of glycogen. The increase of gaseous metabolism is observable even with therapeutic doses (Edsall and Meana, 1924). The asphyxia may also cause hyperglycemia and glycosuria.

Effect of Convulsants on Temperature.—All convulsant poisons (antimony, picrotoxin, strychnin) produce characteristic changes in heat regulation. Small doses cause increased heat loss and a slightly smaller heat production. Larger doses increase metabolism, through muscular action, and hence increase heat production, which is accompanied by a further increase of heat loss. Paralytic doses diminish the heat production very greatly. The temperature is accordingly variable. Small doses tend to lower it; moderate convulsive doses would increase it; paralytic doses lower it greatly. The heat loss is particularly conspicuous in small and young animals, while larger animals tend to show a rise of temperature, with moderate doses.

Lactic Acid.—Strychnin and other convulsants cause the appearance of lactic acid in the blood, provided that the glycogen store is adequate (Lusk, 1910).

Nux Vomica.—The preparations of Nux Vomica, and its second alkaloid, Brucin, act essentially like strychnin.

Brucin.—The action of brucin is much weaker than that of strychnin, the ratio varying with different animals. The paralytic and curare effects are relatively stronger (resembling methyl-strychnin), so that brucin is less useful therapeutically (cf. Dixon and Abercromby, 1900).

Brom-Strychnin.—The two mono-brom-strychnins act similarly to strychnin, but are only ½ or ¼ as effective. Dibrom-strychnin is also convulsant, but in frogs it produces mainly the curare effect (C. R. Marshall, 1912).

Other Spinal Convulsants.—Spinal tetanus, in every respect similar to that of strychnin, is produced by caffeine, thebaïn (an opium alkaloid), geocin, calabarain and pyridinin, etc. It is also a late phenomenon in morphinized frogs. Tetanus toxin likewise induces spinal tetanus, the minor differences being due mainly to peculiarities of absorption (Froehlich and Meyer, 1912).

The Convulsant Action of Subphosphated Dyses, Inhibitory Action of Cerebrum.—Acid Fuchsin (Barbour and Abel, 1910), and other water-soluble, nephrophilic sulphonated dyes (Macht, 1912), produce strychnin-like convulsions in frogs. In normal frogs, the tetanus occurs only after a long latent period (up to twenty hours), and requires relatively large doses. If the anterior third of the cerebrum is removed (either before or after the injection), the convulsions occur much more promptly (within thirteen minutes), and very much smaller doses (¼ 0 to ½ 9) suffice. The anterior cerebrum therefore exercises a strong inhibitory effect on the convulsant action of these drugs (much less if any, on other convulsant poisons). With the cerebrum intact, the latent period is also shortened by voluntary fatigue.

Thomas, 1920, finds that identical results are produced by injury to any part of the motor axis, and inclines to attribute the greater effect to the rapid penetration of the injured tissue.

Constricted Frogs.—Joseph and Meltzer, 1911, found that the late convulsant action of acid fuchsin, and of morphin, could be greatly hastened, and that a very much smaller dose would suffice, in frogs in which the heart had been tied, the circulation of the blood being thus arrested. According to Abel, 1912, this interesting observation is explained by the peculiar distribution of the poison. The irritation of the heart prevents the excretion of the poison in the body, and the anterior lymph hearts drive the solution directly into the communicating vessels of the central nervous system. This is therefore more speedily than in the more concentrated solution. At the same time the interruption of the normal circulation, and the partial asphyxia, increase the sensitivity of the nervous system to convulsants; for the outbreak of these is hastened even if the heart is excised after the drug has been injected. Meltzer, however, did not accept this explanation.
Carbon Dioxide.—This also greatly hastens the convulsions, when its tension in the air exceeds 20 per cent. (Joseph, 1913). The gas also lowers the threshold for strychnin convulsions (Pflüger and Sollmann, 1915).

Therapeutic Use of Strychnin in Paralyses.—Strychnin and nux vomica are used to preserve muscular nutrition in paralysis from functional neurites and high lesions; to raise the tone of the rectal and vesical sphincters in incontinence of urine or feces; to improve the effects of cathartics, especially in atonic constipation. They are also used (but probably useless) in sexual impotence. Most of these uses have been discussed in the text.

Paralytic Disorders.—It should be remembered that strychnin only increases the excitability of existing structures. It must therefore be useless in organic lesions of the cord. In spastic paralysis, and in inflammatory conditions, it would be contraindicated. Moderate doses (1 to 2 mg., three times a day) may be useful in functional depression of the cord (lead poisoning, or sometimes in diphtheritic paralysis); but its main indications are for maintaining the muscular tone, and thereby preventing muscular atrophy while awaiting the repair of cerebral lesions (apoplexy); but large doses of strychnin may bring apoplectic attacks in predisposed patients. The trophic effect should be supported by massage and electricity. Strychnin is also said to lessen the pain of some old paralyses.

Incontinence of Urine.—Strychnin would be useful only if the incontinence is due to atony of the sphincter; if due to overaction of the detrusor urine, the indication would be for atropin.

Medullary Actions of Strychnin.—These are analogous to its effects on the spinal cord, consisting in a more or less violent and convulsive exaggeration of the reflex excitability, particularly of the respiratory and vasomotor centers, followed by paralysis with toxic doses. These effects are modified by the coexistence of asphyxia.

These medullary stimulations are very marked and violent with convulsive doses. With therapeutic doses, they are so slight that they can not be demonstrated with certainty, either clinically or experimentally. The therapeutic use of strychnin as a respiratory or circulatory stimulant therefore rests on a very insecure basis. It was doubtless due mainly to the uncritical transfer of the results of convulsive doses to therapeutic doses.

Therapeutic Doses on the Circulation.—These produce either no effect whatever, or a very slight (10 to 20 mm.) rise of blood pressure, fairly well sustained. The rise is rather more marked in the diastolic pressure. Direct observation of the vasomotor center may also, but exceptionally, show a slight and doubtful stimulation; but in asphyxia, the same doses (0.05 mg. per kg.) cause intense vasomotor stimulation (Pflüger and Sollmann, 1915). These effects (aside from asphyxia) are so inconstant and small that they could be accidental. The cardiac contractions are not changed. Clinical observations on the blood pressure and heart rate, in health and in various diseased conditions (cardiac diseases, fevers, etc.), give similarly negative or inconclusive results, even when rather large doses (1/8 gr. every hour) are used (Cabot, 1904; Parkinson and Rowlands, 1913 and 1914; Newburgh, 1915; Lucas, 1914). Positive results of Cook and Briggs, 1903, or Marvin, 1913, must therefore be viewed with caution.

The pulse-flow (the change of blood flow during the pulse cycle) is also unaffected in man by 3 to 6 mg. (Hewlett, 1917).
Convulsive Doses.—While small doses of strychnin have but little effect on the circulation, convulsive doses cause very conspicuous changes; especially a large rise of blood pressure, due to central vasomotor stimulation, produced mainly by the direct action of strychnin on the center; but aided by the convulsions and asphyxia. This is followed by vasomotor depression.

These effects are synchronous with the convulsions: the typical course is shown in Fig. 5. With the onset of the irregular spasms at (b) the mean pressure rises (central vasomotor stimulation), the heart being slowed and strengthened (central vagus stimulation). During the tetanus (c), the pressure is very high (intense stimulation of vasomotor center), the heart beats are faster and smaller (reflex vagus depression, mainly though muscular exertion). At the tetanus disappears (d) the pressure falls below normal (central vasomotor paralysis), and the heart beats become very slow (intense vagus stimulation, mainly asphyxial). The phenomena b to d are repeated during each spasm.

![Image](https://example.com/image.png)

**Fig. 5.—Convulsive doses of strychnin on blood pressure.**

As death approaches, and the respiration stops permanently, the pressure remains low, and the heart beats rapidly but weakly (total paralysis of vasomotor and vagus centers), and finally stops.

This description applies almost equally well to the effects of convulsions produced by any other cause; and particularly to asphyxia (see Fig. 6). These are both present in strychnin poisoning, and must be contributory factors. However, they are not the main cause of the rise of blood pressure; for this occurs when convulsions are excluded by complete curarization; and when asphyxia is prevented by artificial respiration. Only the portion (d) of the tracing is entirely asphyxial.

**Vasomotor Center.**—Plichter and Sollmann, 1915, found that the vasomotor center is greatly stimulated by convulsive doses, independently of the convulsions or asphyxia. Very large doses (above 1 mg. per kg.) depress and paralyze the center.

The skin pressure, which is also unchanged by therapeutic doses, rises during tetanus, indicating cardiac insufficiency (Capps and Matthews, 1913).

**Vascular Areas.**—During the strychnin rise of pressure, all the splanchnic vessels contract, while those of the skin (Wortheimer and Beleznay, 1897) and cerebrum (Roy and Sherrington, 1899) dilate. The vessels of the pli mater and retina are constricted (Blindlebeld, 1915).
Vasomotor Convulsions.—In curarized animals, the rise in blood pressure occurs spasmodically (S. Mayer, 1872), and can be brought on by reflex stimulation, just like the convulsions in ordinary animals. The dose required to produce the convulsive and the vasomotor action are also identical. This supports the view that the action of strychnin on the medullary centers is essentially identical with its action on the spinal centers.

Vasomotor Reversal.—According to Bayliss, 1908, contraction of the vessels through the vasomotor center is always brought about by stimulation of the vasocostrictor nerves and simultaneous automatic inhibition of the vasodilators—the reciprocal innervation of Sherrington. Bayliss claimed that this is modified by strychnin and chloroform in exactly the same sense as with skeletal muscle; and there is the same antagonism between the two drugs. The vasocostrictor nerves are so much more powerful than the dilators, that under strychnin, every reflex stimulation will cause a rise of blood pressure; under chloroform, a fall through inhibition. Langley, 1912, however, failed to confirm the "reversal" of depressor fibers by strychnin; small doses simply increase the response of the pressor fibers and large doses (10 to 20 mg. per rabbit) produce transient paralysis of the depressor response, but never "reversal."

Paralysis of Autonomic Ganglia.—Large doses of strychnin and brucin, like curare, paralyse all autonomic ganglia. This can be antagonized by stimulant doses of nicotine.

The fall of blood pressure resulting from the paralysis of the peripheral nerve cells cannot be permanently restored by any means (Langley, 1918).

![Graph](https://via.placeholder.com/150)

**Fig. 6.—Asphyxia on blood pressure (Dog).** The trachea was tied at X. The respiratory movements are at first exaggerated, but become shallow, and stop at X. The heart stops at 40, but it often gives a few isolated beats (b) after having stopped for several minutes.

**Heart.—** Among clinicians, the opinion prevails very widely that strychnin is a "cardiac stimulant." This clinical term does not necessarily imply that the drug stimulates the heart directly; but merely that it improves the pulse. The expression is used so loosely that the student is advised to discard it altogether.

As a matter of fact, strychnin has no effect whatever on the heart in therapeutic doses with living animals. Convulsant doses cause some stimulation of the ventricles (Wiggles, 1916); Cameron claims increase of cardiac tone in animals with 0.03 mg. per kilogram; but this lacks confirmation.

When perfused directly through the excised heart, the effects are first stimulant, then depressant (Hedbom, Igersheimer, 1905); but the necessary concentration could not be maintained in vivo.

Perfusion of Cardio-Inhibitory Center.—This produces stimulation (cardiac slowing, in turtles (A. D. Bush, 1919).

**Epinephrin Output.**—Large but subconvulsive doses of strychnin (1/2 to 1/3 mg. per kg., hypodermitic, corresponding to 1 to 2 mg grain for a man) considerably increase the output of epinephrin by stimulation of the thoracic cord, independently of convulsions or asphyxia. The increase may be 10 to 50 times the previous concentration, but does not exceed the maximal normal concentration. It persists for a considerable period (145 hours). The epinephrin content of the adrenal glands is not lowered, so that there must be increased manufacture of the base. Smaller doses of strychnin may temporarily lower the output (G. N. Stewart and Rogoff, 1915, 1920).

It is conceivable that this increased epinephrin output might benefit the circulation, but this is very improbable in view of the negative clinical results.

**Cardiac Poisons and Irregularities.**—M. I. Smith, 1937, found the effects on excited hearts of frogs and rabbits purely depressant; but this tended somewhat to correct
the overstimulation irregularities resulting from toxic doses of aconit, ouabain, or other stimulants. Killing the surviving animals, however, were not saved by strychnin from toxic doses of the stimulants. Irregularities due to impaired conduction (cocain) or to myocardial depression (spasmoxin, ergotoxin) were not benefited by strychnin, but rather aggravated.

Respiration.—In animals, therapeutic doses of strychnin increase respiration mainly by acceleration (Cushny, 1913). This is due to increased excitability of the center, and indirectly to the increased movements. The increase of respiration is not always conspicuous, on account of the variable excitability of the respiratory center. Clinically, it is practically absent (Newburgh, 1914; Edsall and Means, 1914; Higgins and Means, 1915, 4.5 mg. hypodermically). It is presumably more conspicuous when the excitability is partly depressed, as in anesthesia or morphin poisoning (Billerfield, 1904).

Similarly, strychnin causes a distinct and fairly lasting improvement of respiration when this has been depressed by cerebral compression (Loevenhurt et al, 1918).

With toxic doses, the respiration is spasmodic, arrested during the tetanus; accelerated immediately after; and depressed during the intermissions.

The respiratory tetanus is reflex, like the muscular tetanus; for it does not occur if the posterior roots have been divided (Pike et al, 1910).

Therapeutic Use of Medullary Stimulation.—The supposed circulatory and respiratory actions of strychnin led to its use in collapse following concussion or hemorrhage; fevers; depressant poisons, alcohol, anaesthetics, coal-tar derivatives, snake venom, etc.) and in exhaustion of the respiratory center (pneumonia, phthisis). It is probably inefficient. In any case, it should be remembered that it would be only a temporary remedy to tide the patient over a crisis; it could not in itself produce any permanent improvement in the central nervous system. It would merely raise the reflex excitability; and it is doubtful whether the permanent maintenance of this artificially raised irritability is ever of benefit.

Toxic Effects of Strychnin.—The medullary and spinal functions all show a curious mixture of stimulant and depressant response to strychnin; the stimulation predominating during the convulsions, the depression during the intermissions. The paralytic effects
gradually increase as death approaches, the respiratory center, vasomotor center, and the cardiac muscle failing in about this order—Exhaustion and asphyxia, as well as the direct depressant action of strychnin, are important factors in this paralysis.

Contributory Factors in Strychnin Paralysis.—That exhaustion is an important contributory factor is shown by the fact that life may be greatly prolonged by preventing the convulsions through chloral or curare. The prolongation of life by artificial respiration shows the contributory action of asphyxia. However, animals die from large doses of strychnin, when exhaustion and asphyxia are both excluded, in the manner indicated. Indeed, the direct depression seems generally to be the main factor (Henn and Loewe, 1913).

There is reason to believe that in the frog the paralysis of the central nervous system is caused largely by the failure of the circulation through cardiac paralysis, but this is not the sole cause, for the heart is often still beating when the reflexes have disappeared. In the case of mammals death usually occurs before the heart has stopped.

Importance of Treating the Paralysis.—It is important to bear in mind that the convulsions are not in themselves the dangerous element in strychnin poisoning. Death is rather due to paralysis. Remedial measures must therefore be directed not only against the convulsions, but also against the subsequent paralysis.

Tetanus alone is not such a dangerous condition. Thus, tetanus quite as violent as that of strychnin has been produced, e.g., by camphor, without being fatal, and the very severe convulsions of traumatic tetanus may last for weeks, whereas large doses of strychnin may kill after a single twitch or even without any signs of convulsions (death may then, however, be due to cardiac paralysis).

Special Senses.—Strychnin (2 to 3 mg.) increases the sharpness and field of vision for all colors (Dreser, 1894), and also the olfactory sense. The sense of touch is little, if at all, affected. These actions are central. In the eye it acts probably also on the retinal ganglion cells, the effects being obtainable unilaterally by injection into the temple or under the conjunctiva. It has been employed to arrest the progress of optic atrophy amaurosis (Naged), sometimes with temporary improvement, 1/2 to 1 c.c. of a 1/2 per cent. solution (5 to 5 mg.) being injected into the temple.

Bitter and Tonic Actions.—Strychnin is extremely bitter (perceptible in dilution of 1:400,000 to 1:100,000, according to the sensitiveness of the observer). It shares the stomachic effect of other bitters, and is therefore used to improve appetite and digestion in nervous dyspepsia, chronic gastric and intestinal catarrhs, hyperemesis, seasickness, etc., and thus favor nutrition. The increased tone of the muscle creates a feeling of vigor which contributes to the "tonic" effect. To enhance the local action, the tincture of nux vomica (1 c.c. diluted, before meals) is often preferred to the alkaloid (1 to 2 mg.). It is often combined with other tonics (Elixir Ferri, Quinine et Strychninae Phosphatum). If the bitter effect alone is desired, the dose of the tincture may be reduced to 1 or 3 drops, which is too small to produce any central effects.

In measles it has been employed as a prophylactic in conjunction with atropin (Skinner, N. Y. Med. Jour., December, 1893; Girard, 1909).

Drug Habits.—The bitter and tonic actions of strychnin make it a useful adjuvant in the treatment of chronic alcoholism and other drug habits.

Diabetes Insipidus.—Strychnin is said to be occasionally effective in reducing the polyuria. There is no pharmacologic explanation for this action, if it exists.

Periodicity.—Strychnin is often used as an addition to other cathartics ("Alcin, Belladonna and Strychnin") with the idea of improving their action, especially in atomic constipation. It stimulates the Auerbach ganglia on direct application (Langley and Magnus, 1907). It has not been shown whether this action would occur in its ther-
Strycnин Group

Strychnin. Hypodermically, it probably has no direct effect in ordinary doses, while toxic doses weaken or arrest peristalsis (Pollak, 1910). Any results may perhaps be explained by increased tone of the spinal centers which influence intestinal movements and defecation. For this purpose, the extract of Nux Vomica is generally used (2-5 mg. in pills).

Other Peripheral Actions.—Strychnin, when used systemically, has practically no peripheral action on muscle, nerve, or glands except the bitter effect.

The local application of strong solutions paralyzes most nervous and muscular tissues; for instance, the heart muscle, superior cervical ganglion, striped muscle endings.

The hot effect (curare action, Lapicque, 1912) also occurs weakly in living frogs. Small doses seem to sensitize the neuro-muscular junction, lowering the threshold to indirect stimulation, and delaying fatigue (Hammott, 1946). The curare effects are stronger in brine and methyl-strychnin may be counted in the curare group. After death, strychninized frogs cease to respond to sciatic stimulation much earlier than normally (Guthans and Meltzer, 1912).

Phagocytosis.—This is hindered by strychnin in vitro (Arkin, 1913); but the doses are very different from the clinical.

Strychnin.—Action on Invertebrates.—Strychnin acts as a weak proteolysmic poison on ameboid cells, yeast, etc. Higher invertebrate animals are also relatively unsusceptible. Many insects are quite immune; others are only slightly injured (Juch- enack and Griebel, 1910).

It reverses the positive phototropic reaction of certain aquatic larve. It expands the chromatophores in others.

Strychnin reverses the reciprocal inhibitory innervation of the muscular system of earthworms, planarians and starfish, but not of medusae or sea- anemones (A. K. Moore, 1911, 1916). Its antagonism with nicotine on starfish is described by Moore, 1920.

Kanzens, 1884, also reported characteristic effects of strychnin on jellyfish and sea-urchin.

Absorption.—Strychnin is promptly absorbed, mainly from the intestine. In rabbits, none is absorbed from the stomach proper; it is not known whether this is also true for man.

Gastric Absorption.—Rather variable results have been obtained by different investigators when strychnin was placed in ligated stomachs. Generally, alcoholic solutions are absorbed readily, aqueous solutions scarcely at all. These results seem to depend partly on the ligature; for from unligated stomachs (Pawlow's pouch) aqueous solutions are well absorbed, better than alcoholic (Ryan, 1912).

Excretion.—A small part of the strychnin is excreted unchanged, mainly by the urine, practically none in the bile and feces. The excretion by urine starts within five minutes after absorption (Ippen, 1862); and is practically completed within forty-eight to seventy-two hours (Bukinin and Majone, 1906; Hatcher and Eggleston, 1911), although traces may be found even after five days (Plagge, 1885; Hale, 1909; Kueuter, 1911). In the remarkable case of a patient who had swallowed 1.3 grains and survived, Hackett, 1911, recovered 0.7 grains from the first stomach washings, and a total of 2.5 grains from the urine, mainly between the first and tenth hour. Traces were present on the fourth, none on the fifth day.

The urinary excretion of strychnin can be considerably increased by very active diureses (sodium sulphate injection); but even when this is maximal, it does not save life after doses only 20 per cent. larger than the M.F.D. (Hatcher and Eggleston, 1916).

Destruction.—At least a fourth, and often much more, of the administered strychnin can not be recovered from the excreta (Kobert); nor from the tissues of mammals, if these survive the administration three hours. The disintoxication occurs mainly in the liver, chiefly by destruction, but somewhat by storage in a loose combination (Hatcher and Eggleston, 1917). Both processes can be demonstrated by the perfusion of the excised liver. Hashed liver, however, destroys only small amounts.

The rapidity of the disintoxication is illustrated by the high tolerance of the repeated administration of sublethal doses. When the administration is spread over 12 days, 3 times the ordinary fatal dose does not produce any permanent damage (Hatcher and Eggleston, 1917; they also discuss the older contradictory literature).

Lindol, 1918, claims that strychnin is disintoxicated by cholesterol and therefore by the cholesterol content of antitoxinus serum. Confirmation is desirable.

Distribution in Body.—In fatal cases, the strychnin is found mainly in the blood, liver and kidneys, in frogs especially in the spinal cord; but there is no evidence that strychnin is bound by spinal cord emulsions (Dixon and Kanzens, 1912).
W. Koch and Mostrom, 1911, found that phosphatides increase the solubility of basic strychnin; but this is probably a simple solution phenomenon, and has nothing to do with its selective action on the nervous system. Lombardi, 1913, also claims that the toxicity of strychnin is somewhat diminished when it is first digested with brain substance; but not if the brain of a strychnin-poisoned dog is used.

Influence of Absorption and Channel of Administration on Effect. Since the capacity for the excretion and destruction of strychnin is relatively great, the effect of the same dose will vary considerably with the rapidity of its absorption. Hypodermic injections are therefore twice to eight times more active than oral administration; intravenous injections are two to three times more active than hypodermic. The effects of rectal administration approach more closely to hypodermic than to oral administration. The toxicity of strychnin is slightly reduced by the administration of large quantities to fluid (Kleiner and Meltzer, 1912). Colloids have a marked retarding effect (Hatcher, 1904).

Even very large doses may produce no symptoms, if the experiment is arranged so as to make their absorption very gradual; for instance, by injecting it into the ligatured limb of a guinea pig. A considerable quantity will be gradually absorbed through the ligatured tissue; and if the ligature is released, after several hours, the effects will be correspondingly small.

Influence of Age.—Children are said to be comparatively insusceptible to strychnin. In old people with atheromatous arteries, large doses might lead to apoplexy.

Increased Susceptibility on Continued Administration.—The continuous use of strychnin does not lead to tolerance; on the contrary, the repetition of its action "educates" the nervous system to respond more readily, so that the effects are apparently slightly increased.

After the repeated administration of equal tetanic doses to frogs, the spasms occur earlier and last longer (Mostrom and McGuigan, 1917). In mammals, the experiments of W. Hale, 1909, gave rather inconclusive results, some indicating increased susceptibility, others slight tolerance.

Susceptibility of Different Animals.—This varies greatly. With subcutaneous administration, man, cats, and dogs require about the same dose, 0.75 mg per kilogram, to produce a fatal effect; rabbits are slightly more susceptible. Guinea pigs and frogs require about six times, and snakes eighteen times, this dose. With the frog, the spasms appear with one-sixth the fatal dose; with the guinea pig they only set in when at least 95 per cent. of the fatal dose has been given. The differences for oral administration are even greater. Some birds are almost insusceptible to oral poisoning, the fatal dose for chickens by mouth being 30 to 40 mg per kilogram; subcutaneously, 3 to 5 mg.

Temperature on Convulsions in Frogs.—Smaller doses suffice to produce tetanus when the temperature is either below or above the ordinary (55° to 75°F). In the cold, the tetanus appears later, but lasts longer (Gibbons, 1913). The rapidity of onset, with large doses, rises with the temperature according to van't Hoff's law (Schromovitz and Chase, 1916). This, however, may depend on absorption.

Toxicology of Strychnin.—The symptoms and course of strychnin poisoning have been sufficiently described under the convulsant effects.

Toxic Dose.—In man, 5 to 10 mg, may exceptionally produce convulsive effects, more pronounced with 20 to 30 mg. These doses may even be fatal. The ordinarily fatal dose, by mouth, would probably be about 125 mg. With efficient treatment, patients may be saved after 250 mg; and even doses of a gram and over are said to have been treated successfully (Hewlett). The fatal dose of Nux Vomica lies about 0.75 to 3 Gm.

Time of Appearance of Symptoms and of Death.—These depend upon the mode of administration, the condition of the stomach, and other factors influencing absorption. With oral administration, the symptoms
generally appear in fifteen to thirty minutes; the convulsions sometimes only after an hour or later. Death occurs usually in one to three hours, but the time may be as short as ten minutes, or as late as nine to twenty hours, or even later.

Differential Diagnosis of Strychnin Poisoning.—Strychnin tетanus may be confused with traumatic tетanus, spinal meningitis, epilepsy, or hysteria. Traumatic tетanus is characterized by previous malaise and slow development. The convulsions begin in the jaw. The muscles remain rigid in the intermission. The course is comparatively slow. Strychnin tетanus may also begin in the jaw, but this is not so conspicuous. In rare cases of strychnin poisoning the muscles also preserve their rigidity during the interval, so that the diagnosis is sometimes difficult. When in doubt, strychnin treatment should be used, as it is beneficial in all similar conditions. The course of the case will clear up the diagnosis.

In spinal meningitis the diagnosis may be made by the fever and history. Epilepsy differs by the loss of consciousness; the reflexes are normal. In certain cases of hystēria the diagnosis may be impossible. Such cases should also be treated as for strychnin.

Postmortal Phenomena.—Death by strychnin is characterized by early and often persistent rigor. This, however, is common to all forms of convulsions, and is presumably due to the increased production of acid. The anatomical appearances are those of asphyxia and violent convulsion: venous congestion, often hyperemia of the central nervous system, and small hemorrhages; in a few cases hyperemia of the alimentary tract.

Identification of Strychnin.—Strychnin may be identified in the suspected material, vomitus, or tissues (after isolation and purification) by its taste, convulsant effects on frogs, and chemical tests (violet and cherry color with bichromate-sulphuric acid).

Strychnin largely disappears during putrefaction; although it may sometimes be found even a year after burial (Sandrich, 1884). The failure to find it is not conclusive proof of its absence (Hatcher and Eggleston, 1917).

Treatment of Strychnin Poisoning.¹—This comprises the prompt administration of chemical antidotes (permanganate, iodin, tannin); evacuation by emetics or stomach-tube (under chloroform); suppression of the convulsions by chloroform and chloral or ether; and artificial respiration. Absolute quiet of the patient is imperative.

Chemical Antidotes.—Potassium Permanaganate is probably the most effective, if it is given sufficiently early, since it destroys the strychnin. One gram (1/4 teaspoonful) should be dissolved in a quart of warm water, carefully decanted, and administered in tumbler doses at short intervals. Iodin (15 drops of tincture in 3/4 glass of water) or tannin (teaspoon in 3/4 glass of hot water) merely delay absorption, but this is distinctly useful. Tea or coffee should be avoided, since the caffeine is synergistic. Charcoal, or better caramel or Fuller’s earth, are useful by adsorbing the strychnin and delaying its absorption (Sahabatii, 1914; Fantus, 1915); but their efficiency is limited.

Emesis.—Emesis by snuff or copper sulphate or mustard may be tried, or apo- morphin (although the depression is theoretically objectionable). Gastric lavage should be done if the patient is thoroughly under chloroform—otherwise it may start a fatal convulsion. Diuresis and catharsis are probably of little use. Very energetic diuresis (as by 2 per cent. sodium sulphate intravenously; or drinking large quantities of hot water) removes some strychnin (Hatcher, 1916; Kleiner and Meltzer, 1917); but it is unable to save the animal if the minimum fatal dose is exceeded by 20 per cent. (Eggleston and Hatcher, 1917).

Physiologic Antidotes.—Chloroform, chloral, paraldehyde, ether, etc., suppress the strychnin convulsions. By preventing their painful and

¹ The student should review the general "Treatment of Poisoning."
exhaustive effects, they conserve the energy of the patient so that he may more successfully resist the strychnin depression. They also lessen the danger of tetanic asphyxia, and are therefore the most useful antidotes

Chloral is given in doses of 2 Gm. (½ dram), with the addition of another gran (15 grains) after half an hour or longer, as necessary. There is some danger that its para lytic effects coincide with those of the strychnin, and thus increase the risk. For the reason chlorform or ether is preferred, since their action can be better controlled. Etche has the advantage that it is not liable to the dangers of late chloroform poisoning Githens and Melzer, 1911; advise the intranasal insufflation of air and ether, combined with intravenous injection of nigerin's solution. Bickes and Bzyszewski, 1915; found differences in the antispasmodic action of the various narcotics; amylne hydrat being especially effective, veronal very little, and chloral between.

Morphin is theoretically objectionable, since its action on the spinal cord is sync gistic to strychnin. It has been employed, however, and its analgesic and euphoristic action would be useful; but it does not take the place of ether or chloroform, which should be preferred. Other depressants which have been used, but are of doubtful efficiency are bromid, nicotine, and pilocarpin.

Epilepsia counteracts the cardiac depression, on local application (Januschki 1910); but systematically, it increases the convulsive effects, so that there is no therapeutic antagonism.

Artificial Respiration.—This prevents or suppresses the convulsion and may save life if it is carefully maintained until the patient is out of danger. The effect is probably due mainly to the removal of the synergistic effects of asphyxia.

There are, however, some conflicting theories and data: Osterwald, 1900, claims that strychnin spasms are diminished by excess of oxygen in the air, and size wera. This might suggest that the result is due to destruction of the strychnin by oxygen, but there is no other evidence for this view. Meltzer and Ges, 1905, found that serone rhythm movements of the chest were also important, for these prolonged E1 even when the animals were in an atmosphere of pure hydrogen. They suggest that this is due to a reflex inhibitory effect on the convulsive centers. It is also conceivable that it might be due to removal of carbon dioxide. Paradoxically, however, Ryan and Guthrie, 1908, find that the inhalation of carbon dioxide also arrests strychnin convulsions, in frogs and mammals. Difference of dosage may explain the contradiction.

It is claimed as a result of animal experiments that the application of external heat also decreases the strychnin mortality.

PREPARATIONS—STRYCHNIN

Strychnina, U.S.P., B.P.; C15H14N2O3—An Alkaloid obtained from exu vomica; is another plant of the Loganiaceae. Colorless, transparent crystals or white, crystalline powder. Very slowly sol. in water (1:64:50); slightly sol. in alc. (1:120). Dose. 1 mg., ½ gr, U.S.P.; 1 to 4 mg., ½ to 1½ gr, B.P.

"Strychninae Nitriti (Strychn. Nit.), U.S.P.; C15H14N2O7NO2—Sol. in water (1:45) slightly sol. in alc. (1:150). All strychnin salts occur as colorless crystals or white powder; intensely bitter, even in dilute solutions. They are incompatible with alkaline, iodides and bromides (slow precipitation); tannins, anesantes and arsenites. Dose (of all Strychn Saltis). 1.5 mg., ½ gr, U.S.P.; 1 to 4 mg., ½ gr, 1½ gr, B.P. Maximum dose, not over 5 gr. per 24 hr.

(The limits of incompatibility with alkalies, iodides and bromides were investigated by Finnemore and Williamison, 1914.)

Strych. Sulph., U.S.P. (C15H14N2O3·H2SO4·H2O).—Sol. in water (1:50) and in alc. (1:81). Dose, etc., see "Strych. Nit.

Inject. Strych. Hyp., B.P.—0.25 to 0.75 cent. Dose, 0.5 to 0.6 c.c., 5 to 15 minims, B.P.

Liq. Strych. Hydrochl., B.P.—1 cent. Dose, 0.2 to 0.5 c.c., 2 to 5 minims, B.P.

Liq. Strych. Phenachl., N.F.—The dose of 0.5 c.c., 0.5 gr. (about) Strychnin, 1½ mg., ½ gr; Quinin, 45 mg., ½ gr.; Ferric Phosphate, 90 mg.; 1½ gr.
**PICROTOXIN GROUP**

Syr. Ferr. Phosph. c. Quin. et Stryc.; B.P. (Easton's Syrup).—Ferrous Phosphate, 1.2 per cent.; Quin. Sulph., 1.5 per cent.; Stryc., 0.55 per cent. Dose, 2 to 4 c.c., 1/2 to 1 dram, B.P.

Nux Vomica, U.S.P.; B.P. (Strychni semen, P.L.).—The dried, ripe seeds of Strychnos Nux Vomica, East Indies; yielding not less than 2.5 per cent. of total alkaloids, U.S.P.; not less than 1.25 per cent. of strychnin, B.P. *Dose*, 0.06 Gm., 1 gr., U.S.P.; 0.06 to 0.2 Gm., B.P. Maximum dose, 0.35 Gm., 4 gr.

The constituents are strychnin, brucin, tabnin, fat, etc.

The drug was unknown to the ancients, and was probably introduced by the Arabs.

The first good description occurs in 1740. Strychnin was discovered in 1828.

The bark contains the same principles in less amount, but relatively more brucin.

It was formerly used in commerce under the name of "false angostura." Several arrow poisons are also derived from the genus Strychnos, especially the Upan Tiraté from Java. Some of the strychnos species do not contain any active principle.

Nux vomica contains a small quantity of a third alkaloid, igasurin, which has not been closely studied, but which seems similar to strychnin.

Est. Nuc. Vom. Liq., B.P.—1.5 per cent. of strychnin. *Dose*, 0.06 to 0.18 c.c., 1 to 5 minims, B.P.

*Extraction Nucis Vomicae* (Est. Nuc. Vom.), U.S.P.; Est. Nuc. s. v. Sicc., B.P.—A powdered extract; 1 Gm. representing about 4 Gm. of drug, 10 per cent. of total alkaloids, 5 per cent. of strychnin. *Dose*, 15 mg., 1/4 gr., U.S.P.; 16 to 20 mg., 1/4 to 1 gr.; B.P., as pills. Maximum dose, 60 mg., 1 gr.

*Tinctura Nucis Vomicae* (Tr. Nuc. Vom.), U.S.P., B.P.; *Tincture of Nux Vomica*—to per cent. of drug, 0.15 per cent. of alkaloids, 0.125 per cent. strychnin, in about 75 per cent. alcohol. Miscible with water and alc. Incompatibilities as for Strychn. *Dose*, 0.5 c.c., 8 minims, U.S.P.; 0.3 to 1 c.c., 5 to 15 minims, B.P. Maximum dose, 0.5 c.c., 40 minims.

**PICROTOXIN GROUP**

General Statement.—The pharmacologic group of which picrotoxin is the main representative produces a conspicuous stimulation of the medullary centers, with characteristic convulsions, slowed pulse, etc.

There is also some stimulation of the spinal cord. These effects are followed by paralysis. The actions are not utilized therapeutically, but are of some toxicologic as well as scientific interest, since the members of the group have often caused poisoning.

The Principal Members of the Group.—These comprise *picrotoxin* from Cucullus indicus (the seed of Anamirta punctulata, "Fish-berrties," used for poisoning fish, the seeds of which becomes toxic; also for adulterating beer; and in "knockout drops.

The external use against pediculosis has given rise to toxic effects; *Cicutoxin* from the rhizome Cicuta virosa. "Water Hemlock," an umbelliferous plant eaten by mistake for parsley, etc. (the American species, Cicuta maculata and bullifera, are also toxic). Cicutoxin is a complex pyrrole derivative, occurring as an unstable resinous substance (C.A. Jacobson, 1913). Some of the decomposition products of digitalis (digitalin, etc.) are also counted in this group.

Less important members are: Coriandrin (from Coriaria myrtifolia); and *Tulin* (from Coriaria species of New Zealand) (C. R. Marshall, 1910). W. W. Ford, 1910, found that tulin combines with nervous substances, thereby losing its toxicity; but no tolerance is acquired.

Chemie Nature.—Most of the substances are non-alkaloidal, non-nitrogenous "neutral principles," more soluble in alcohol than in water. Some are glucidos. *Picrotis* itself consists of a mixture (or perhaps a feeble combination; Siedisch, 1912) of many essential parts of picrotoxin and picroin (Cervello, 1913; structural formula, Arigato, 1912). These are closely allied chemically and have identical actions, but picrotoxin acts far stronger. *Coriandrin* seems to vary. That first isolated by Meiss was very soluble, while Merck's is almost insoluble, but probably more active (Minhall, 1912).

Picrotoxin Convulsions.—The characteristic effects on the frog, and the localization of the convulsions in the medulla, are described in the "Laboratory Experiences." In mammals, also, the convulsions are not modified by destruction of the hemispheres (Greenevald, 1909; Morita, 1915) or section below the optic thalami (Pollock and
240

MANUAL OF PHARMACOLOGY

Holmes, 1913). Direct application of the cerebral motor cortex produce some stimula-
tion. The white matter does not respond to direct application (Maxwell, 1906 and
1907). Spinal Tetanus may often be observed in frogs after the medulla is destroyed.
The spinal stimulation having previously been masked by the more intense stimulation
of the higher centers (Luchsinger, 1878). The convulsions are not so much dependent
upon repetitive stimulation, so that they are probably in part due to a direct stimulation.
According to Baglioni, 1900, the action is located in the sensory cells. The muscle
creatin is not increased (O. Rieser, 1910).

 Symptoms of Picrotoxin Poisoning in Mammals.—The effects of convulsive or
non-fatal doses were described by J. Crichton Brown, 1875, as: Salivation and vomiting
(central; Eggleston and Hatcher, 1919); then quiet and apathetic; then restless and
aggressive; then trembling of legs; lies on side, with efforts to stand; progressively
stronger twitching of face and neck muscles; head drawn back. Then, suddenly
generalized clonic convulsions; clonic champing of jaws; closing of eyelids; marks
fracturing at mouth; involuntary urination; pupils dilated during the convulsions.
The clonic spasms change imperceptibly to running movements, become slower, and final-
ly cease. The animal remains quiet on its side, and then, after some efforts, regains
the erect position. After a time, varying with the dose, the convulsions may recur.

With digitalis, toluene, and oleanendrin, the convulsions are preceded by
immobility.

Respiration.—This is stimulated before the convulsions; becomes irregular during
the initial twitching and arrested during the clonic spasms (Pollock and Holmes, 1913).
These authors point out the similarity of the respiratory, convulsive, and circulatory
changes with those of epileptic attacks (Pollak and Treadway, 1913). The throat of
the respiratory center to CO₂ is lowered by cortiamytin (Wieland, 1912).

Spasms of the laryngeal muscles lead, with the frog, to distention of the body
air and to a characteristic cry similar to that sometimes heard with strychnin.

Circulation.—In the early stages, the blood pressure may rise from stimulation
the vasomotor center. About three to eight seconds before the convulsions, the blood
pressure falls, remaining low until asphyxia sets in (Pollock and Holmes, 1913).

Vagus Center.—The heart is greatly slowed, and may even cease for a time. If a
division of the vagi, the heart returns almost to normal. There is, however, some
depression of the cardiac muscle involved in this slowing. Later there may be a quiet-
ning, partly due to stimulation of the accelerator center and partly to paralysis of the
vagal reflex that is fatigue of its ganglia.

The vomiting, salivation, and sweating centers are also excited. The sweat may
however, be suppressed by vasomotor constriction.

Autonomic Centers.—Grunewald, 1900, pointed out that picrotoxin produces the
symptoms of parasympathetic stimulation: Contraction of pupils, salivation, vomiting,
slowed pulse, contraction of urinary bladder, erection, etc. These effects are central
for they do not occur after section of the nerves. They are not hindered by
decerebration.

Vagus-gastric Centers.—In turtles, the injection of picrotoxin produces powerful
tetanic contraction of the stomach. This does not occur if the vagi have been divided
(F. T. Rogers, 1918).

Diuretic Spasms.—These have been observed, and depend probably on stimulation
of the thoracic cord, since they cease upon destruction of this organ.

Paralysis.—With larger doses, all the stimulant effects give way to paralysis.

Hemolytic Action.—Picrotoxin, cicutoxin, and phytolacca decandra are said to
similarity to saponin.

Excretion.—This occurs by the urine; picrotin is partly unchanged; the picrotoxin
is decomposed (Chistoni, 1912).

Toxic Dose.—According to Lewin, 0.03 to 0.24 Gm. of cocculus is toxic, 2.4 Gm.
fatal. Of picrotoxin, 20 mg. are toxic. The fatal dose is not known.

The Symptoms of Poisoning in Man.—These consist in burning sensation, nausea,
salivation, cold sweat, pallor, colic, vomiting, diarrhea; pulse slowed or quickened;
palpitation; shallow respiration. These are rapidly followed by confusion, stupor and
unconsciousness. After one-half to three hours, trembling, clonic and tonic convulsions.

These generally pass into paralysis and death by asphyxia, after several hours.
The postmortem findings are those of asphyxia. The poison disappears rapidly
during putrefaction (within one or two weeks); so that the toxicologic analysis must be
made promptly. The characteristic effect of the isolated poison on the frog constitutes
the best test. The intensely bitter taste (discernible in dilutions of 1:80,000) may
arouse suspicion.

Treatment.—The chemic alkaloidal precipitants would not be efficient. The best
 treatment would be emetics (if vomiting has not occurred), permanganate, chloro-
CAFFEIN GROUP

Caffeine, Theobromin, and Other Methyl-Xanthins

Members.—This group comprises the various methyl derivatives of xanthin (dioxypurin). These occur in several plants; as products of metabolism in animals; and may also be obtained synthetically. The most important are caffeine (trimethylxanthin), the principal alkaloid of coffee, tea, kola, guarana, maté, etc.; theobromine (3,7 dimethylxanthin) from cacao; and theophylline (1,3 dimethylxanthin), which is usually prepared synthetically. Xanthin itself, and all its other methyl derivatives, produce the principal actions of the group.

Nature of Caffeine.—Caffeine is capable of forming salts, and is, therefore, an alkaloid; but it is so feeble a base that it does not turn litmus, and the salts are dissociated by water. Its solubility is also peculiar. It was isolated from coffee in 1820 by Runge, Pfeiffer and Caventou, and Robiquet. Its identity with the alkaloid of tea (sometimes called Theia) was surmised by Berzelius, and confirmed by Jobst and Müller in 1838. Commercial caffeine is now produced almost exclusively from tea.

Occurrence.—Caffeine occurs in plants of at least six families, which are scattered over many portions of the globe. It is rather remarkable that these plants have nearly all been discovered and consumed by the natives as stimulants. The plants often contain volatile products or tannin, which slightly modify their effects. Theobromine is often associated with the caffeine; in cacao, the theobromine predominates.

The chemical structure and derivation of the purine derivatives have been elucidated by Emil Fischer. The most important are as follows:

- **Caffeine**
  - 
  - 
  - 
  - 

- **Theobromine**
  - 
  - 
  - 
  - 

- **Theophylline**
  - 
  - 
  - 
  - 

These structures show the positions in which radicals may be introduced.
Principal Actions.—1. Increase of the reflex irritability of the central nervous system from above downward; leading to stimulation of the psychic areas (insomnia, etc.); of the medullary centers (respiratory, vas motor and vagus); and with large doses to heightened reflexes and tetanic convulsions. With toxic doses, the stimulation is accompanied by paralysis.

2. Increased ease of muscular contraction, progressing to loss of elasticity and to rigor; this affects all forms of muscle to a varying degree. The heart rate is thereby quickened.

3. Vasodilation by a direct action on the vessels, with moderate dose this combines with the cardiac stimulation to quicken the circulation.

4. Diuresis results through the interaction of several factors. Caffeine is used as a psychic, muscular and respiratory stimulant; as a cardiac tonic and diuretic. Theobromin and theophyllin are probably more effective when the peripheral actions are desired.

Psychic Functions.—In man, moderate doses of caffeine (to 0.3 Gm. produce a quicker and clearer flow of thought; disappearance of drowsiness and fatigue; more sustained intellectual effort; more efficient appreciation of sensory impressions, and more perfect association of ideas (Kraepelin, 1872; Dietl and Vintschag, 1878; Ach, 1900; Hollingsworth, 1913). The central actions of theobromin are relatively much weaker than those of caffeine (Flich, 1886). Theophyllin is intermediate (Dreser, Pouch, Thomas).

With larger doses, these effects pass into wakefulness, excitement, and the unpleasant reactions described under the toxicology.

The lower mammals react by restlessness and excitement. The cat is said of to become frantic. Frogs do not exhibit any symptoms referable to the brain.

Motor and Mental Efficiency.—Hollingsworth, 1913, conducted a series of tests on normal human subjects, which led to the following conclusions: Motor speed (tapping) is increased by small and large doses (0.00 and 0.3 Gm. of pure caffeine, respectively). With the more complicated typewriting, speed is also increased by the small dose, but retarded by the large. Errors in typewriting are fewer with all doses. Association tests (naming colors or opposites; calculations) are speeded by all doses. Choice (cellulations, etc.), seems retarded by small, and stimulated by larger doses. Unconditioned tremors (of the muscles is a frequent result. None of the stimulant effects are followed by depression. The effects start in 5 to 3 hours after oral administration, and last from 2 to over hours; the mental effects being more persistent than the purely motor.

Use as Antidote in Narcotic Poisoning.—Caffeine is used as an antidote against acute poisoning by morphin (Bennett, 1874); alcohol (Bin, 1878); paraldehyde (Schroeder, 1887); chloral (Airila, 1913; Sollmann). The psychical actions are directly antagonistic, the mental and muscular coordination being immediately improved, although the effect is not lasting. The respiration (Voeglin & Wiggers, 1918) and circulation may also be somewhat stimulated, but the effects easily become additive so that with fatal alcohol poisoning, caffeine is actually deleterious. With morphin, the conditions are probably more favorable.

As a stimulant antidote, the caffeine is usually administered as very strong, hot black coffee, to secure the synergistic stimulant action of the heat and oils. Strong boiled tea, through its tannin, would be a chemical antidote in poisoning by corrosive metals. Coffee has not this precipitant effect.

Mutual Antagonism of Alcohol and Caffeine.—This has been studied especially by Flich, 1932. He found that with the smaller doses, each drug tends to act qualitatively as if present alone. In alcohol sleep, small doses of caffeine cause awakening, revive the reflexes, and diminish the fall of temperature. With larger doses, there is a qualitative

MANUAL OF PHARMACOLOGY
tive change in the direction of greater depression. Light alcohol coma is intensified by moderate or large doses of caffeine; the reflexes are further depressed. With 

Medullary Centers.—These are moderately stimulated by caffeine, similarly to strychnin. There are, however, some important differences; With caffeine the stimulation is on the whole weaker for toxic doses, but rather longer and much more prolonged with therapeutic doses; and there is little or no subsequent depression, even with toxic doses. The most conspicuous effect is on the respiration. The stimulation of the vasomotor and vagus centers is interfered with by other factors, as described under “Circulation.”

Respiration.—In man, the respiration is only moderately increased (Edsall and Means, 1914), or scarcely affected by oral therapeutic doses (Newburgh, 1914; Taylor, 1914); unless cardiac dyspnea is improved by the circulatory effect. With hypodermic injection of 0.15 to 0.25 Gm., there is definite evidence of respiratory stimulation.

The CO₂ tension is markedly lowered. The rate and depth of the respiration, and the minute-volume are increased. There is also increased gas metabolism, and sometimes bronchial dilation (Higgins and Means, 1915).

The respiratory response to CO₂ was not significantly altered by small or large doses, in normal human subjects (Crafts and Means, 1917). Anesthetized animals respond by increased rate (Bina, 1878; and generally also increased depth of the respiration (Helm, 1890; Impens, 1899). The latter is probably due to partial awakening from the anesthesia; for with de cerebrated animals, the increase is confined to the rate, the depth being unchanged or more shallow (Cushny, 1928). Inhibitory reflexes are less effective.

Life in Animals.—Coffee sometimes gives relief in asthmatic attacks. The action is probably partly psychic, partly bronchial; for in guinea pigs, it relaxes the bronchial spasm produced by peptone or muscarin (Pal, 1917). Bronchial dilation is also sometimes observed in man (Higgins and Means, 1915). F. Meyer, 1915, concludes that caffeine acts mainly by stimulating the respiratory center to greater effort. He considers it less efficient than atropin, ephedrin or nicotine.

Respiratory Paralysis by Cerebral Compression.—In this condition, caffeine was a less effective stimulant than strychnin or especially cyanid (Loevenhart et al., 1918).

Spinal Cord.—Ordinary doses of caffeine heighten the reflexes (Wood, 1912; Luewen, 1913). Toxic doses produce convulsions of spinal origin (Bing, 1901), which agree in all essential respects with those of strychnin; except that the tetanus is neither as violent nor as prolonged. The exhaustion in the intervals is also less pronounced. The tetanus may produce death by fixation of the respiratory muscles. The convulsant dose is relatively large, and it is therefore doubtful whether it has ever been observed in man. Ordinary toxic doses produce only tremor. In frogs, the tetanus is not increased or hastened by removal of the cerebrum (difference from morphin; Githens, 1924).

Paralytic action of large doses can be shown in frogs by protecting the muscles from rigor; e.g., by ligating a leg exclusive of the nerve. Caffeine will then destroy its reflexes.

Skeletal Muscle.—Ordinary doses of caffeine increase the functional activity of skeletal muscle so that it contracts more readily and more completely and powerfully, and is less easily fatigued (Wood, 1912). This improvement can be demonstrated by the ergograph, as well as in the excised or curarized frog's muscle (Fig. 7). It is, therefore, at least in large part, peripheral. Larger doses depress the muscle, and eventually cause it to go into rigor, even in the living animal.

The Stimulant Phase.—A smaller stimulus suffices to produce contraction (Paschick and Pal, 1886). The latent period is shortened. The height and rapidity of the contraction are greater, and a larger weight can be lifted (Robert, 1851). Fatigue is lessened, and a greater amount of work can be performed (Dreser, 1890), so long as the
load and stimulation are optimal; but with excessive load or stimulation, caffeine diminishes the total work (Goldowinsky, 1915). The other methyl-xanthins affect muscle qualitatively like caffeine (Goldowinsky).

---

As the dose or concentration is increased, these effects are reversed. The contraction becomes less powerful, and the curve resembles that of a fatigued muscle: i.e., it is lower and more drawn out. This lengthening shows first in the relaxation (Ruckenhein and Schröder; Goldowinsky, 1915; Lee, 1900). The elasticity is lessened. The muscle is exhausted more rapidly by tetanus.

Similar muscular effects are produced by xanthin (Paschkein) and creatin (Dreser).

---

Resemblance to Fatigue. The successive increase and diminution of the muscular functions by caffeine resembles the successive phenomena of work and fatigue; and suggests that a part of these may be due to the accumulation of the xanthin products which are formed in metabolism; but other products which accumulate during work also influence the muscle similarly to fatigue (Lee, 1900).

---

Caffein Rigor. This was observed by Voit, 1860, and then investigated by Johanneu, and by Schmiedeberg, 1873. Its occurrence in the living body can be demonstrated by hypodermic injection in certain species of frog (the European Rana temporaria, and the ordinary American laboratory frog, R. pipiens); while another European frog (R. esculenta) is less susceptible to the rigor, and therefore succumbs to spinal convulsions. In both cases, the frog becomes rigidly extended; but the rigor (as distinguished from tetanus) persists after division of the sciatic nerve (Johannsen) and occurs after curare. The heart may continue to beat strongly for some time. Mammals also show some stiffness after large doses of caffeine, but usually rigor results only if the alkaloid is injected directly into an artery. The coagulant action is possessed by other xanthins, being strongest with xanthin itself, and progressively weaker with theolobrin, theophyllin, and caffeine (Filehne, 1886; Dreser).

The muscle in caffeine rigor is inexcitable and appears white, bloodless, stiff and considerably swollen and shortened, and is acid to litmus (Ransom, 1911).

---

Muscular fibers are inexcitable, and appear white, bloodless, stiff and considerably swollen and shortened. Short of disorganization, the changes are reversible. The disorganized fibers are eventually regenerative, provided their nuclei are intact. Hardening and true rigor is confined to the destroyed fibers. Similar changes are produced by organic poisons and other poisons, and in other vertebrates, although mammals require higher concentrations.

---

Perfusion of the muscle with saline or blood, if undertaken soon after the onset of the rigor, restores the plasticity but not the excitability (v. Fühk).

---

Coagulation of Muscle Extracts. Rigor may also be produced in living animals by the injection of a number of other substances in sufficient concentration; for instance, by chloroform. All of these, as well as caffeine, favor the coagulation of muscle extracts (v. Fühk, 1906). However, there need not be any relation between rigor and this coagulation; for certain substances coagulate muscle extracts even more actively, but are incapable of producing rigor during life.

Muscular Effects in Man. Morse showed by the ergograph that moderate doses of caffeine (0.1 to 0.5 gm.) increase the muscular work. In the first hour this may be raised four or five times; the effect then lessened, but extended over two to seven hours. Practically all subsequent experimenters have confirmed the increase, although it was not always as great (Helleisen, 1904). Sometimes the increase was mainly in the height of contraction (Kraepelin); with others, in the number (Rossi). This indicates that the action is both on the muscle substance (height) and on the motor centers (fatigue). Rivers and Weber, 1907, found it quite variable, and sometimes followed by a decrease. Schumberg showed that the effect is less when the experiment is made fasting on an exhausted muscle. Hyde, Root and Curl, 1917, in fasting subjects, found considerable increase of muscle power and endurance after 0.9 to 0.15 Gm.; but
CAFFEINE GROUP

marked depression after 0.5 Gm. (by mouth, as beverage). The increase of efficiency is due partly to a lesser feeling of fatigue (Rivers and Weber), but it is at least in part peripheral, since the efficiency is also increased when the muscle itself is stimulated electrically.

*Create*—Caffeine increases the creatin content of the muscles, even after curare (Rieesser, 1916). He attributes the effect to increase of the sympathetic muscular tone.

**Use of Caffeine Against Fatigue.**—The psychic and muscular action of caffeine are popularly used against fatigue. This will be discussed under the.” “Caffeine Beverages.”

**Use in Headache.**—Fairly large doses of caffeine (0.5 Gm. = \(7\frac{1}{2}\) grains) are rather effective against certain forms of headache, such as migraine, neuralgia, etc. It may be combined with acetanilid. It does not prevent the depressant effects of the latter; but rather increases its toxicity (Hale, 1909; Salant, 1912); it also increases the toxicity of alcohol and barium chlorid by its circulatory action. Caffeine is useful in some cases of *nervous dyspepsia*.

**Smooth Muscle.**—The effect of caffeine on smooth muscle consists in a longer and more persistent contraction curve. Larger doses prolong the period of relaxation. The tone seems to be affected differently in various muscles. The arteries are relaxed by relatively small doses; whereas the cacao has a tonic effect on the pelvic portion of the ureter (Lucas, 1907). It has very little effect on the uterus (Kühne).

**Intestines.**—Caffeine has little or no effect on normal peristalsis (Nasse, 1866); but direct contact with excised intestine modifies the functions. Salant and Schwartz, 1916, state that the contractions are stimulated by dilute solutions (Caffeine, 1:10,000; theobromin, 1:25,000; theophyllin, 1:50,000). Higher concentrations (1:2,000) produce marked depression of the rhythm and tonus.

**Other Peripheral Actions.**—Caffeine has no action on peripheral nervous structures when it is used systemically (Aubert, 1872); nor does it cause any local irritation.

It has a paralyzing action only when it is applied in a very strong paste directly to the nerve (Pratt). It does not act on any glands, nor on any glands other than the thyroid; nor on red corpuscles, nor on fibrin formation. Small doses increase the movements of leukocytes in siled blood, whilst higher concentrations kill them. Arkin, 1893, found *Phaenocystis* unaffected, in vitro.

**Lower Organisms.**—The action of caffeine on these are not characteristic (Brunton, 1872; oxygenation of guinea; Haskins, 1903; gas formation by yeast; Bokorny, 1894, and Krenitschewsky, 1905; anemae; Romanes, 1867; meduse: Soliman, 1898; adult and embryonic fish; Pickering, 1841; embryonic chick’s heart; Ranson, 1912: germination of red beans).

**Metabolism.**—The results of different investigators have been contradictory, but it appears that caffeine causes a rather small and variable increase in urea and CO₂. Both effects are probably indirect; the urea being explained by the diuresis, the CO₂ by the increased movements. This also explains the slight rise of temperature.

**Basal Metabolism.**—Meas, Aub and Du Bole, 1917, find constantly in man increase (5 to 25 per cent.), of basal metabolism from doses of 0.5 to 0.65 Gm.; the maximum occurring in 1 to 2 hours. The respiratory quotient was not changed. The elimination of water from the lungs and skin was increased. The total nitrogen of the urine was also increased by 6 to 37 per cent. The pulse-rate showed no significant changes.

The earlier investigations claimed diminished urea excretions (J. Lehmann, 1857; Bocher, 1874, and others), with varying results as to CO₂. The earlier work has not been confirmed, and may possibly be explained by imperfect methods. (However, Parr and Wecker, 1912, describe decreased N elimination after theophyllin in health and in renal disease; whilst Endluy claims an increase of N after theophyllin or theobromin. The contradictions probably depend on differences of diuresis.) C. J. Lehmann, Voil, Toux and others have demonstrated increased urea excretion after caffeine; Richter, increased heat production; Heerlein, 1897, Edsall and Meads, 1914, and
Higgins and Means, 1915, found increased CO₂ and O₂ metabolism, with therapeutic doses. Salant and Phelps, 1910, and Salant and Rieger, 1914, found slight changes in the excretion of creatin and creatinin.

Temperature.—The rise was demonstrated by Binz and Peretti, 1879. It is very slight in normal animals (1°C to 1.5°C). It is perhaps rather more effective in preventing the fall of temperature which occurs in light narcosis, but is ineffective in deep narcosis (Buchanan, 1913). It is much less in thyroïdectomized dogs (Karelkin, 1914).

Glycosuria.—During the caffein or theobromin diuresis, there is commonly a slight hyperglycemia and glycosuria, especially in rabbits fed on carbohydrate food. However, it occurs also in fasting animals (E. Hirsch, 1913). It may be induced by oral administration, also in cats, but not in dogs (Salant and Knight, 1909). The phenomenon, which occurs also with other diuretics, has not received a satisfactory explanation (Mieulich, 1912). It is not renal, for sugar appears in the urine only when there is a considerable rise of blood sugar (Hirsch). The hyperglycemia indicates increased glycogenolysis, which resembles that produced by pique (Nishi, 1909). Like this, it is generally (but not always; Jarisch, 1914) prevented by section of the splanchics, excision of the suprarenals (A. Mayer, 1908) and by nicotine (Hirayama, 1911). It must therefore usually central, perhaps through increased reflex irritability; but under certain conditions it is also peripheral (Jarisch).

Digestion.—The effects will be discussed under the beverages.

Circulation.—Caffein acts on the heart and blood vessels, peripherally and centrally. The effects are therefore complex and vary with the dose and other conditions. The predominant action of therapeutic and moderate physiologic doses consists in vasodilation, combined with sufficient cardiac stimulation to maintain the blood pressure, or even to raise it somewhat. Both actions should combine to favor the blood flow, and would therefore be useful in circulatory diseases; the diuretic action being a further desirable feature. On the other hand, the effects of caffein are not so powerful nor so lasting as those of digitalis; and its side actions often interfere with its use. The other methyl-xanthins act very similarly to caffein, and the same description probably applies to all.

Stage of Action.—The effects in animals may be divided into the immediate effects of intravenous injection, the more persistent effects of moderate (stimulant) doses; of larger depressant doses; and fatalities (Sollmann and Pilcher, 1911; Wood, 1912; Salant, 1913; Pilcher, 1912).

Intravenous Injection of Caffein.—This produces a fair severe fall of blood pressure, with prompt recovery. The acute fall of pressure is presumably due to depression of the myocardium by the concentrated drug. It does not occur with other methods of administration, and therefore has little practical importance. It is not characteristic for caffein, but occurs with many other drugs. The organ volume (oncometer) falls with the pressure (indicating that the action is cardiac). Direct observation of the heart shows dilation with diminished excursions. The heart rate is quickened and the vaso-motor and respiratory center are stimulated by the low pressure.

Stimulant Doses.—Small and moderate doses (10 to 20 mg. per kilogram) generally produce a slight (10 to 20 mm.) rise of blood pressure, usually with more or less increase of the heart rate. The tone of the heart is increased, and the amplitude of its excursions may be greater. This and the faster rate, raise the output of the heart. The vein pressure is not changed (Capps and Matthews, 1913). The blood flow is increased (Landgren and Tigerstedt, 1892; Loewi, 1905). The volume of the splanchic organs (Phillips and Bradford, 1887; Albanese, 1881; Gottlieb and Magnus, 1901; Loewi, 1905) and of the cerebrum (Roy and Sherrington, 1887) increases. This oncometric change is more marked and more persistent than that of the blood pressure, and therefore indicates a marked vasodilatation. It has been claimed that the dilation is more powerful in the kidney than in other organs (Phillips and Bradford; Loewi); but
CAFFEIN GROUP

in fact it seems to be about equal; at least in the splanchnic area (Sollmann and Pilcher). The vasodilation is peripheral, since the perfusion method shows that the vasomotor center is actually stimulated. Ordinarily, the peripheral dilation is more powerful than the central constriction; but under some conditions the constriction may predominate, so that the osmometer falls with the rising pressure. This, however, is very exceptional. The older conception of a powerful and constant constriction was based on slender and indirect evidence (mainly on the experiments of Wagner, 1885, and Schroeder, 1886). Vinci, 1895, found that caffeine gave a much larger rise of blood pressure (presumably cardiac) in animals which had been weakened by anemia or starvation.

Depressant Doses.—Doses of caffeine above 40 mg. per kilogram progressively lower the blood pressure, until a level of 0 to 85 mm. is reached, with doses of about 140 mg. per kilogram. This level is then maintained until death approaches. If the original pressure was low, it may not be further lowered. The tone of the heart is decreased, so that it gradually dilates, and the amplitude of the excursions and the output are diminished. The osmometer falls with the blood pressure, so that cardiac depression is the dominant element. It is accompanied, however, by a progressive and finally complete vasomotor paralysis, when epinephrin, splanching, and other forms of vaso- motor stimulation become less and less effective. (Epinephrin still causes a relatively small rise through cardiac stimulation.) The vasomotor center can be shown (by the perfusion method) to be stimulated even after very large doses; but this stimulation cannot become effective against the peripheral paralysis.

Fatal Doses.—Death occurs by acute cardiac failure. Caffeine serves to lower the resistance of the heart, so that the fatal dose may vary greatly in different animals.

Nature Involved in the Circulatory Actions of Caffeine.—These may be summarized as follows: Cardiac stimulation or depression, according to the dose and rapidity of injection. Increased heart rate, not due to vagus depression. If the vagus is intact, there may be slowing through central stimulation, but with large doses the heart escapes from the vagus tone.

Vasodilation, through peripheral depression of the vasocostrictor mechanism. Also convulsive stimulation.

Central vasocostrictor stimulation generally ineffectual; also convulsive stimulation.

Cardiac irregularities, with large doses.

Direct Action on Blood Vessels.—These tend to dilate when excited organs are perfused with caffeine (Beco and Plummer; Cow, 1911). The effect is not very great with caffeine alone, since the vessels are already dilated after death; but very little caffeine suffices to counteract the constrictor effect of epinephrin (Sollmann and Pilcher). The effete must therefore act on or beyond the structure stimulated by epinephrin; i.e., on the receptive or muscle substance.

Special Vessels.—The Coronary Vessels are not affected directly by caffeine or theobromin (Bonde, 1911; Rabe, 1911); but in intact animals there is increased blood flow and some passive dilation with therapeutic doses, when the blood pressure rises (F. Meyer, 1913). Toxic doses generally dilate (Sakai and Sasayoshi, 1915; Macht, 1915). The Lung Vessels are first constricted, soon ceding to dilation (Berecz, 1914). Macht, 1914, observed dilation of excited pulmonary artery. Theobromin was practically inactive. Baehr and Pick, 1915, found no effect with caffeine on long perfusion. The Liver vessels are dilated (Berecz, 1914). The vessels of the pig under and retina are dilated during life (Hirschfelder, 1915). The dilation of the eye-vessels may raise the intraocular tension even with falling systemic blood pressure (Wessely, 1915).

However, Raphael and Stanton found no changes in the human brain volume (plethysmograph) after intravenous injection of 0.25 Gm. of (absolute) caffeine.

De Heart Rate.—When the vagi are intact, small doses of caffeine may cause some slowing through stimulation of the vagus center (Swirski, 1904) and increased vagus excitability (Fredericq, 1913). This slowing does not occur in all animals. With larger doses, or always if the vagi are paralyzed, the rate is markedly quickened. With the vagi divided, 2 mg. per kilogram increases the rate by 25 per cent.; 20 mg. per kilogram by 15 per cent.; to 100 mg. by 50 per cent. Beyond this there is no further increase, but the heart shows dysrhythmia and irregularity. The quickening is evidently not due to vagus depression, since it occurs after section of the vagi or atropin (Johannesen, 1860, and others). The vagus tone is indeed lost after large doses (Aubert, 1872, and others),
and the response to vagus stimulation is uncertain; but direct central vagus stimulation may still cause marked slowing.

Quickening due to stimulation of the accelerator mechanism. The effect occurs after excision of the stellate ganglia and in the excised mammalian heart. Swirski, 1904, found that when the caffeine quickening had reached its maximum, a further increase would be obtained by stimulating the accelerator. (Large doses destroy the response to accelerator stimulation, Fredericq, 1913.) Cashaw showed that the details of the cardiac curve are different in caffeine and accelerator stimulation. Dixon, 1903, found that caffeine quickens the heart after aperoidea, which paralyzes the accelerator endings. Pickering, 1893, observed it in the embryonic chick's heart before the nervous structures had become developed. The quickening must therefore be due to increased contractility of the muscle substance itself.

Frog's Heart.—Small doses increase the rate (Vot, 1860), excursions (Wagner, 1885), pulse volume, and especially the absolute force or maximal resistance (Dresser, 1885–87). The diastole is shortened more than the systole.

Large doses cause slowing and weakening (Maki, with diastolic tendency (Fawal). The heart beats for some time after the skeletal muscles are in rigor (Wagner). The final arrest may be either in systole (Johannsen, 1869) or diastole (Fawal).

With hypodermic injection, the stimulant dose is 5 mg.; the depressant 25 mg. (Wagner). Dropped on the exposed heart, 1:10,000 is stimulant, and 1:100 depressant (Sollmann).

The terrapin's heart responds similarly to the frog's (Beyer, 1885).

Perfusion of the medulla in turtles with 0.02% of caffeine has practically no effect on the heart rate, in contrast with strychnin (A. D. Bush, 1919).

Excised Mammalian Heart.—When studied by modifications of the Langendorf method, caffeine and the other xanthins produce increased rate, amplitude, and force of the cardiac contraction, and generally quickened coronary flow (Hedbom, 1899; O. Lob, 1904; Beco and Plummer, 1906; Lifschitz, 1907; Plavec, 1909). The increased amplitude is first in the systole, then also in the diastole; but the cardiac tone is not increased (Plavec). The stimulation is greatest with theophyllin, then theobromin, then caffeine. The coronary vasodilatation is also greatest with theophyllin, but least with theobromin. This holds true, the increased dose flow is not simply due to the increased contraction. These experiments seem to refer only to stimulant concentrations, and they may be considerably modified by changing the conditions (Lifschitz, 1907; Plavec, 1909; Boc, 1900).

Electrocardiograms from the excised mammalian heart show that whilst the three principal methyl xanthin's agree in quickening the rate, they differ in their effects on conduction. This is depressed by theobromin, increased by caffeine and theophyllin (Sakai, 1912).

Mammalian Heart in Situ.—The effects of the various doses were studied by Plöcher, 1912, with the results described under the general discussion of the circulatory effects. Experimental Heart-block.—In complete block, caffeine increases the strength of the ventricular contraction. Larger doses produce ventricular extrasystoles and cardiac fibrillation. The strength of the surges is temporarily quickened (Edgmond, 1913).

Circulatory Effects in Man.—These correspond with what would be expected from animal experiments. With doses to 1.5 Gm., the acute effects are inconstant and generally slight. The heart rate may be slowed or quickened or unchanged (literature, Sollmann and Plöcher; Wood, 1912). Palpitation is common, but apparently largely subjective. The blood pressure may rise (Wood, 1913); or fall (Miran, 1905); or remain unchanged (Lucas, 1914; Newburgh, 1914). The volume of the human arm is diminished (Hewlett, 1913). The blood flow tends to improve by increased systolic output.

Human Blood Flow.—Hypodermic doses of 0.4 to 0.5 Gm. in resting men, produce a definite increase of the total blood flow (Krogh-Lindhard method). The improvement occurs by increased systolic output. It does not occur during work. Means and Newburgh, 1912, attribute the resist effect to increased venous return to the heart, by some action outside of the heart. During work, the venous return is adequate even without caffeine, and is not materially increased by the drug.

Blood Pressure.—In advanced myocarditis, full and continued doses of caffeine (about 1 Gm. per day) cause a progressive and permanent lowering of blood pressure, reaching a total of 10 to 30 mm. This is parallel to the diuretics, and to the relief of the edema.
and other symptoms (L. Taylor, 1914). Theobromin does not lower the pressure, although it is otherwise equally or more efficient.

**Therapeutic Effects on Circulation.**—The methyl-xanthins are used as cardiac stimulants in syncope, and especially in cardiac dropsies. They lack the permanent, tonic action of digitalis, but are useful as adjuvants or when a quick effect is desired. In Taylor's myocarditis series, the results were excellent in one-half, moderate in one-fourth, and unsuccessful in one-fifth. Theobromin is effective on the first day, if at all, so that its usefulness can be determined more quickly than with caffeine. Furthermore, the side actions of caffeine interfere with its employment, especially in excitable patients. Theobromin therefore deserves preference.

In hypotension and infectious diseases, caffeine fails to improve the circulation (Newburgh, 1914; Lucas, 1924).

**Clinical Side Actions.**—Effective doses of caffeine, especially in cardiac cases, produce palpitation, insomnia, nausea, vomiting, headache, vertigo, restlessness, anxiety and sometimes delirium. Theobromin is relatively free from these objections, but they may arise (Seifert, Nebenwirkungen, 1915, p. 128). They are also produced by theophyllin (Widmer, 1914; Seifert, L.C., p. 131). The side actions occur much more violently, and with much smaller doses (0.3 Gm. of caffeine per day, or even less) in patients with interstitial nephritis (L. Taylor).

**Effects on the Urine.**—The most important therapeutic effect of caffeine consists in a considerable diuresis. The increase concerns mainly the water of the urine. The absolute quantity of all urinary solids is also increased, but less than the water, so that their percentage is lowered. The efficiency varies with conditions, especially with the amount of water in the body (Widmer, 1914); the diuresis is most abundant in dropsical conditions, and fails entirely with dry food. It is much greater in man and in wet-fed rabbits than in dogs. Cats practically do not respond. It fails also in glomerular nephritis, but is effective in tubular nephritis unless the vessels are involved. The albumin in nephritis may be increased. Theobromin and especially theophyllin are more effective. This difference is explained in part by the relatively larger doses which can be taken without prohibitive side actions.

**Mechanism of the Diuresis.**—No agreement has been reached on this subject. The fact, that the output of all the urinary solids is increased, points to increased glomerular filtration, either by improvement of the circulation, or by a change in the endothelium. The increased renal circulation resulting from the simultaneous cardiac stimulation and vasodilatation must be a powerful factor, and may in itself suffice to explain the diuresis. The theory of stimulation of the "secretory epithelium," which is still widely accepted, was advanced by von Schroeder, mainly because he could not explain the diuresis by the blood-pressure changes; but he was ignorant of the dual and complementary action of caffeine on the heart and vessels. At present, its main support is the occasional failure of complete agreement, in minor details, of the circulatory and urinary changes; the perfusion experiments of Richards and Plant, 1915; and the increase of oxygen consumption (Bierrodt).

**Relation of Caffeine Diuresis to Circulation.**—Schroeder, 1886 and 1887; and independently, Langaard found that morphinated rabbits often fail to respond to caffeine. Assuming this to be due to vasoconstriction, he administered chloral to paralyze the center, or divided the renal nerves, and now found caffeine uniformly effective. This
appeared to show that the diuretic effect was opposed by the assumed vasocostrictor
effect of caffeine. However, it is now known that caffeine ordinarily causes vasodilatation
and not vasocostriction; and von Schroeder's results have not been always confirmed
by later observers (Loewi, 1893). They were probably due to the morphology. It is known
that chloral heightens the response to caffeine, but von Schroeder himself showed that
the same result is attained by paralysis by doses which certainly did not paralyze the
vasomotor center. The synergism may perhaps be explained as a simple summation of
the vasodilator effect of the two drugs (Albanese, 1900). The combination of caffeine
with these also gives a greater diuresis than either at doses which form a mixture of
the several methylxanthins only gives simple addition (Schlosser, 1912).

When the diuresis is compared with the changes in the oncometer (Phillips and
Bradford, 1887; Gottlieb and Magnus, 1901; Loewi, Fletcher and Henderson, 1903)
they are found to exhibit a remarkable parallelism. During the intravenous fall, the
urine flow ceases; as the oncometer recovers, the urine resumes, to reach its maximum
with the rise of the oncometer, after which both shade gradually back to the normal.
After large doses of caffeine, there is neither dilatation nor diuresis.

If the conditions are otherwise unfavorable to diuresis, as in dry-fed animals or when
the kidneys have been injured, the caffeine dilution may fail to result in diuresis (Loewi;
Phillips and Bradford). Other discrepancies have occasionally been noted (Gottlieb
and Magnus, 1901), but they are exceptional and usually insignificant; especially in
view of the statement of Loewi that the blood flow may be increased (as judged by the
arterial color of the blood in the renal vein) even when the kidney volume is kept con-
stant by excising it in plaster.

The restitution of blood after hemorrhage is not modified by the caffeine diuresis, so
that there is no sign of altered permeability of the vessels (Gaissboeck, 1911). The vis-
cosity of the blood is said to be diminished (Loria, 1912).

Denervated Kidney.—Excised and re-implanted kidney, after resumption of its
normal function, responds in the normal manner (oncometer and diuresis) to theo-
bromin and caffeine; also to urea and hypertonlic saline (Quinby, 1917).

Perfusion of Excised Mammalian Kidneys.—Munck, 1887, adding caffeine to the per-
fusing blood, found a large increase of ureret flow and a moderate increase of vein flow.
This result is certainly exceptional (von Schroeder, 1887; Kobert, 1886; Sollmann and
Hatcher, 1907). It would naturally be explained by the vasocostrictor action; but Rich-
ards and Plant, 1915, report increased urine flow even when the perfusion flow is kept
constant. This would mean that a diuretic effect occurs apart from circulatory changes.
Further observations are desirable.

Oxygen Consumption of the Kidneys.—The oxygen consumption of an organ varies
in the same direction as its work. Barcroft and his co-workers have investigated diuretics from this standpoint. In contrast to the simple saline diuretics, caffeine causes increased oxygen consumption, and therefore increased work. However, there was no real diuresis in these experiments. Hypertonlic saline causes a similar increase. Therefore, the "work" under caffeine consisted in the reabsorption of water rather than in the secretion of urine; and may, therefore, have been a result, instead of the cause, of the diuresis.

Changes in the Site of Excised Kidney Cells and Absorption of Saline Solutions.—
Sections of kidney treated with caffeine absorb less fluid from hypotonlic salt solutions
than do control sections (Fincham and Biberfeld, 1902); but the change is small and in-
constant (Sollmann and Hatcher, 1907). Histologically, the epithelium of the convol-
huted tubules tends to swell slightly in caffeine solution (W. W. Williams, 1907).

Intra-venal Staining.—Schwermsky found that caffeine (and saline) diuresis prevents
the intra-venal staining of the tubular nuclei by indigocarmine. Assuming that the
staining is due to reabsorption, he argued that this reabsorption was paralyzized by caf-
feine; and extending this, he argued that the diuresis is due to failure to reabsorb the
glomerular fluid. There is no secure basis for either assumption, and the absence of
pigment would be the natural result of the flushing of the kidneys by the diuresis.

Uterus Peristalsis.—Lucas, 1907, found that caffeine has a toxic effect on the pelvic
portion of the uteret. This would have but little influence on the urine flow, since this
is not influenced even by a considerable negative uteret pressure (Sollmann).

Perfusion of Frog's Kidney.—Cullen claims that if the perfusion is arranged so that
the caffeine acts only on the glomeruli, the effects are unsatisfactory; if it is confined to
the tubules, it increases the perfusion flow and starts the urine. This result would indi-
cate that the action of caffeine is on the tubules; but it is opposed to the findings
in mammalian nephritis; and the conditions are too complex to be satisfactory.

Renal Irritation by Caffeine.—Ordinary doses of caffeine give no indications of injury
to the kidney cells; in nephritic patients, however, large doses may be followed by marked albuminuria. Animals also respond to large doses (40 mg. per kilogram),

250 MANUAL OF PHARMACOLOGY
especially when long continued, by definite nephritic changes: albuminuria of 1.4 per 1000; leukocytes, epithelium and casts in the urine. The kidneys show dilated vessels, dusty swelling, to vascular degeneration and necrosis of the epithelium, and slight interstitial swelling. These histologic changes may be present even when the urine appears normal. Dogs are more subject than rabbits, but the lesions are usually only transient, disappearing a few days after discontinuance. No lesions are perceptible with doses of 5 to 10 mg. per kilogram, corresponding to 5 to 10 grains in man (Vinci, 1914).

Caffeine in Experimental Nephritis.—Hellin and Spiro, 1939, found caffeine ineffective is glomerular and general nephritis, but quite effective in pure tubular nephritis. This has been confirmed by Schlager and Hedinger, 1957; and by Pearce, Hill and Eisenrey, 1930; and these further showed that the failure of diuresis is accompanied by failure of the osmotic reaction. This is important evidence that the diuretic action is exerted on the gomexuric cells alone and not on the tubular epithelium.

In uranium nephritis, diuretics, including caffeine, are effective during the early pyuric stage; but they become ineffective when the anuric stage is reached, although the circulatory response may be well preserved (MacNider, 1912; Boycott and Ryffel, 1912). This depends on the exactness of the renal epithelium (MacNider, 1914). In the subcutaneously fatal form, caffeine and the other methylxanthines did not prolong life (Christian, 1914). The phthalein excretion was rather improved, but the nitrogen retention in the blood was not materially affected (Christian, 1913; Christian and Gleaves, 1931; Fitz, 1913).

For chronic nephritis, on the other hand, theobromin and thecin were distinctly harmful, since they diminished the phthalein output and the animals died more promptly (Thier, 1915), although the nitrogen excretion was unchanged, and the elimination of urea and chlorid was increased (Fitz, 1914). Finally, the kidneys ceased to react (failing?). This is especially marked if the caffeine has been preceded by several injections of saline (Mosenthal and Schlayter, 1913).

Failure of Caffeine Diuresis.—Aside from glomerular and general nephritis, there are a number of other factors which may interfere with diuresis. The quantity of water in the tissues is very important; and also the water in the food, which is the ultimate source of the water of the urine. There is, consequently, a conspicuous difference between dry-fed and wet-fed rabbits (von Sobiersk, 1890; Loewi, 1905); and presumably the limited water intake of dogs accounts in part for their lesser diuresis response (Sobiersk). Schroeder, 1887, found the water content of the rabbits' blood decreased by 10 per cent. after an effective diuresis. The same factor is active in the poor diuresis of hemorrhage (Michaud, 1904), and in the superior diuresis in dropsy (Hofmann, 1880); but other factors may operate. On the other hand, when an effective water diuresis has been secured by excessive continued water administration (Sonnol and Hofmann, 1905) or in diabetes mellitus (Meyer, 1905), there is no further increase when caffeine is added.

The Diuretic Response in the Normal Human Subject.—This is comparatively small, Raphael, 1904, found the daily urine increased (under otherwise constant conditions) by 8.5 Gm. theobromin sodium salicylate, 2 per cent.; 1.5 Gm., 14 per cent.; 5 Gm., 53 per cent. This was much less than the increase secured by the consumption of an extra liter of water or beer (100 per cent.); whilst a liter of milk increased the urine by 123 per cent.

Interference by Vasconstriction and Vagus.—Whilst the vasomotor stimulation has not ordinarily the importance attributed to it by von Schroeder, it may sometimes be sufficiently powerful to overcome the peripheral dilator effect. At all events, the diuresis is aided by the hydrocarbon narcotics. Curare is also said to aid the diuresis (Cervello and LeMonaco).

Corin, 1886, claimed that the vagi exert an inhibitory influence, which Anten, 1901, attributes to an inhibitory influence of the vagi upon the secreting cells. Atropine would therefore increase the diuresis. This claims need confirmation.

Failure of Repeated Administration.—It is a common clinical experience that caffeine may become ineffective after a time (LeNoir and Camus,
1903). This is not surprising when it is remembered that the factors which favor and impair the diuretic response are apt to vary from time to time. The disappearance of the edema, for instance, would decrease the response.

In experiments, it is also noted that repeated injections become less and less effective (Phillips and Bradford, 1887; Loewi, 1905). This, however, is simply due to the fact that the depressing dosage is gradually attained.

**Habituation.**—H. B. Myers, 1918, gave rabbits a daily hyperdermic injection of 100 mg. of caffeine for several months, without apparent damage. However, these animals required for diuretic response the intravenous injection of about twice as much caffeine, of the same strength as the theobromin, as required by normal animals. A certain degree of tolerance had therefor apparently been induced.

The Composition of the Urine.—von Schroeder, 1886, showed that the urine in caffeine diuresis is more diluted (its molecular concentration may fall below that of the blood; Dresser, 1892); but that the absolute quantity of the solids—urea as well as salts—is increased. Entirely similar changes occur in other forms of diuresis, so that they are not characteristic of caffeine, and throw no light on its actions. The urinary protein in nephritis is ordinarily not increased.

Different investigators disagree as to which of the solids is most increased, the salts (LeNoir and Camus, 1902), or the urea (Anten). Presumably this varies with circumstances. In rabbits, the salts may be increased without diuresis (Katsuyma, 1898 and 1901); and this may also occur when caffeine is given in human diabetes (E. Meyer, 1904). On the other hand, Selle, 1912, describes theophyllin diuresis with little change in the specific gravity or solids. In rabbits, theophyllin increased the K and Na, but not parallel with each other or with the diuresis (Bock, 1913). The chlorid-retaining mechanism is broken down in rabbits (Pototsky, 1907; Loewi, 1902), but not in dogs or man (Sollmann, 1901; Haskins, 1904; Sollmann and Hofmann, 1905; Saccose, 1911). However, E. H. Mason, 1918, believes that theophyllin lowers the chlorid-threshold of the kidneys in clinical acute nephritis, so that the plasma chlorid drops noticeably.

Sollmann and McComb, 1899, found that caffeine did not increase a physiologic albuminuria and Emerson, 1903, saw no increase of albumin in acute or chronic nephritis under theobromin. Pouchet and Chevalier, 1903, claim that large doses of theophyllin injure the glomerular and tubular epithelium.

Astolfani, 1905, states that caffeine, in common with other diuretics, increases hippuric acid synthesis, when benzoic acid is administered. The secretion of milk is not affected by caffeine (Ott and Scott, 1912).

Relative Efficiency of the Xanthin Derivatives.—Caffeine has been largely supplanted, as a diuretic, by theobromin (diuretin), and by theophyllin (theobrin), which are credited with a much more powerful action. With theobromin, this is not surprising, since the customary dose is four times as large as with caffeine; with theophyllin, the superiority is genuine. Both are superior to caffeine in producing less of the nervous side actions. Theobromin also acts much more promptly, i.e., within a day, whilst caffeine requires four days to reach its full efficiency. Exceptionally, caffeine succeeds where theobromin fails (Christian, 1913).

No reliable quantitative experiments on the relative diuretic action of the various xanthin derivatives have been made—the much-quoted experiments of Ach being based on too few animals. The attempt to correlate the diuretic and muscular action (Schmiedeberg) is therefore premature. Mendel and Kahn, 1913, found that most of the newer methylated xanthins are not diuretic.

1779 trimetyl C 8 dioxypurin (John) was examined by Salant and Connct, 1918. It is a weak cardiac stimulant, little if at all diuretic for rabbits, and much less toxic than caffeine.
Differences in the Members of the Group.—Caffein has the most powerful central nervous action, with relatively weak peripheral effects. The strongest diuretic action is produced by theophyllin (theoecin), which also causes the most marked cardiac stimulation and coronary dilation. Its central effects and its action on muscle approach those of caffeine. Theobromin (diuretin) acts most powerfully on muscle; its effect on the heart and urine are intermediate. It causes very little central stimulation.

The pharmacology of theobromin was first investigated by Mitchell, 1859, and later by Filene, 1886. It was used experimentally as a diuretic by von Schroeder, 1878, to avoid the supposed vasoconstriction of caffeine. He found it effective without clinical, and the action on oral administration extended over twenty hours—presumably because its insolvability caused slow absorption. This led to its clinical introduction by Gram.

The toxicity of theobromin to isolated muscle is 1/4 times that of caffeine (Veley and Walker, 1910).

Therapeutic Use of Diuretic Action.—The methyl-xanthines are employed mainly for the removal of cardiac effusions. The diuresis is proportional to the effusion, sets in promptly, and ceases when the drug is withdrawn. It is therefore especially useful for two or three days at the beginning of the more slowly acting but more permanent digitalis treatment. Caffein is the least active of the series. It may be given in the doses of 0.3 Gm. (5 grains) of citrated caffeine, in watery solutions, three times a day, but Taylor found at least 0.5 Gm., four times daily, necessary for a full effect.

Theobromin (1 Gm. or 15 grains of theobromin-sodium-salicylate, or diuretin, in water, four times a day) has the advantage of producing a better diuretic response with the least side actions. Taylor found that a daily dose of 30 grains produced very little effect; 40 grains a moderate diuresis; but 80 grains (5 Gm.) were required to secure the maximum efficiency. This quantity, when divided into four doses, was well tolerated. It has also been used intravenously, 20 c.c. of 5 per cent., Neuhof, 1913; but it is doubtful whether this is justified. Theophyllin (theophyllin-sodium-acetate, or theoecin) is the most powerful, but has been charged with sometimes causing renal irritation. Its dose is 0.3 Gm. = 5 grains, three times per day, administered in hot tea.

In renal or hepatic effusions, the efficiency is less certain. In acute or chronic parenchymatous nephritis, there is often no response whatever, while chronic interstitial nephritis usually responds (J. Miller, 1912); but unless the dosage is very small and carefully watched, the toxic side actions may set in, and the renal condition grow worse. Theophyllin and theobromin may cause renal irritation; it would therefore be better to avoid the methyl xanthines when the kidneys are acutely irritated. Inmania, the methyl xanthines are generally ineffective. Christian et al., 1913, and 1916, state that diuretics are generally ineffective in chronic nephritis, unless there is edema. They would therefore be of little use against nephritie toxemia.

Clinical Efficiency of Theophyllin.—Christian, 1916, reports on the response of atients with acute and chronic nephritis and cardioide disease, to doses of 0.1 Gm. three times daily:

In the absence of edema, these had little or no value. The urine volume and the furosomico elimination were but little increased; the pthulme output was often diminished.

In cardioide disease with marked edema, positive benefits were observed, especially when used in conjunction with digitalis. There was an active diuresis, increased chlorid
elimination; and diminution of the edema. This was often followed by diminished uric excretion, which was interpreted as a secondary depression of renal function, making it advisable not to continue the drug too long. This interpretation, however, is doubtful.

Absorption, Fate and Excretion.—Caffeine is readily and completely absorbed: none appears in the feces even after large doses. Only a small fraction is excreted unchanged in the urine. This excretion starts almost immediately, but traces may continue for two or three days (Salant and Rieger, 1912). A somewhat larger fraction loses a part of its methyl groups, and appears in the urine as di- and mono-methylxanthins. It is not known whether this is effected by oxidation or hydrolysis. The remainder—up to 80 per cent.—is completely oxidized to uric acid. Practically none of the caffeine is converted into uric acid (which is largely excreted as xanthin and oxypurin).

Theobromin undergoes changes similar to caffeine, but a larger fraction (32 per cent.) escapes decomposition. The greater part leaves as heteroxanthin.

Quantitative Excretion.—The quantity of caffeine which is excreted unchanged varies with the dose and with different animals, being only 1 per cent. in carnivora, less than 8 per cent. in man, and 0 to 20 per cent. in rabbits (Kost, 1865; Salant and Rieger, 1912). The relative quantity of the various mono- and dimethylxanthins also varies in different animals, representing 10 to 40 per cent. of the caffeine (Albanese, 1865; Bondy and Gottlieb, 1895, Krueger and Schmidt). The literature has been summarized by Bloch, 1906. The demethylxanthine is retarded by alcohol (Salant and Phelps, 1912). Emory and Salant, 1909, report experiments on the decomposition of caffeine in the liver. A trace appears in the stomach, intestines and in the bile (Salant and Rieger). The gastro-intestinal excretion is higher when the kidneys are excised (Salant and Rieger, 1913). The loss of methyl groups occurs in pretty much all organs (J. Schmidt, 1910).

Uric Acid.—In man with a purin-free diet, the continued administration of caffeine, 1 gm. per day, produced a slight but definite and progressive increase of uric excretion (S. R. Benedetti, 1916).

Toxicology.—The fatal dose of caffeine is so large (presumably about 10 Gm.), 1 that no fatal case of poisoning is on record; but doses above 1 Gm. may produce alarming symptoms, and even therapeutic doses may cause unpleasant side actions.

With larger doses, the pulse is full and hard, quickened or slowed, with palpitation and precordial distress (sometimes anginal attacks). The head is heavy, throbbing, constricted, with intense headache and great anxiety. Restlessness and excitement, insomnia (sometimes mild delirium, apophasia, fever). Vertigo, nausea, general discom- fort, fatigue, weakness (sometimes burning in the throat, gastric distress, heat flashes, perspiration, inanition pharynx, swollen tongue, ringing in the ears, flashes in the eyes), tremors of jaws, hands and feet, and muscular stiffness. Quickened, embarrassed respiration. Increased micturition (sometimes ardent urine and erection). In very severe cases, there is vomiting (sometimes violent diarrhea and tenesmus; violent choric tremors. Collapse, with small, irregular arrhythmic pulse, cold extremities, dilated pupils. Consciousness is usually intact, but there may be delirium.

Doses of 1 Gm. and higher have been taken to evade military service, especially by producing tachycardia (sometimes to 160 per minute). The drug is easily detected in the urine (Holland and Thevenon, 1910).

Toxic Effect on Animals.—The symptoms in animals correspond fairly to those observed in man: restlessness and increased reflexes; increased respiration, vomiting and diarrhea; muscular weakness. Then: clonic or tetanic convulsions, during which expiration may stop, with or without resumption; exhaustion and increasing paralysis. Death in one to four hours. The fatal dose lies about 0.15 Gm. per kilogram. Dog and cats are somewhat more susceptible than rabbits and guinea pigs. The dose for a mouse is about 0.5 Gm., which is less than the intravenous dose, except in rabbits (Salant and Rieger, 1912).

1 The doses refer to pure caffeine; the corresponding doses of citrated caffeine would be twice as large.
Recovery is usually complete within a day, even when the symptoms were violent. Some restlessness and weakness may remain for a time. It is claimed (Kunkel) that large therapeutic doses have been followed by nephritie urine, but on the other hand, daily doses of 1.25 Gm. have often been given without detriment (Becher, 1884). *Idiiosyncrasy* toward caffeine is marked, as every one knows. Children and nervous and weak individuals appear to be relatively more susceptible. Overdoses should be avoided, especially in *myocarditis*.

The treatment. This consists in evacuation and narcotics—bromid, alcohol, chloral, or morphin. It is important to reassure the patient.

**Theobromin and theophyllin**, in excessive doses or in susceptible individuals, may produce toxic effects similar to caffeine: headache, nausea, vomiting, epileptic spasms, albuminuria, gastric hemorrhage, etc. (Kobot, Schmiedeberg, Seifert). These manifestations are, however, rare. In epileptic patients, large doses of theophyllin are said to have provoked attacks (Schlesinger, 1905). Chevalier, 1914, claims that some commercial theobromins contain toxic impurities; this requires confirmation.

Two deaths from cardiac failure are attributed to Cadbury, 1910, to theophyllin (about 1 Gm. in divided doses). However, the patients were under digitalis treatment for heart disease. The causation is therefore rather doubtful.

**PREPARATIONS—CAFFEINE GROUP**

* Caffeine, U.S.P.; B.P.; Caffein (Thein); CaH6N4O6 + H2O.—A feebly basic alkaloid, usually prepared from tea. White, silky, needle-crystals; odorless; bitter taste. Sol. in water (1:46) and in alc. (1:56). Its solubility in water is greatly increased by heat, citric acid, benzoates or salicylates, bromids, antipyrin and a number of other substances. *Incompatible with tannin.* *Date:* 0.12 to 0.3 Gm., 1 to 5 gr.; B.P.; in capsules. Maximum dose, 0.5 Gm., 8 gr.

* Caffein Citrate (Caffein. Cit.)., U.S.P.; [Caffeina Citras,]., B.P.; Citrated Caffein; Caffein Citrat.—A mixture of caffeine and citric acid, containing not less than 48 per cent. of caffeine. White powder, odorless; slightly bitter, acid taste. Citrated caffeine gives a clear syrupy solution with a little water, but precipitates on dilution. The precipitate redissolves on the further addition of water, the solubility being about 1:32. Incompatible with carbonates. *Date:* 0.3 Gm., 5 gr.; U.S.P.; 0.12 to 0.2 Gm. 2 to 10 gr., B.P., in water. The free acid renders this unsuitable for hypodermic use. Maximum dose, 1 Gm., 15 gr.

* Caffein Citra Efferens (Caff. Cit. Eff.), U.S.P.; Caffeina Citra Efferens (Caffein. Cit. Eff.), B.P.; Efferents Caffein Citrate.—A granulated mixture of Sodium Bicarbonate and Tartaric and Citric Acid, with about 2 per cent. of caffeine. *Date:* 4 Gm., 1 dram; U.S.P.; 4 to 8 Gm., 1 to 2 drams, B.P.

* Caffein Soda-benzoat (Caff. Soda. Benz.), U.S.P.—A mixture of about 50 per cent. caffeine with sodium benzoate. A white powder; odorless; bitter taste. Freely sol. in water (1:2.1), sol. in alc. (1:50). *Date:* 0.3 Gm., 5 gr., by mouth; hypodermic, 0.2 Gm., 1 gr., U.S.P.; the most suitable compound for hypodermic use. Maximum dose, 1 Gm., 15 gr.

Theobromin, Theobromin.—A dimethylanthranil prepared from Cacao seeds (Theobroma Cacao) or synthetically. Very slightly sol. in water.

* Theobromin Soda-saliclylas (Theobrom. Sodio-Sal.), U.S.P.; Theobrom. et Sod. Saliyly., B.P.; Theobromin-sodium-saliclylate (Duretin),—Sodium Theobromin (C,H,N,Na) and Sodium Salicylate, in approximately molecular proportions. Not less than 46.5 per cent. of theobromin. White, odorless powder; sweetish saline and somewhat alkaline taste. Freely sol. in water (1:3); slightly sol. in alc. It gradually absorbs carbon dioxide from the air with the formation of theobromine, becoming partially insoluble in water. It must therefore be protected against exposure to air, and is incompatible with acids; also with chloral. It should not be given with meals, to avoid
precipitation by the gastric acid. Dose, 1 Gm., 15 gr., U.S.P.; 0.6 to 1.2 Gm., 10 to 20 gr., B.P.; well diluted. Solutions do not keep.

Other Theobromin Salts.—The following are listed in N.N.R., but have no special advantage: Soda-aceato (Agurate); Soda-formate (Theoborin).

* Theophyllina (Theophyll)., U.S.P.; Theophyllin (Dimethylxanthin, Theobrin); C6H4N4O2 + H2O.—White crystalline powder; odorless; bitter taste. Sol. in water (1:100) and alc. (1:50). Dose, 0.25 Gm., 5 gr., U.S.P., three times a day, in warm tea. After two or three days, it should be replaced by theobromin.

Theophyllina Soda-acetas, N.N.R. (Soluble Theobrin).—Contains 80 per cent. of the alkaloid. It dissolves in 2.5 parts of water.

Guaran. U.S.P.—A dried paste consisting chiefly of the crushed seeds of Paullinia Cupana, yielding not less than 1 per cent. of caffein. Dose, 2 Gm., 30 gr., U.S.P.

Fideali, Guaran., U.S.P.—4 per cent. of Caffein. Dose, 2 c.c., 50 minim, U.S.P.

**CAFFEIN BEVERAGES**

Caffein is an important article of popular consumption, in the form of coffee, tea, and other beverages. The usual per capita consumption in the United States is about 10 pounds of coffee and 1 pound of tea (Graham, 1912). A cup of coffee or strong tea contains about 0.1 Gm. (1-1/2 grains) of caffein. Its effects are somewhat modified by the associated products (the volatile products causing more psychic stimulation, the tea-tannin and coffee oil deranging digestion); but essentially the actions are those of the alkaloids. They consist in increased mental and physical efficiency, psychical stimulation, comfort, and relief from muscular and mental fatigue and from their attendant unpleasant sensations. These effects may be useful in certain conditions, as in those exposed to severe hardship, hunger, fatigue, etc., but ordinarily they are mere luxuries—pleasant, but superfluous. They may do no harm if the consumption is kept within bounds; but nervous individuals, who are the most apt to be injured by caffein, are most likely to exceed these bounds. The bad effects are usually not very serious, and disappear promptly if the habit is discontinued. They consist in nervousness, tremor, palpitation, insomnia, headache, and digestive disturbances.

The habitual consumption of caffein confers a very limited tolerance. Its withdrawal does not produce any marked abstinence symptoms. Coffee and chocolate are useful flavors and extemporaneous beverages, especially for castor oil and cod liver oil.

Coffee (Caffea) consists of the dried seed of Caffea Arabica, Rubiacceace. The constituents of the "green bean" are caffein, fat, coffic acid and chlorogenic acid, saccharose, etc. The chlorogenic acid gives a green color with iron, similar to tannin, and in its impure form it was formerly called "Caffeotannic acid." Gorter, 1910, has found it in about 100 plants. On oxidation it yields caffic acid. It differs from tannins in that it does not precipitate proteins, and is therefore not astringent. The percentage of caffein varies in different specimens from 3/5 to 25 per cent., usually about 1.2 per cent. (Koenig). It exists mainly as caffein-potassium chlorogynate (Gorter, 1908).

In the process of roasting (i.e., heating the seed to 300° to 350°C.) a small amount of caffein is volatilized; but since about 0.2 per cent. of water is driven off, the percentage of caffein is actually a trifle higher (1.25 per cent.). The main change in roasting consists in the production of aromatic, brown and oily products. This oil (Caffoil or Caffon), according to Erdmann, 1902, and Grae, 1912, consists of 50 per cent. of furfural alcohol, and small quantities of valerianic acid, phenol, pyridin, and a nitrogenous aromatic substance. It is probably derived mainly from the hemicellulose.

The beverage, caffoil, is a decoction made with 0.1 to 0.5 per cent. of the drug. Practically the entire caffein (perhaps 90%) is thus extracted; so that a cup of strong coffee, prepared from 15 to 17 gr., contains about 0.1 to 0.12 Gm. of the alkaloid.

The use of coffee arose in Arabia and Egypt about the middle of the fifteenth century. Coffee and tea were introduced into Europe about the last quarter of the seventeenth century, about the same time as the potato, cinchona, tobacco and chocolate.
Action of Coffee Oil.—The volatile aromatic constituents produce local irritation and reflex stimulation, in the same manner as the condiments. The hot water contributes to this effect; and possibly the greater reactivity induced by the caffeine heightens the reflex response (Schmiedeberg). The local irritation stimulates peristalsis, and with excessive use, tends to nervous dyspepsia. It is doubtful whether the quantities taken in the beverage cause any direct central stimulation.

Wilhelm, Rorer, and Reichert could not obtain any effects with coffee distillates. J. Lehmann, Archangel, and Fere and Marshall, and Erdmann found, with small doses: pleasant stimulation; increased respiration; increased heart rate, but fall of blood pressure; muscular restlessness; insomnia; perspiration; congestion. Large doses: increased peristalsis and defecation; depression of respiration and heart; fall of blood pressure and temperature; paralytic phenomena.

V. Graf, 1915, believes that the products of roasting contribute to the action. The intravenous injection of coffee is more toxic than the corresponding caffeine. This is presumably due to the potassium (Aubert). By mouth, however, the potassium (0.44 Gm. KCl in 20 Gm. coffee) is not sufficient to produce any effect.

Decaffeinated coffee does not produce the cardiac or diuretic effects of coffee or caffeine (Buquet and Titaren). 1912). The caffeine-content of commercial decaffeinated coffees and other coffee substitutes is given by Street, 1916.

Tea (Thea) consists of the dried leaves of Thea sinensis, Theaceae. Constituents: Caffein (1.4 to 3.5 per cent., usually 2 to 3 per cent.); tannin (to 30 per cent.); traces of theobromin, theophyllin, xanthin, adenosin, and volatile oil. The black and green tea differ only in the treatment to which the leaves are subjected—a fermentation with the black variety, which mainly alters the color and flavor; the green tea is rather more rich in volatile oil. The beverage is a to 4 per cent. infusion. A cup of strong tea prepared from 5 Gm. of leaves, contains about 0.1 Gm. of caffeine (Aubert). A quick infusion extracts practically all the caffeine, but only a part of the tannin (which is especially abundant in the finer sorts). The customary brief infusion is therefore commendable, since the tannin may be deleterious to digestion, by precipitating proteins and albumoses, by lessening absorption, and by irritating the gastric mucosa.

The tea-distillate is credited by Archangel, with actions similar to those of coffee. Lehmann and Tendal found it inactive.

Coca (Kola, the seed in Cola acuminata, Sterculiaceae).—This is used extensively by the natives of Africa, the fresh and often germinated seed being chewed. The dried seed, which has been introduced as a popular "tonic," contains caffeine (1.6 to 3.5 per cent., usually 2.5 per cent.); theobromin (1.6 to 2 per cent.), tannin (Kola red); fat, sugar, etc.

If the fresh nut, the caffeine is combined with a glucosidal tannin (“Kolanin,” Goris, 1907). This compound, which was formerly termed “Kalalin,” is partly decomposed by drying, by an oixadase, into free caffeine, glucose, and Kola red (Chevrotier and Figue, 1907).

Garana.—A dried paste, prepared by the Indians of South America, consists chiefly of the dried and pounded seed of Paulinia cupana, Sapindaceae. It contains 4 to 5 per cent. of caffeine, tannin, etc. Maté (Paraguayan tea) consists of the leaves of Ilex paraguayanus. It contains 0.13 to 1.85 per cent. caffeine (2 per cent, Bertrand and Devarg, 1910), 20 to 16 per cent. of tannin, etc. It is used in South America for preparing a beverage.

Cacao is consumed extensively as a beverage and in the form of chocolate. (The latter is a mixture of melted cacao and sugar, often with the addition of flavors, starch, etc.). It contains theobromin, instead of caffeine, and therefore acts less on the nervous system. It is also rich in fat, which is nutritious. A part (about half) of this fat (Oleum Theobromatis or Cacao Butter) has been removed from the commercial powdered cacao. The name Cacao should not be confused with Cocoa (the palm yielding the cocoa seed), nor with Coca, the source of coca.

Cacao consists of the fermented, dried and often roasted seeds of Theobroma Cacao, Sterculiaceae. Constituents: Theobromin (1.5 to 2.5 per cent., usually 1.5 per cent.); a trace of caffeine; 30 per cent. of fat; starch, tannin, etc. The theobromin is liberated from a glucosidal during the fermentation.

The fat is generally considered rather indigestible, but Neumann, 1906, showed that it is digested as well as other fats.

Chicory.—The roasted root of this plant is used as an adulterant and substitute for coffee. It probably contains similar empyreumatic substances, but no caffeine.
Phenomena of Chronic Caffein Poisoning.—These have been described most commonly in excessive tea drinkers. A good analysis of the effect is given by Bullard, 1886. The first symptoms are usually dyspeptia epigastric uneasiness after meals, and a general lowering of the men and physical tone. This is succeeded by restlessness and nervous excitation, tremors, and disturbed sleep, soon followed by anorexia and headache, vertigo, confusion. Constipation is very common, but more so than in individuals who are not addicted to tea. Palpitation generally associated with irregularity, becomes distressing, and is often accompanied by dyspnea. In the severer cases, these symptoms become aggravated and continuous. Neurological, sensory and hysterical disturbances are common, but it is not easy to say whether these are the cause effects of the caffeine habit. Children who drank coffee were found by Taylor, 1912, to average below the normal weight, height and strength.

The quantity of tea required to develop these symptoms varies greatly with individual. The daily average consumption of Bullard’s patients was five cups, which corresponds to about 0.6 Gm. or 8 grains of caffeine. The susceptibility is much greater in youth, anemia, weakness, insufficient food, exhaustion, and in “nervous” individuals.

Differences between Tea, Coffee, and Cacao.—The effects of excess coffee consumption differ only in minor details from tea; whilst tea tends to constipation, coffee is laxative. Both interfere with digestion, but in different ways: the coffee through the irritant effects of its volatile oil the tea through the coagulant action of the tannin. It may therefore be observed that different individuals are more injured by one or the other. The caffeine itself probably contributes to the digestive derangements through its vasodilator action. This may account for the common tendency to hemorrhoids. Cacao may disturb the digestion through its richness in fat, but the other symptoms are not common; partly because the is less inclination to its excessive use.

The acute effects on digestion deserve special mention. Cushny states that coffee and tea retard the action of the ferments considerably (in test-tube experiment), while caffeine slightly accelerates the action. The secretion of gastric juice has been investigated by Pincussohn, 1906, using dogs with the Pawlow gastric pouch. Coffee is a considerable but brief increase of quantity and acidity. “Malt coffee” (the type the coffee substitutes prepared by toasting cereals) has a similar, but weaker action. Tea and ordinary cacao decrease the secretion; but cacao in which the fat has been removed to 15 per cent. causes some increase.

With normal men, a liter of coffee or tea, hot or cold, taken with meals, has a definite effect on the acidity or the evacuation time of the stomach. Cacao, 15 to 20 liter, decreased the acidity and delayed evacuation (R. J. Miller et al., 1920); presumable through its fat.

Chronic Caffein Poisoning in Animals.—Salant and Rieger, 1910, found that continued administration of doses which did not cause acute effects, eventually produced emaciation, often ending in death. The stomach and, to a less degree, the intestine showed inflammatory changes.

On the other hand, they found that habituation increased the tolerance to acute poisoning, the fatal dose being 35 to 80 per cent. larger than ordinary. Gould and others 1937, also claims a “histogenetic” habituation.

Mice kept continuously under caffeine were found to exhibit less than the normal activity, but showed a normal gain in weight (Nice, 1913).
MORPHIN GROUP

OPium, Morphin and Related Alkaloids

Members.—Opium contains two chemically distinct groups of alkaloids. The group of morphin, or the phenaanthrene derivatives, is practically the most important. It comprises morphin and the esters formed by replacing the H of one or both hydroxyls of morphin. Some of these occur naturally in opium (methylmorphin or codein; dimethyl-morphin or thebain). Others are produced synthetically (ethyl-morphin or dionin, diaetyl morphin or heroin, etc.).

The second group, or isoquinolin derivatives, is represented by papaverine and thecarchin. Similar alkaloids also occur in other plants of the poppy family. Their actions depend apparently on the presence of the benzyl radicle; and are shared by simpler synthetic benzy! derivatives.

Since morphin is the most important of the opium alkaloids, it will be considered first.

Central Nervous System.—The most important actions of morphin are on the central nervous system. It depresses the brain, especially its higher functions. The medullary centers are first stimulated, then depressed. The reflexes and the spinal functions are mainly stimulated. The effects are broadly identical in all vertebrate animals, although the dosage varies greatly, and the symptoms show considerable differences in the relative prominence of certain phenomena and in the time required to produce the successive actions.

Narcotic Action.—The descending depressant action of morphin is well illustrated by the frog, in which the development of the symptoms corresponds closely to those produced by progressive removal of the brain. This is also the general course in mammals; but with these the symptoms are more confused. The difference is explained by the more rapid action of the drug, and by the more intimate correlation of the nervous centers.

Effects of Morphin on Frogs.—After doses of 20 to 50 mg. the symptoms start with diminution, and then absence, of voluntary movements, but the animal reacts normally when stimulated. (This corresponds to irritation of the hemispheres.) The frog sits quietly in the normal position; he will climb up an inclined plane and give the croaking reflex when stroked. When placed in a tumbler filled with water and inverted in a large vessel of water, it will leave the glass to seek the air. As the narcosis deepens, it will remain under the glass. Placed on the table, its leaps become more and more clumsy, and it does not avoid obstacles in jumping (corresponding to excision of the corpora quadrigemina). Then the animal falls to sleep even when stimulated (paralysis of medulla); but when turned on its back, it will resume its normal sitting position. The reaction also becomes more and more delayed, and can be obtained only by reinforcing the stimulation through pinching, etc., until finally it falls altogether (paralysis of medulla oblongata). The reflexes are weakened, but present. The respiration is decreased.

Morphin TETANUS in Frogs.—After the frog has remained in this depressed condition for some time (a few minutes to several hours; the shorter, the larger the dose), the respiration becomes spasmodic, resembling superficially the Cheyne-Stokes type; then the spinal reflexes return; and the frog passes gradually into a tetanus of the strychnin type, located in the spinal cord. The delayed appearance of this tetanus is due to the slow absorption of the effective dose, for it appears at once on intravenous injection (Stockman, 1891). The convulsions occur more promptly if the heart is tied off (Githens and Meltzer, 1911), presumably because thus more of the morphin reaches the nervous axis (Abel, 1912). The onset is also hastened, and the necessary dose reduced, by cold, and by removal of the cerebrum, which inhibits convulsions. The results are more prompt if the medulla is not destroyed (Githens, 1912).

McGuigan and Ross, 1915, find that the previous injection of morphin sensitizes frogs to strychnin, so that strychnin tetanus develops more quickly—provided that a latent period of one-half to two hours elapses between the morphin and strychnin
injections. They believe that the tetanizing action is due to an oxidation product of morphin, since an artificially oxidized morphin tetanizes more rapidly. Along the same lines, they explain the usual absence of tetanus in mammals by assuming rapid destruction of the tetanizing substance. The explanation involves some unproven assumptions.

Death.—The tetanus is mixed with paralytic phenomena, the animal dying fax between the spasms. Eventually the paralysis becomes permanent and ends in death. The heart is still beating at this stage and is indeed little affected directly. Death may also occur during a spasm. The convulsive stage may be absent with very large or very small doses.

Recovery.—If recovery occurs, the depressed functions recover in inverse order to their appearance (Witkowski, 1877). This paper also gives the older bibliography of the experimental work with morphin.

Textbooks do not show typical morphin effects.

Narcotic Symptoms in Human Subjects.—The first effect, produced by doses too small to elicit any other symptoms (5 mg.), consists in diminished sensibility to lasting impressions; especially such as give rise to pain, cough, fatigue, hunger, discomfort, and other disagreeable sensations.

Somewhat larger doses (10 mg. or more) depress the attention and thus weaken the appreciation of other external impressions. A sudden stimulus may evoke a normal or exaggerated reflex response; there is even increased acuteness of perception of external impressions (Kraepelin, 1892); but persistent or gradual stimuli are neglected. The stimuli are evidently transmitted to the brain, but do not fix the attention. The faculties of concentration, of judgment and of memorizing (Weygandt, 1903) are all seriously disturbed, constituting a narcosis. Through this exclusion of external stimuli, the patient is quieted, and then passes through a dreamy, apathetic, drowsy state, into natural sleep. Exceptionally, the disturbed balance of the brain leads to excitement (especially in cats) and even to delirium.

Larger doses cause a much more extensive depression, the sleep becoming so profound that the patient can be aroused only imperfectly and with difficulty. Eventually the coma and insensibility are complete.

Psychologic Experiments on Man.—Macht and Isacks, 1910 and 1917, find that 4 to 8 mg. generally produce a primary stimulation, i.e., they shorten the reaction-time. This is often followed after one-hour delay by delayed reaction. With larger doses, the primary stimulation is very short and may be absent; and the secondary depression is predominant.

Association (arithmetic) is delayed more readily, and mistakes are more numerous, than with simpler reactions.

Potency of the narcotics occurs in most individuals by the addition of narcotin and other opium alkaloids.

Behavior of Rats.—Macht, 1920, studied the influence of opiates on the behavior of rats that had been trained to a maze. He found that morphin, even in minute doses, markedly impaired the memory and the activity. Both series of opium alkaloids were depressant, but the papaverin group much less than the morphin group. Mixtures with the isonquinolin alkaloids appeared less depressant than corresponding doses of morphin alone.

Relative Analgesic Action of Opium Alkaloids.—Morphin is decidedly the strongest hypnotic and analgesic member of the group.

Analytic Experiments on Man.—Macht, Herman and Levy, 1910, investigate the influence on the sensory threshold by a quantitative method. They find the efficiency highest with morphin; then comes papaverin; then codein; narcotin, narcotin acetin and thebain are practically not analgesic. However, narcotin had a considerable potentiating action on morphin.

With hypnotic doses, 5 mg. of morphin produced no measurable analgesic effect; with 10 mg., the analgesia was marked in two subjects; the third responded by

1 Narcotics are substances which stupefy: Opium, alcohol, cannabis, atropin and similar drugs.
Morphine Group

Hyperesthesia, especially to larger doses, although all the other narcotic effects were present. When 20 to 25 mg., the patient was only slightly, with papaverin, 40 mg., it was as strong as with 10 mg. of morphin, but slower and shorter; with morfina, 7.5 mg. was ineffective; 20 to 40 mg. produced first some hyperesthesia; then slight anesthesia. Papaverin and thebain, 10 mg., were ineffective. With a mixture of equal parts of morfina and morfina, containing 53.5 mg., the analgesia was almost as great as with 10 mg. of morphin alone. This combination was also effective in the subject who resisted morphin.

Excitant Effects in Man.—Some Eastern races, especially the Malays, as also some individuals of other races, particularly women, are apparently more excited than depressed by morphin. This can perhaps be explained by diminished restraint, rather than by direct stimulation. The same explanation probably holds true also for the flights of imagination which fill the period preceding the sleep.

Effects of the Other Members of the Group.—Codein and diacetylmorphin are less quieting, and perhaps more exciting and convulsant than morphin. Codein does not inhibit, but rather increases the convulsions of camphor, etc. (Januschke and Masslow, 1913).

Imagination.—It is self-evident that an unrestrained imagination will take very different directions, according to the individual. In some it will tend directly to sleep; in others, it may even prevent sleep; in some it will be highly unpleasant, whilst others will seek to repeat the experience and thus fall easy victims to the morphin habit. The aphrodisiac effects, which occur in some, and the anaphrodisiac action in others, depend upon the action on the imagination.

Special Senses.—These are not affected directly. They may appear disturbed through the impaired attention, or through the heightened reflex irritability.

Symptoms in the Lower Mammals.—The effects are almost purely depressant (apathy, stupor, analgesia, sleep and coma) in the dog, rabbit, guinea pig, white rat, mouse and sparrow. The acute reflexes are heightened, but firm pressure, which would be much more painful in normal animals, elicits no response. Dogs exhibit a peculiar clumsiness and incoordination in their voluntary movements. They stand and walk unsteadily, and often drag their hind legs ("hymnoid walk") (B. Bernard). These symptoms resemble those of ablation of the motor areas. On the other hand, one often sees convulsions, tremors or choreiform twitchings of the limbs. The excitability of the motor areas to electric stimulation is not altered even by the largest doses (Hilde, 1872). The respiration may at first be very rapid, but is eventually depressed. Vomiting and defecation occur early.

In the cat (and also with the horse, ass, beef, sheep, pig and goat and sometimes in dogs) the coma is preceded by more or less excitement. The cat particularly exhibits a violent mania, races about as if in extreme terror, with prominent eyes and widely dilated pupils, scratching and clawing wildly. Sometimes there are even convulsions. The symptoms have been interpreted as stimulation. In fact, however, the psychic reactions are depressed; the animal does not avoid obstacles in its career, marked analgesia is present. The excitement is apparently due mainly to terror, to which the senses contributes greatly, and which is not inhibited by the normal restraining impulses (since these are dulled by morphin). The excitant effect on cats is also produced by codein and thebain; whilst papaverin and morfina are mainly depressant (G. H. Miller, 1908).

Relative Toxicity for Different Animals.—The tolerance for morphin differs remarkably. Man is by far the most susceptible, the fatal dose for man being no greater than that required for a frog of but 2500 g, the weight. Pigeons, goats, rabbits and pigs require nearly 100 times the human dose, per kilogram; dogs and cats about 15 times; hares and cows two to four times.

Respiratory Center.—Morphin and its derivatives depress the excitability of the respiratory center. The spontaneous rhythm and the response to asphyxia, and to reflexes are all lowered. There is also a marked decrease of the cough reflex; this action probably involving a somewhat different mechanism and depending partly on the analgesic effect.
Very minute doses (2 mg. of morphin for man) lessen the cough reflex without producing any other noticeable change. Somewhat larger, but still non-narcotic doses (3 to 15 mg. of morphin), diminish the excitability for carbon dioxide, and to a lesser degree for other afferent impulses (Y. Henderson and Scarbrough, 1910). The threshold to CO2 is raised (Higgins and Means, 1915). The respiratory rate may be slowed (Gescheider, 1866), or slightly quickened (Higgins and Means, 1915). With the smaller of these doses, the depth and efficiency of the respiration is somewhat increased, especially if it has been superficial. Dyspneic respiration is quieted, and "air hunger" relieved.

Toxic doses cause very marked decrease of excitability, rate, depth, and efficiency; periodic respiration (Filehne; Barbour, 1914), resembling the "Cheyne-Stokes type" (Fig. 8); and finally arrest of respiration, before the heart is seriously injured.

Codlein, heroin, and all other morphin derivatives produce the same effects (Isselkutz, 1911).

Codlein has the material advantage of relative freedom from undesirable side action and is therefore preferable in cough. Heroin has no real advantage; it is at least as liable as morphin to induce habit formation; and it is much more toxic (Harnack, 1899). Morphin is much more effective than its derivatives in quieting dyspnea.

Some of the minor opium alkaloids stimulate the respiratory center; so that opium is rather less depressant to the respiration than would be expected from its morphin content (Macht, 1915).

Rate and Depth of Respiration.—The effect of morphin, as of most drugs acting on the respiratory center, is mainly on the rate. With small doses, the depth is affected only secondarily, namely, increased in the attempt to compensate for the slowed rate, especially if the respiration was previously superficial (Isselkutz, 1911). The effects, therefore, resemble those of section of both vagi: this suggests that the effect might be due to blocking of the normal augmentor vagus impulses; but this is not the correct explanation, for morphin does not block the response to electric stimulation of the vagi, and it also causes a further slowing after both vagi have been divided (Cushny, 1913). In the dog, the hypodermic injection of morphin first causes a quickening of respiration (perhaps through nausea) followed in fifteen minutes by the typical slowing (Mayo, 1908). In frogs, the slowing is succeeded by quickening, just prior to the convulsive stage. A secondary quickening is also seen in rabbits (Filehne, 1879; Cerha, 1892) but never in man.

Decrease Excitability of Respiratory Center.—This is shown by the fact that apnea is more easily produced, and more lasting (Filehne, 1879; Cushny and Lieb, 1915). The blood becomes more venous, the oxygen content being decreased and the carbon dioxide increased (Filehne and Klonka, 1895). Apnoeia produced by the inhalation of carbon dioxide or deprivation of oxygen in normal animals increases the depth and rate of respiration. Under morphin, this response is of the same type, but very much decreased (A. Loewy, 1890; Lindhard, 1911; Cushny, 1913; Cushny and Lieb, 1915). Afferent inhibitory respiratory reflexes are rendered more effective; but acute augmentor re-
flexes are not materially altered (Cushny). The response to persistent irritation (cough) is of course diminished.

Since the reactions of the center to reflexes and CO₂ stimulation preserve the normal type, Lieb ascribe the action of morphin to slowing of the intrinsic rhythm of the respiratory center. The hydrocarbon narcotics (urethane), on the other hand, depress mainly the asphyxial reflex.

Drugs on CO₂ Hyperpnea.—Decreased response to CO₂ accumulation is also caused by heroin, codein and chloroform. This depression is removed by moderate doses of caffeine. Atropin stimulates slightly after morphin. Stimulation by camphor and epinephrin is doubtful (Veogtlin and Wiggers, 1919).

Morphin Derivatives on Respiration.—Heroin was introduced by Dreser, 1888, with the claim that therapeutic doses lessen the cough reflex and slow the respiration; but that the inspirations are deepened and more powerful, so that the alveolar air is more effectively ventilated. Independent workers, however, have shown that there is no real difference from morphin (Cushny, 1913). The deepening of the respiration is not constant (Santesson; Lewandowsky; Harmack, 1899), but is seen only with small doses, when the slowing is excessive or when the respiration has been shallow (Fraenkel, 1890). Appropriate doses of codein, dionin, and even morphin produce practically the same effect (Fraenkel; Isecutz, 1911). In man, the respiratory effect of 5 mg. of heroin correspond almost quantitatively to those of 15 mg. of morphin (Higgins and Means, 1915).

Dreser also claimed that heroin did not alter the excitability of the center to carbon dioxide, but lessened the reflex excitability (to stretching of the lungs). Impens, under Dreser, likewise claimed the carbon dioxide threshold unaltered by heroin (and dionin), but used by codein, and, of course, still more by morphin. Winternitz, 1899, found that the opposite result, the threshold being raised by heroin, but not by codein or dionin. The difference is probably insignificant: none of the derivatives raise the threshold as much as morphin, and they are, therefore, less effective in relieving dyspnea.

Separate and Combined Opium Alkaloids on Respiration.—This subject has been investigated by Macht, 1915. He finds the effects of morphin on rabbits and dogs essentially as described. Small doses (0.1 mg. per kilogram) markedly slow the rate, but somewhat increase the minute-volume and alveolar ventilation; but the response of the center to CO₂ is somewhat decreased. Full doses (1 to 5 mg. per kilogram) diminish the rate, minute-volume, alveolar ventilation, and response to CO₂.

Small Doses of Codein (1 to 2 mg. per kilogram) generally slow the rate, without much change in the minute-volume, alveolar ventilation or CO₂ response. Convulsive doses (20 mg. per kilogram) increase the ventilation and CO₂ response. Naron and hyperton increase the CO₂ response, although the rate may be slightly slowed. Narcon, thebain and cryptopin produce either no effect, or slight stimulation of the respiratory center. Combination of the stimulant alkaloids with morphin gives simple summation of their respiratory action; i.e., their stimulation partly counteracts the morphin depression. This is true for opium as well as for artificial mixtures. It also holds for the refusé respiratory center.

Bronchial Muscles.—These are slightly relaxed by therapeutic doses of morphin, and more powerfully by papaverin and narcotin (Pal, 1915; Macht, 1915); whereas large doses of morphin, codein, dionin and especially heroin, narcotin and thebain, produce marked constriction. Higgins and Means, 1915, observed bronchial constriction in man with 15 mg. of morphin or 5 mg. of heroin. The relaxation may play a part in the relief of bronchial spasm (asthma); whilst the constriction may contribute to the asphyxia of toxic doses.

The effects are peripheral, for they occur on excised bronchial muscle (relaxation, Oudin, 1912) as well as in pithed (constriction, Jackson, 1914, 1915 and 1916) and in intact animals (relaxation with small, constriction with large doses; Brodie and Bunn, 1903). The constrictor action is not antagonized by atropin, and must therefore be on the muscle or myoneural junction. It can be overcome by powerful dilator (sympathetic) stimulation (epinephrin, hordenin, Jackson, 1914 and 1915).

The combination of morphin and narcotin in dilator concentration gives less dilatation than either alone (Macht, 1915). This is similar to the behavior of the coronary.
Bronchial Secretion.—Unless there is nausea, the secretion of mucus appears diminished; particularly in bronchitis. This may be explained largely by the suppression of cough, permitting a longer sojourn of the mucus in the bronchi, with consequent removal of its water by absorption and drying; but there may also be a central depression, analogous to that of the salivary secretion, for a decrease of tracheal secretion has been demonstrated in animals (Rosbach, 1882).

Circulation.—Therapeutic doses of morphia or its derivatives do not affect the circulation materially. In man, there is generally an (indirect) increase of pulse rate immediately after an injection; this is quickly followed by persistent moderate slowing, with increased fullness and force (stimulation of vagus center). The blood pressure, after a short rise, may remain level (Anders, 1913), or falls slightly (Guinard, 1805), through the slowing, and perhaps through incipient depression of the vasomotor center. The cutaneous vessels are markedly flushed.

With toxic doses, the fall of blood pressure is more marked (central vasomotor depression), and the pulse becomes weak, varying in rate, and often arrhythmic (stimulation of vagus center and disturbed cardiac conduction).

The heart muscle suffers indirectly, by the low blood pressure and asphyxia (hence danger in cardiac insufficiency, especially when combined with dyspnea). Ordinarily the circulation remains fairly good, until death occurs by paralysis of respiration. Direct depression of the heart is produced only when morphin, or especially its derivatives, are perfused directly through the heart.

Hering, 1915, believes that the increased vagus tone resulting from large doses may indirectly produce ventricular automatism, or even fibrillation, especially in pathologic hearts tending in that direction.

Vagus Center and Cardiac Conduction.—Dogs show the same phenomena in more marked degree. The preliminary acceleration is due to nausea. The typical slowing does not occur after section of the vagi, and is therefore central. It occurs with very small doses, increases with larger doses, and passes into arrhythmia (van Egmond, 1911; Anders, 1913). Electrocardiograms also show central vagus stimulation (Einthoven; Cohn, 1913); and sinus-auricular and auriculo-ventricular heart-block, separate or combined, removable by atropin (Eyster and Meek, 1912, 1913). The reflex excitability of the vagus center is also increased (Jackson and Ewing, 1914).

The effect on the pulse rate is inconstant in cats, absent in rabbits (Egmond). Anders found constant slowing in rabbits, the vagus stimulation being partly central, partly peripheral through decrease of the negative thoracic pressure.

Morphin sensitizes the vagus center to epinephrin (Heinekamp, 1910).

The cardio-inhibitory center of the turtle is stimulated by perfusing morphin through the medullary circulation (Bush, 1920).

Cardiac Muscle.—On the Langendorff excised mammalian heart, morphin and all its derivatives first increase the rate and amplitude; this is followed by decrease, and finally systolic stasis (Vinci, 1907).

The heart of dogs shows only depression with morphin or heroin; and heroin is also purely depressant to the heart of rabbits, and is 2 to 4 times as toxic as morphin (Arbuzow, 1917).

The rate of the perfused, atropinized frog's heart is quickened by dilute, slowed by more concentrated solutions of all the papaveraceous alkaloids; morphin being the least delerious (Hale, 1909). Lippens, 1908, found peronin highly toxic for the turtle's heart. Narcoth is the most toxic of the opium alkaloids, for the heart (Macht, 1913). Papaverin lowers the cardiac tone (Pal); this is followed by considerable tachycardia (Renon and Desbois, 1914).

Cardiac Ganglia.—These show degenerative histologic lesions, similar to those of alcohol or chloroform (Lissauer, 1914).

Coronary Circulation.—This is quickened, by dilation of the coronary vessels, by most of the opium alkaloids. The action is most marked with narcoth and papaverin,
MORPHIN GROUP

ACTION ON SKIN.—Morphin and its esters have a direct mild irritant action on the skin, resulting in erythema, itching and wheals. These effects are marked with local application to the scarified skin, and occur to some degree after the internal administration of therapeutic doses.

Circulation of the Skin; Vasodilatation Action.—The cutaneous vessels are specifically dilated even by small doses. The skin is reddened, warm, and the perspiration increased. This action is utilized, in the form of Dover’s powder (Pulvis Ipecac et Opii, o.5 Gm. at night) for the “abortion” of colds. In susceptible individuals, the cutaneous dilatation may give rise to exanthema. With toxic doses the skin becomes pale (vasodilatation of the splanchnic area), and cyanotic (asphyxia).

Other Poisons which may Produce Erythema on Systemic Administration are: atropin, quinin, chloral, barbital, benzol derivatives (antipyrin, cichophen, salicylates, aspirin, etc.), iodids, bromids, sera, etc.

Wheals.—The local application of solutions of morphin or any of its esters to the scarified skin results in the production of an urticarial wheal (Philippon, 1889; Toisik and Rei, 1902; and Roth, 1914; Sollmann, 1915). Similar wheals which are produced by histamin, peptone, emetin, and calcium chloride (Sollmann and Pilcher, 1917).

Conjunctival Reaction to Ethylmophin (Dionin).—The direct application of a 1 to 5 per cent. solution or ointment produces burning pain, hyperemia, and acute edema of the lids and conjunctiva, which disappears without any ill effects. This reaction is used in opthalmology for the removal of old inflammatory products.

The edema, which is ascribed to vascular congestion, appears in a few minutes and lasts for several hours. There is also some more persistent local anesthesia. The pupils are at first constricted, and the intraocular tension is raised (Toczyski, 1912). The edema does not occur in rabbits, but readily in dogs or cats (Axenfeld, 1907).

Benzyl-morphin (peronin) is said to act in the same way: but the effect does not occur with morphin, codein, heroin, or any of the natural opium alkaloids.

Effect on Pupils.—In man (not in animals) even small, scarcely analgic doses of morphin constrict the pupils. The miosis is due to a stronger constrictor (oculomotor) tone; for it disappears when the oculomotor endings are paralyzed by atropin; whilst it is scarcely affected by cocain, which stimulates the sympathetic endings. The action is central, for it is not produced by local application. It has been suggested that morphin depresses the inhibitory impulses which normally keep the oculomotor tone in abeyance (Meyer and Gottlieb). There is a fairly lasting rise of intracocular pressure (Myashita, 1913). Ethyl-morphin produces a shorter rise.

The oculomotor center (pupillo-constrictor) appears to be normally in a state of partial inhibition through a variety of sensory impulses. When these are diminished—as by sleep, narcosis, and in a specific manner by morphin—the oculomotor tone increases.
and the pupils contract. When the inhibitory impulses are reinforced—as by emotion, electric stimulation of the cerebral cortex, asphyxia, etc.—the oculomotor tone is diminished, and the pupils dilate. That this type of mydriasis is not due to stimulation of the sympathetic (dilator) center, is shown by the fact that it occurs after division of the cervical sympathetic nerve (Braunfels, 1894).

Pupil Changes in Animals.—In cats, the pupils are dilated, in conformity with the general excitement. In dogs, the effect is variable, but generally dilator.

Spinal Cord.—Morphin and all the members of the group increase the spinal reflexes. Large doses, in frogs, produce convulsions which are indistinguishable from those caused by strychnin. Mammals generally die from the respiratory depression before the convulsant stage can develop; but the smaller mammals may exhibit muscular stiffness and tremors. Convolusions are sometimes seen, even in man, when toxic doses (3 grains) are taken (A. Gordon, 1915; Keen). In dogs, the intraspinal (subarachnoid) injection of morphin produces marked convulsions (McGuigan and Ross, 1915).

A tonic patellar responded by marked increase of spinal reflexes to a toxic dose (2 grains) of morphin (Ornato, 1918). The convulsant action is especially strong in the human, so that this is generally placed in the strychnin group.

The spinal stimulation would seem to contrindicate the use of mor- phin in convulsant conditions of spinal origin, as in strychnin poisoning. Practically, however, the analgesic effect may offset this disadvantage; nor does the theoretical objection hold against convulsions that are not spinal.

Sensory Nerves.—Opium and its alkaloids have no action whatever on the sensory endings, or on the peripheral sensory nerves, for the site of application is no more affected than other regions of the body (Jolly and Hilsmann, 1874). Their local use is therefore irrational. Any apparent success is largely psychical; although there may be some central analgesia, since morphin is readily absorbed from wounds and mucous membranes, and to a slight extent even from the unbroken skin. With the time- honored “Lead and Opium Wash,” the precipitate formed by the lead with the gums and meconic acid furnishes a soothing protection. (The morphin is not precipitated by the lead.)

A slight local analgesic effect was reported by MaGe, Johnston and Ballinger, 1916, and confirmed by Solimann, 1917 (endemic method). This, however, is so slight, brief and superficial that it is doubtful whether it has any part in the therapeutic analgesia.

Curare Action.—All the members of the group, when applied directly to a muscle-preparation, exert a weak and slow curare action: If the motor nerve is stimulated with a tetanizing current, the muscle responds with a series of rapid separate contractions, instead of a fused tetanus. Larger doses paralyze the muscle-nerves endings completely. Diacetil morphin acts more powerfully than morphin or codein; but the action is too weak to be observed in intact mammals (Hale, 1906).

Morphin on Urinary Bladder.—Morphin, in toxic doses, produces spasm of the vesical sphincter (either through depressed inhibition or analogous to pyloric spasm), leading to distention of the bladder and constant but ineffective desire for micturition. This sometimes occurs in the therapeutic use (Czapek and Wassermann, 1914). In guinea pigs the distention may rupture the bladder (Tappeiner, 1899).

The other phenanthrene oxiium alkaloids also produce powerful contraction on intra- venous injection in dogs (D. B. Jackson, 1916). The isouquinolin alkaloids (papaverin) relax (Macht, 1918).

Strab's Mouse Test.—White mice respond to the hypodermic injection of morphin (0.02 mg) or its esters by a characteristic S shaped stiff erection of the tail. The same effect is produced by other convulsants, but generally only with larger doses.
MORPHIN GROUP

(Rasmussen, 1916), for instance by nicotine, 1 mg. per 15 gm. mouse (Jensen and Sunry, 1918).

With all these drugs the phenomenon appears to be due to intense tenesmus of the anal (and bladder) sphincters, originating in the medulla and transmitted through the pelvic nerves (Van Leersum, 1918).

Macht, 1920, attributes the effect to stimulation of the smooth muscles by the piperid radical of the morphin; for it is produced by piperidin, and not by phenanthenren. Pijperidin also stimulates other excited smooth muscles.

Ureter.—The phenanthenren (morphin) alkaloids increase the contractions and tonus, whereas the isouquinolines (papaverin) inhibit the contractions and relax the tone. With the combined alkaloids (papatinium) the inhibitory action predominates (Macht, 1916). This would aid the analgesic action in renal colic. Opium would be more effective than papaverin.

Seminal Ducts.—These react like the ureter (Macht, 1916).

Uterus.—Morphin probably tends to delay the progress of labor, by its psychic soothing action, largely by preventing the reinforcement of labor pains by the contraction of the abdominal muscles (Barbour and Copenhaver, 1916). It has practically no effect on the normal uterine contractions in animals, in situ (Barbour, 1915). When applied directly to the excised uterus, the tone is somewhat increased (Barbour and Copenhaver, 1915); but this would have no clinical bearing.

Effects on the Digestive System.—Morphin tends to produce nausea and vomiting, and thus disturbs digestion. The effect is independent of the mode of administration, the action being central. The severity varies greatly in different individuals. In some cases it is so serious, and accompanied by so much depression, as to preclude the use of the drug. It may sometimes be lessened by bromid or by atropin (I. Simon, 1907).

Larger doses are antemetic.

Morphin is one of the most efficient drugs for checking peristalsis. Small doses suffice for this purpose. The effect is evidently peripheral, but its mechanism is complex, involving several factors, one or the other of which may predominate under certain conditions. The known factors are closure of the gastric sphincters, delaying the entrance of food into the intestines; decreased responsiveness to defecation reflex; and a direct reflex action on irritated (not on normal) intestine. With opium, there is also the direct depression of intestinal tone by the isoquinolin alkaloids (papaverin, etc.).

Of the individual opium alkaloids, morphin acts most powerfully on the alimentary canal. However, the minor alkaloids, especially papaverin, narcomin and codein, are also constipating, with less narcotic action (Gotlieb and v. d. Eechkout, 1908; Zehbe, 1913; Hess and Neukirch, 1913; Macht, Herman and Ley, 1916). These differences, and the delayed absorption, may explain the clinical preference for opium when the constipative effect is desired.

Nauseant and Emetic Action.—This is essentially central (Eggleston and Hatcher, 1917). It may conceivably be aided by reflexes from the gastric spasm; for atropin appears to diminish the emetic tendency. There is no evidence of local gastric irritation, although the alkaloid is rapidly excreted into the stomach. Vomiting occurs more readily with hypodermic than with intravenous injection; probably because the latter depresses the vomiting center too rapidly.

The emesis is produced by absolutely pure samples, and is therefore not due to contamination with apomorphin (even prolonged boiling does not convert morphin into apomorphin; Feinberg, 1913).

Relative Emetic Action of Opium Alkaloids.—Morphin is more nauseant and emetic than the other isolated alkaloids (Macht, 1916). Opinions differ as to the position of the combined alkaloids. Eggleston and Hatcher, 1915, believe that the emetic effect of papasin and narcomin is more powerful than would correspond to their morphin content. As narcomin alone is not emetic, it would be conceived as sensitizing the center to morphin. Macht, Herman and Ley, 1916, incline to the opposite conclusion.
Salivary Secretion.—The nausea, as usual, is accompanied by salivation. In the absence of nausea, the mouth is dry and the patient thirsty, from depression of salivary cells (V.E. Henderson, 1910). The appetite is diminished, through lesser perception of hunger, and through gastric derangement.

Secretory Action.—Morphin starts the gastric secretion in the empty stomach (therefore contraindicated in gastric ulcer), but is said to diminish the secretion when the stomach contains food (Chiar, 1913). It also increases the pancreatic secretion. Opium, on the contrary, causes a marked decrease of pancreatic secretion (Bickel and Pincussohn, 1907; O. Colnhein and Modrakowski, 1911). In chronic morphinism, gastric secretion is said to be abolished (Hitzeig).

does not respond to irritant enemic or aperient. This has been attributed to paralysis of the vomiting center; but could also be explained by the firm contraction of the cardiac sphincter (Magnus, 1890) for morphin, codein, or heroin are antemetic in doses which are not narcotic, while chloral or urethane, to prevent vomiting, must be exhibited to full narcotic action (v. Ischoltz, 1912; Rahn, 1911). Papaverin is not antemetic (Ruth). Conspicuous Action in Milk Diarrhea.—New light was thrown on morphin constipation by A. Magnus, 1906 and 1908, who tested its effect on experimental diarrhoea. A very suitable physiological form of diarrhoea can be maintained in cats by a exclusive milk diet. This diarrhoea is very effectively stopped by morphin. The remedial action is equally pronounced when the intestinal nerves have been divided so that the action is certainly peripheral. On the excited intestine, however, morphin increases peristalsis (except with enormous doses), indicating that its constipating effect is not due to peripheral intestinal depression. (The excited intestine has also been studied by Popper, 1912.)

Gastric Tonus.—To solve the riddle, Magnus investigated the passage of the alimentary contents by the bismuth X-ray method of Cannon. He now observed that morphin acts exclusively on the stomach, producing prolonged contraction of the sphincter antrum pylori, as also of the pyloric and cardiac sphincters. As a result, the food remains for hours in the fundus, the complete evacuation occupying twenty-five hours instead of the normal three hours. The intestines thereby are granted a very large amount of physiological rest, the food entering very slowly and gradually, being more perfectly macerated and digested, and presumably relatively aseptic. This furnishes the whole explanation of the constipating action in milk-diarrhoea; for the same method shows that the movements of the small intestine are scarcely affected by the morphin, whilst those of the large intestine, as also the defecation of enemata, are quite unaffected by the drug. (Schweiter, 1912, using a similar method, describes relaxation of the large, and probably also of the small, intestines.) Nor has morphin any constipating action in experimental diarrhoea from certain irritant cathartics, viz., senna, castor oil, or magnesia.

Entirely analogous phenomena are observed in the dog (Magnus; E. Zane, 1900), and in the human subject. They are probably a highly important factor in the therapeutic effect. Magnus himself, however, suggested that morphin may possibly have further indirect actions on peristalsis, by modifying intestinal secretion or absorption.

Colocynth Diarrhoea.—This surmise was confirmed by the results of his pupil, Fohberg, 1911, in colocynth diarrhoea. This drug produces excitation and increased movements throughout the alimentary tract. Both effects are antagonised by morphin (and much more by opium), even when the food is already in the intestine. The action of morphin on colocynth diarrhoea is therefore different from its action in milk, senna, castor oil or magnesia diarrhoea, in which morphin would not affect the progress of the food after this has reached the intestine.

Other Opium Alkaloids on Colocynth Diarrhoea.—Takahashi, 1914, found that codein acts similarly to morphin, but weaker. Mixtures of morphin and codein act stronger than either alone (potentiation), so that constipation occurs by combining one-fourth of the minimal active dose of morphin with one-fourth to one-fourth hundredths of the minimal active dose of codein. Equal parts of the two alkaloids constitute the best. The other alkaloids do not seem to contribute, but rather to interfere; so that Funtolium, for instance, is inferior. Codein also potentiates the gastric spasm, but only with much larger doses than are needed in colocynth. When used alone, the codein does not produce gastric spasm.

Observations on Man.—The results are rather inconstant; but those of Zebbe, 1913, with the X-ray method are fairly representative for normal subjects. The amount of the total sojourn of the food was nearly doubled.
by the opiates; more by opium and pantopium than by morphin and nar-
cophin. That in the stomach and small intestines was each delayed by
about a third. The main effect, however, was on the colon and rectum.
The defecation-reflex is delayed or suppressed (Sterlín and Schapiro, 1912;
Schapiro, 1913; Mahlo, 1913).
On the other hand, Pancost and Hopkins, 1915, observed the main
delay in the small intestines; but little in the colon; the defecation-reflex
was not observed. The effects, however, are extremely inconstant in
different individuals. Small doses were more effective than large.
Hydropneuma and oral administration produced the same results.

Older Explanations.—Prior to the conclusive experiments of Magnus, the constipat-
ing action was explained either by peripheral depression of the local reflex (the cells
of lanbacht’s and Meissner’s plexus); or central stimulation of the inhibitory splanchic
fibers (Nøthnagel, 1888). Neither theory was satisfactory. The apparent results
of Nøthnagel were probably accidental (Magnus, 1910) and need not be discussed.

Other Opium Alkaloids on Peristalsis.—Whilst the phenanthren alkaloids (morphin,
thebain and codein) increase the pendulum movements of excited intestine, these are
said to be decreased by the isooquinolin alkaloids (papaverin, narcotin and nacrein)
(Fager and Frankl, 1912 and 1911). Pal, 1913, claims that the latter also remove
spastic contractions of the stomach and intestines clinically.

Meissner, 1910, however, disclaims this grouping. He states that there is no sharp
differentiation between the phenanthren and isooquinolin alkaloids; and that the various
phenanthren alkaloids have diverse actions.

With excised rabbit’s intestine he found high concentrations of morphin and
its esters inhibitory. Smaller doses of morphin stimulate; but thebaïn always inhibited.

Cathartic Action.—Large doses produce catharsis in dogs and some other animals,
but not commonly in man. The action is presumably due to local irritation.

Gall-bladder and Bile Flow.—Large doses of morphin increase the tone of the
sphincter of the biliary papilla, and thus hinder the flow of bile (Reach, 1914). Lieb
and McWhorter, 1915 state that the musculature of the bile-bladder is not affected;
but Mach, 1917, claims that the gall-bladder reacts to the opium alkaloids like the
uterus, i.e., that it is stimulated by morphin and depressed by papaverin.

Metabolism.—The output of CO₂ and to a less degree of urinary
nitrogen, are materially decreased, mainly by the muscular quiet; in pro-
longed experiments also by the digestive derangement. The CO₂ content
of the blood rises, through the defective respiration. The urine often
contains reducing substances, partly morphin-glucuronic acid (F. Mayer,
1899), partly glucose from the asphyxia. The flow of urine is said to be
decreased (Ginsberg, 1912). The body temperature is lowered through
diminished heat production.

Lessened CO₂ Output.—That this is due to muscular depression is shown by the fact
that cats exhibit an increase (Boeck and Bauer, 1874), and this is also the result in other
animals with the more stimulant members of the group, as codein. In man, however,
the oxygen consumption is not altered, whilst the CO₂ production is decreased. The
urine is not explained (Higgins and Means, 1913).

Ratio of Urea to Total Nitrogen.—This is not altered.

Albii Reserve.—Large doses of morphin would be expected to produce asphyxial
advises. Smaller doses (10 mg. per Kg. for dogs), however, appear to increase the
alkali reserve for several hours (Hjort and Taylor, 1910). The urine becomes
strongly alkaline, by the excretion of carbonates; after narcotic doses in dogs; rabbits’
urine does not show any change of reaction (Underhill et al., 1917).

Hyperglycemia.—Large doses of morphin produce considerable hyperglycemia,
preumably due at least partly to the defective respiration. In dogs, the hypodermic
injection of 10 mg. per Kg. increases the blood sugar, on the average, by 60 per cent. in
45 hour and 77 per cent. in 14 hours (E. L. Ross, 1918).

The morphin hyperglycemia is much greater after partial destruction of the pancreas
(Auer and Kleiner, 1917).

Morphine insensitiva.—A peculiar reducing substance in human urine is described
by Spitta, 1908.
Temperature.—The fall (which is sometimes preceded by a slight rise) may be as great as 2°C. with large doses; the extent depending, however, more upon idiosyncrasy than upon the dose. The cooling is particularly great if the animal is kept in cold surroundings. With small doses, the fall may be explained by increased heat loss from cutaneous vasodilatation; but with large doses it is due mainly to diminished heat production, and finally to circulatory collapse. The heat production may be reduced by 80 per cent. in extreme cases, reaching its minimum in the third hour. The heat loss is diminished (up to 20 per cent.), partly through the effort of the heat centers to compensate for the diminished production, partly through the depressed circulation (Reichert, 1901).

Regulation of Blood Volume.—Morphin hinders the transfer of injected saline solution from the blood to the tissues (Robett, Underhill and Mendel, 1916).

Leucocytes.—These are diminished in acute and chronic morphin poisoning (Coezza, 1903). The injection of morphin inhibits the migration of leucocytes in inflamed frog’s mesentery (Ikeda, 1916).

Morphin also diminishes phagocytes in vitro (Arkini, 1913); but the concentrations would be very different from those obtaining clinically.

Protozoa.—The papaverin group is very toxic to these organisms; whereas the morphin group is relatively ineffective (Macht and Fisher, 1917). Trypanosoma brucei is killed in vitro by both groups, but especially by the papaverin group. In vivo (rats) both groups are ineffective (Macht and Weier, 1918). The amebicidal action of emetine, which is also an isquinolin derivative, prompted Fick and Wasicky, 1915, to suggest the trial of papaverin against amebic dysentery; but it does not seem to have been successful.

Absorption, Fate and Excretion.—Morphin is rapidly absorbed from all mucous surfaces, and from the abraded skin; but scarcely, if at all, from the intact skin. It disappears from the blood, being partly fixed in the organs, and largely destroyed, so that only a fraction can be recovered at autopsy. A part is excreted unchanged, especially by the alimentary tract. The saliva and gastric juice show its presence in a few minutes. Some of this excreted morphin is reabsorbed—hence the indication of emptying the stomach in morphin poisoning, even after subcutaneous administration. The intestinal excretion proceeds somewhat more slowly. In acute poisoning with large doses, administered hypodermically to dogs, one to two-thirds of the morphin can be recovered from the feces. The urine participates in the excretion to a smaller degree. The destruction is much more complete in habituated animals, thus accounting partly for the increased tolerance for morphin.

Some of the morphin is said to be excreted by the milk and to cause morphinism in sucklings. It also passes through the placental circulation to the fetus, sometimes killing the latter in utero (Jung, 1914).

The investigation of the fate of morphin is of great scientific, as well as of practical, toxicologic interest. Unfortunately it is beset with considerable difficulties. The methods of isolation are complicated, and the more or less firm combination and partial alteration of the morphin in the body render its quantitative isolation in pure form practically impossible. Marquis, 1896, believed that it exists in the tissues in three different forms.

Disappearance from the Blood.—The morphin usually ceases to be demonstrable within twenty minutes, although it is not destroyed by the blood (Coezza, 1903). It must therefore have passed into the tissues.

Excretion by the Urine.—The statements in regard to this are contradictory. Kaufmann found it qualitatively in less than two up to thirty-six hours; negative in fifty hours. Recent investigators agreed that it can be demonstrated only after large doses, and then merely in traces. However, Kaufmann-asser, 1913, finds that dogs and rabbits excreted by urine 3 to 9 per cent. of the morphin in acute poisoning; and to 39 per cent. in chronic poisoning.

Excretion by Milk.—Contrary to the usual statement, Koldewijn, 1910, found that this does not occur (in cows and goats). The subject requires investigation.

Excretion by Saliva.—Rosenthal, 1893, showed its presence in man, after 0.05 Gm. per day.
Gastric Excision.—This was discovered by Marmé, 1889. Aly, 1886, demonstrated morphin in the stomach (by lavage) in two and one-fourth minutes after hypodermic injection; the excration rose for five minutes, then remained steady for twenty-five to thirty minutes, and was arrested in an hour (Kauzmann). He also showed the benefit of gastric lavage after hypodermic injection. This indicates that part of the excrated morphin is ordinarily reabsorbed; Leineweber, 1883, and Bongers, 1895, also observed the gastric excretion. This is increased by the presence of hypertonic solutions (10 per cent. NaCl) in the stomach. Heroin behaves similarly (Langer, 1912; Kleiner, 1912). The gastro-intestinal excretion of morphin is greatly diminished by vegetarian diet in dogs (Valenti, 1914).

Excretion by Intestine.—Marquis found morphin in the large intestine one hour after intravenous injection; in the small intestine only after two hours. The large intestine contains the larger amount. This indicates that morphin is excreted by the mucosa of the whole alimentary tract. With oral administration, the morphin may reach the intestine directly, within half an hour (Kauzmann). The bile may contain traces in twenty-five minutes, but is generally negative (Kauzmann). The intestinal excretion is increased by intestinal irritants (quillaja, senega, alcohol), even when the morphin has been administered hypodermically (McCrudden, 1910).

Quantity Excreted in Feces.—Faust, 1906, found that non-habituated dogs excreted by the feces 65 per cent. of the morphin which had been injected hypodermically (Cleotta, 1903, recovered 23 to 27 per cent.). With repeated injection, as the animals became habituated, the feces contained less and less morphin (twenty-six per cent. after twenty-one to twenty-four days; 8 per cent. after twenty-nine to thirty-two days; none after forty days); although the later doses were up to 20 times as large as the earlier doses. It is evident, therefore, that the power of the organism to destroy morphin is greatly enhanced by habituation.

Presence in the Tissues.—These contain only a fraction of the morphin—for the most part mere traces. The largest quantity is usually found in the liver and in the contents of the alimentary canal (Kauzmann, 1868; Marquis, 1896). The brain of poisoned animals is very poor in morphin, although in vitro, brain substance fixes the alkaloid much better than liver pulp (Cleotta, 1903).

The Distribution of the Morphin in Various Organs.—This is described for cats and rabbits by Humm and Munch, 1916; for man by van Rijn, 1905.

Quantity of Morphin Recovered from the Tissues.—Cleotta, 1902, succeeded in recovering about one-third of the injected morphin from the entire bodies of non-habituated mice and pigeons killed in five to twenty-four hours after the injection of large doses of morphin. The same quantity was recovered from animals which had been habituated, but left without morphin for two days prior to the final injection (to permit the complete elimination of retained morphin). This indicates that the destruction is not a rapid process, even in habituated animals.

 Destruction of Morphin in the Body.—The facts described in the preceding section leave no doubt that the morphin is largely destroyed; but as to the place and manner of this destruction, the evidence is incomplete. It indicates that the morphin may be destroyed in various organs, and more actively in habituated animals.

Thus, for example, Humm and Munch, 1916, claims the disappearance of one-sixth to one-third of the morphin digested with oxygenated emulsions of lung, liver, and especially brain; no destruction with filtered extracts; so that the action is not due to soluble fermen, but presumably oxidative. The destruction is increased in habituated animals. Albanese, 1909, found practically no destruction by liver pulp, from either normal or habituated animals; but marked destruction during abstinence following habituation. Other organs showed similar but weaker destruction. Durandcourte, 1913, again claims that morphin is destroyed by liver in vivo, and that this is increased by habituation. (Theories of decomposition, Spitta, 1908.)

Failure in Chick-embryo.—If morphin is injected into fertilized eggs, which are then incubated, no destruction of morphin or its derivatives occurs if the embryo dies before it is half developed. If development is completed, heroin is destroyed absolutely; morphin very largely, codein and dionin not at all. The destruction therefore takes place only after a certain development, perhaps of the nervous system, has been reached. The alkyl groups protect the morphin against oxidation, just as they do in the adult organism, while the acetyl groups are evidently easily separated (Grueter, 1913).

Failure in Fros.—In these, the destruction is very small, and no tolerance is acquired. The excretion is very slow, extending over eight days, and occurs exclusively through the alimentary tract (B. Frenkel, 1910).

Recovery after Burial.—This has been investigated amongst others, by Hornberger and Munch, 1916, and Palet, 1919. The latter obtained positive tests after 7 months.

MORPHIN GROUP 271
Fate of Codein.—This behaves quite differently from morphin: about 80 per cent. is excreted unchanged, mainly in the urine, but somewhat also in the feces (Tauber, 1892). Repeated administration does not increase its destruction, nor does it appear to produce tolerance in animals (Bouma, 1903).

Heroin.—The greater part is excreted unchanged in the urine; some also in the feces. A part is destroyed and this destruction is greatly increased in habituation (Langer, 1912).

Odeuous Substances.—The substances which give the characteristic odor to opium are excreted largely by the urine, and also in the breath, sweat and milk.

Toxicology.—Acute Symptoms of Morphin and Opium Poisoning.—Suicidal and accidental poisoning by morphin or opium is common, and familiarity with its successive symptoms is therefore important. The following description of the morphin effects applies equally to opium (with ten times the dose), except that the symptoms do not appear quite (but almost) as promptly.

Moderate Therapeutic Doses (5 to 15 mg.; ½₂ to ⅓ gr. of morphin).—The symptoms set in promptly (five to ten minutes after hypodermic, fifteen to thirty minutes after oral administration). They begin with slight flushing of face, sensation of warmth and comfort; lassitude, giddiness, dreamy state, with free imagination but confused intelligence; mouth dry and thirsty.

The patient becomes sleepy; skin pale; respiration and pulse slowed; pupils constricted. Nausea and vomiting are exceptional with this dosage.

In a short time—the sooner, the larger the dose—a natural sleep sets in, lasting six to eight hours or more; the patient commonly awakens refreshed.

Intravenous Injection.—If the injection accidentally enters a vein, there is tinnitus, tachycardia, fainting, but usually rapid recovery.

Larger Therapeutic Doses (20 to 30 mg.; ⅓ to ½ gr.).—The initial symptoms are the same. Sleep occurs more promptly and is more profound. On awaking there is usually some confusion, nausea, anorexia, and constipation.

Toxic Doses (100 to 300 mg.; 1½ to 5 gr.).—The initial symptoms are as described. The somnolence deepens rapidly into sleep and coma; severe symptoms being generally conspicuous in five to ten minutes after hypodermic, or fifteen to forty minutes after oral administration; rarely delayed for one or two hours.

In the earlier stages of the coma, the patient can be partially aroused to a confused consciousness, but relapses promptly into lethargy.

As the coma deepens (i.e., almost always within two hours, and often in half an hour after taking the poison), the patient can not be roused, the reflexes disappear, the muscles relax, the jaw drops. The miosis becomes extreme ("pin-point pupil"); the skin pale, with cold sweat, finally cyanotic; fall of temperature; respiration very slow, irregular, oftener Cheyne-Stokes; pulse slow, feeble and often irregular. Convulsions are rare in adults, more common in infants; they are sometimes violent, but rarely if ever tetanic.

The respiration stops before the heart. The pupils almost always dilate as the terminal asphyxia sets in. (With heroin, death is due to the convulsions; Langer, 1912.)
The time of death is usually seven to twelve hours; but sometimes two hours or even less. Survival over twelve hours indicates a good prognosis.

Aetiology findings are not characteristic. There are only the common asphyxial lesions: Cerebral and meningeal congestion, sometimes with serum effusion; lungs hyperemic and sometimes edematous; general venous congestion; rarely intestinal or cerebral ecchymoses.

Ordinary Fatal Dose.—With morphin, this is 0.2 to 0.4 Gm. (3 to 6 gr.); with opium, 3 Gm. (45 gr.). There is, however, considerable idiosyncrasy, and 60 mg. (1 gr.) of morphin must be regarded as dangerous. With 150 mg. (4 gr.) the prognosis is unfavorable, even under treatment, although patients have been saved after 4 Gm. (60 gr.) of morphin.

Recovery.—This may occur even after asphyxial convulsions. The respiration and pulse improve, the coma becomes lighter, and passes into a very prolonged sleep, often lasting for one or two days. On awakening, the patient is troubled with headache, constipation and digestive disturbances, often vomiting, itching, impotence of the bladder; exceptionally excessive depression. Sometimes the recovery is interrupted by a serious relapse, perhaps through the reabsorption of morphin from the intestine.

Idiosyncrasies.—Infants are highly susceptible to morphin; as to older children, there is difference of opinion. The female sex, and patients weakened by disease, succumb relatively easily. On the other hand, large doses are well tolerated in diabetes, in delirium tremens and in tetanus. In fever, morphin is sometimes exciting; in neurotic patients it may cause insomnia and delirium, instead of sleep. Nausea and vomiting are very pronounced in some individuals. Urticaria has been observed. Itching of the skin, especially of the nose, is a rather common symptom in poisoning. These idiosyncrasies should be remembered in the therapeutic use of the drug.

Death has been reported from almost incredibly small doses. Lewin cites two fatalities in children from 0.3 mg. (5100 gr.) of opium. In adults, 0.2 Gm. (3 gr.) of opium (1/2 gr. of morphin), is credited with a death. The great variation in the susceptibility of different animals has been described, man being by far the most susceptible.

Hypersusceptibility of Infants.—Young animals are said to be more susceptible than adults, with the exception of cats. Dobell, 1911, from a clinical and experimental investigation, concludes that the hypersensitivity, both in the human and in animals, applies only to the age before weaning, older children following the ordinary rule. This, he finds, is also the opinion of most pediatrics. The special susceptibility of sucklings is perhaps explained by the observation of Hunt, 1910, that a milk diet greatly increases the toxicity of morphin (for mice). The hypersusceptibility exists only for the narcotic action, and is, therefore, insignificant for codein.

Influence of Thyroid and Iodides.—Hunt, 1905 and 1907, found that feeding with thyroid or iodides increases the susceptibility of mice, rats and guinea pigs to morphin. Gehring and Meltzer, 1913, find in rabbits that iodid increases the morphin depression but lessens the tetanic effect, and therefore the fatality.

Diagnosis of Morphin or Opium Poisoning.—A prompt diagnosis is very important for proper treatment. The coma is the most conspicuous symptom, and its gradual development is characteristic. In advanced poisoning, it may be difficult to distinguish the morphin coma from other forms. The symmetrical pin-point pupils are important, but it must be
remembered that these dilate as death approaches (asphyxia). The odor is characteristic of opium poisoning.

**Treatment of Acute Morphin and Opium Poisoning.**—The first indication is to *empty the stomach*, and this no matter whether the drug has been taken by the mouth or hypodermically. If narcosis has already set in, emetics may act too slowly, and it may be necessary to employ a stomach-tube. The best *chemic antidote* is potassium permanganate, about 0.5 Gm. per liter (5 gr. per quart) by lavage; or orally, 0.1 Gm. (1/2 gr.) in a tumbler of water. Tannin is not very effective. The patient should be kept awake as far as possible and in constant movement, since this contributes to the better tone of the medullary center. *Reflex stimulants* may be employed, such as cold ablutions; the inhalation of ammonia in the form of smelling salts, hypodermic injections of ether, etc. Caffeine, especially in the form of strong, black, hot coffee, is the best physiologic antidote. *Atropin* may be valuable if the dose of 1.5 mg. (1/40 gr.) is not exceeded. The patient should be kept warm. If the breathing shows signs of failing, artificial respiration should be supplied.

When the danger is over, the *constitution* which usually follows should be relieved by cathartics and enemata.

**Permanganate.**—De Busscher (1904, 1905) found this effective in rabbits, even when it was administered three hours after the morphin; it was much less successful with dogs. It was quite ineffective if the morphin was given subcutaneously. Nothing could be expected from the hypodermic injection of permanganate, since this would be destroyed before entering the circulation.

**Atropin.**—This has been used extensively and somewhat indiscriminately in the treatment of morphin poisoning. It may be a dangerous remedy. The most conspicuous antagonistic actions of these two poisons are on the pupil, heart-rate, psychic processes, secretions, etc.—i.e., upon functions which are of subordinate importance in dangerous cases of poisoning. Any useful antagonism must be sought in their actions on the circulation, respiration, and metabolism. The effects of morphin and atropin on these functions are antagonistic only with certain stages; whilst more severe grades are actually synergistic. The later paralytic effects of atropin coincide with those of morphin; whilst in the last stages of morphin poisoning the centers are too greatly depressed to respond to the slow and weak stimulation of atropin. The usefulness of this antidote exists therefore only if moderate doses of atropin are given in moderate morphin poisoning (or vice versa). This conclusion is supported by several series of experiments on animals. As a practical deduction, the atropin should be given hypodermically in the dose of 1.5 mg. (1/40 gr.) and this should not be repeated. It is fair to state, however, that this is not the universal opinion. For instance, Roch, 1907, advises 2 mg., frequently repeated, until the pupils begin to dilate.

**Cocain.**—A general antagonism exists also between morphin and small doses of cocain—especially as regards the effects on temperature and metabolism. Larger doses are synergistic, and as the susceptibility to cocain is variable, the hypodermic dose of 0.01 Gm. (1/100 gr.) should not be exceeded.

**Acute Heroin Poisoning.**—Animals are killed by the convulsions; if these are prevented by etherization, almost double the fatal dose may be survived (Lauger, 1912).

The literature of fatal heroin poisoning is reviewed by McNally, 1917.

**Chronic Opiumism.**—Etiology. Opium, morphin, and heroin addictions are unfortunately very prevalent and together with the cocain habit (and to a much less extent of “hashish”) they constitute one of the terrible scourges of modern times. All these drugs produce at first a feeling of well-being, relief and contentment, of stimulation and freedom of imagination, and of ease and facilitation of mental effort. These agreeable effects vary in degree in different individuals, and therefore will do not fall their victims with equal readiness; women and neurotic and dissipated individuals are especially in danger, if they become acquainted with the effects of these drugs.
The majority of the heroin and cocaine addicts begin the use through curiosity or dissipation (Drysdale, 1915; McIver and Price, 1916; Hubbard, 1920); but "patent medicines" (cough, consumption, diarrhea, and cancer "cures," etc.) are responsible for many cases. Over a fourth of the manufacturers of proprietary remedies report that they use habit-forming drugs in their nostrums (A.M.A. Report, 1920, J.A.M.A., vol. 74, page 1324).

Physicians must also be on their guard in prescribing these drugs, even in acute conditions. McIver and Price found that most cases of morphinism arise from the medicinal use.

The continued use of opiates will lead to the habit, or disease, in practically every one, and is therefore excusable only in exceptional conditions, such as hopeless, painful diseases (cancer, etc.). The very susceptible acquire the addiction in 10 days of continuous use; and there is little chance of escape if the drugs are used daily for 3 or 5 weeks (Hubbard, 1920).

Historical.—While the therapeutic use of opium dates back of Hippocrates, its habitual use seems to be of more recent origin. The first authentic records fall in the beginning of the sixteenth century. It would seem that its use is much older in India than in Turkey, and that the Mohammedans learned it through the conquest of the former country. Their acquaintance with cannabis indica is of much earlier date. The existence of the opium habit was at first confined to the Orient; its introduction into Europe and America is of modern date—it began in the United States about 1800.

Prevalence of Opium and Cocain Addiction.—It is impossible to secure reliable statistics; but some idea may be gained from the fact that of about 600,000 pounds of opium, 60% equivalent in morphin, and of coca leaves corresponding to perhaps 500,000 ounces of cocaine, which are imported annually into the United States, at least nine-tenths are used by habitues. The per capita consumption of opiates is 12 times as great as in France (the next highest country); and 72 times as great as in Austria. The drug addicts in the United States have been variously estimated between 200,000 and 400,000 (A.M.A. Report). The alarming increase of the habit may be judged by this, that while the population in the past fifty years has increased 135 per cent., the importation of opium has increased 350 per cent. (H. Wright, 1910); and in addition, the cocaine and heroin habits took their rise only within this period.

Opium Habit in Children.—This is unfortunately not at all rare. It is usually started by the indiscriminate employment of paregoric and other soothing syrups. They present the typical symptoms. Withdrawal of the medicine is followed by restlessness, wakefulness, and every indication of suffering and distress. The treatment would be mainly hygienic.

Forms of Opium Habit.—The drugs are introduced by all possible channels: by the mouth, hypodermically, by smoking, by suppositories; and heroin, like cocaine, by snuffing. The effects are similar in all cases.

Smoking.—This is mainly practiced in the Orient; but the International Opium Commission estimates that there are in the United States probably over 100,000 opium smokers outside of the Chinese.

Smoking opium (chandoo) is prepared by the Chinese, by a complicated process of heating and repeated extraction and evaporation. Its morphin content is about the same as that of ordinary opium. It has been claimed that the opium smoke does not contain morphin (e.g., Moisan, 1892; Hartwick and Simons, 1905); but Pott, 1913, has proved that morphin is indeed the active constituent. It has been said that Orientals are less injured by opium; but this is mainly because, in snuffing, smaller quantities are consumed, with longer intermissions. The hypodermic method is now becoming the new popular, and with it, the Chinese present the same phenomena as Europeans (A. S. Rochester, 1909). The Chinese government has been making serious and successful efforts to suppress the opium evil.

Heroin Habit.—This has become very common, especially in the form of "snuffing" (J. Phillips, 1912; bibliography; Farr, 1915). In fact, the
majority of drug addicts are said to prefer heroin as being most convenient and least liable to detection (Bloodorn, 1919). Heroin exhibits all the phenomena of the morphin habit, and its cure presents similar difficulties and dangers (Manguat and Blondel, 1903; Sollier, 1905; Faumontley, 1907; Duhem, 1907; McIver and Price, 1916). Fatalities from overdosage are also more common. The quantities consumed daily average 0.6 Gm. (McIver and Price), and may reach 1 Gm. (Wholey, 1912) or even 2.8 Gm. (Comar and Buval, 1904), so that considerable tolerance is acquired. Snuffing causes rhinitis.

**Codein Habit.**—Codein is not nearly so apt to induce a habit, although this has been reported (Pelz, 1905; Petteys). Little is known about habit from the other morphin derivatives.

**Drug-reaction of Fish.**—Goldfish (not minnows), when placed in a “graduated tank,” rapidly develop preference for water containing alcohol, cocaine, morphin and certain other substances (Shefford, 1918). However, this is probably a sensory skin phenomenon, and is not analogous to the psychic craving of human drug habits.

**Effects of Opiate Addiction.**—The immediate effects of morphin are essentially the same as in unhabituated individuals; but the response varies quantitatively, and somewhat qualitatively, because of acquired tolerance, and of the imminence of “abstinence-symptoms.” These differ materially as regards the occasional opiate debauchee, and the steady addict.

**Intermittent and Continuous Addicts.**—The occasional user, for instance the opium-smoker, usually pushes the dosage to the toxic point, and thus obtains the dreams and the deep sleep. The steady consumer does not carry the dosage to that stage; partly because he has acquired tolerance; partly because of the side-effects; and partly because it would be impossible for him to work while under the toxic influence. Most patients whose addiction started with the therapeutic use of opiates have never experienced the seductive toxic effects, but only the analgesia and euphoria; their first recognition of the addiction dates often from the withdrawal symptoms.

**Euphoria.**—Confirmed addicts generally use opiates rather as stimulants, or as the only apparent means of escape from the intense discomfort, nervousness, depression, and violent craving that follow the withholding of the accustomed dosage. These are quite analogous to intense hunger or thirst, and increase in intensity for several days, to a degree that is beyond the unassisted strength of most patients; especially when they dispose over the means of relief, i.e., further dosage of the opiates (E. L. Bishop, 1913, 1920).

**Acquired Tolerance.**—The continued use of morphin or heroin leads to the gradual development of very considerable tolerance to the narcotic and toxic effects. This starts before addiction becomes confirmed. Addicts who aim to produce narcotic dreams are therefore driven to the use of ever-increasing doses, sometimes 10 or 20 times as much as would be fatal to an uncustomed individual. The tolerance, however, is never absolute, and death by accidental or intentional overdosage is the most frequent “exclusus letalis” of morphinists.

On the other hand, patients who take their morphin only as stimulant are not so likely to increase their dosage beyond a definite, more moderate amount, soon ascertained by experience; and find it possible to resist or discontinue temporary increases beyond this point (Bishop); precisely
as some smokers keep themselves on a fairly definite allowance whereas others are constantly increasing theirs.

The high tolerance diminishes if the drug is discontinued, but is readily re-acquired; and some degree of toleration persists long after the discontinuance.

The tolerance is explained partly by a very considerable increase in the power of the organism to destroy morphin; but since the destruction proceeds more slowly than the absorption, there must also be an acquired tolerance to the action of morphin. No "antitoxin" is formed.

The daily consumption of morphin: This is generally about 1 Gm. (McVey and Prior, 1916); but as much as 6 Gm. (85 gr., or one and two-thirds of the ordinary bottle) has been reported. Even larger doses are claimed by patients; but their statements are often unreliable, since they are made in the hope that the drug will be withdrawn more gradually.

Bishop, 1913, states that the tolerance persists unimpaired after seven months of abstinence. In animals, at least, it disappears in a few days.

Tolerance in animals:—This can be induced in dogs (Faust), rabbits, goats, rats, and pigeons (Cloetta, 1903). Frogs seem to become more susceptible.

The Explanation of Acquired Tolerance to Morphin.—This has been the subject of many investigations and theories. Marmé, 1883, aimed to show that morphin is transformed in the body into oxydymorphin, to which he attributed actions precisely the reverse of morphin. It would thus explain both the tolerance, and the abstinence symptoms. This theory has only historical interest, since Donath, 1886, and Marquis, 1890, have shown that oxydymorphin is not formed; and, moreover, the properties of this substance do not agree with the assumption of Marmé.

Another theory which may be dismissed is the formation of an antitoxin. Hirsch- neff, 1907, claimed that the serum of habituated animals is protective; but his experiments are discredited by the negative results of Morgenroth, 1903, of Cloetta, 1903, and of Pelinni and Greenfield, 1902.

The increased destruction of morphin (Faust) and of heroin (Langer) in habituated animals must be a factor in the protection, but can not explain it completely. The experiments of Cloetta and of Ruebsamen, 1908, indicate that this destruction is a relatively slow process, so that the tissues must in the meantime be exposed to a large amount of morphin.

van Egmond, 1911, found that habituation to the toxic effect does not diminish the susceptibility to the central vagus stimulation. In dogs, the respiratory center becomes habituated to 1/500 times the initial minimum effective dose; the pupil (dilator) reaction also becomes habituated. The order in which centers become irresponsive in morphin habituation are: pupil; emesis; defecation; narcosis; respiratory center. The gastric sphincters habituate slowly and imperfectly; the vagus center not at all. These differences in centers show that habituation is not a matter of destruction. Rabbits do not become habituated to morphin (as judged by narcosis and respiratory center (Van Egmond, 1911).

Langer, 1912, also states that the acquired tolerance of dogs to the narcotic action of heroin does not extend to its convulsive effects. This persistence of some of the effects proves that the disappearance of others can not be due to destruction of the amin.

Greenfield, 1915, found no difference in the lipid content of the brains of normal and habituated animals.

Creased Tolerance.—Dogs habituated to morphin also show marked tolerance toward heroin and codein, as regards the respiratory effects; slight as to equilibrium; none as to heat or peristalsis. They have not acquired tolerance toward cannabis or chloral (R. B. Myers, 1915).

Rutherford, 1916, confirms the absence of tolerance to scopolin and cocaine and claims that there is none even against heroin.

On the other hand, Blair, 1919, believes that heroin addicts readily acquire tolerance to scopolin; and that it apparently acts somewhat as a substitute.

Mental Phenomena.—The life of the addict is dominated by the abstinence symptoms that start when the effect of the dosage begins to wear off; by the consequent need of obtaining the drug at any cost; and often by the fear of detection. If the supply is regular, the addicts may appear,
quite normal; so much so that the addiction may be kept secret for many years, and the addict may occupy responsible positions. Close observation, however, would generally reveal signs of the addiction; especially variability of moods, depressed or stimulated, according to the interval since the last dose.

Opiate debauches doubtless accentuates the weaknesses of moral character from which they originate. They tend to make their victims slothful, apathetic and unreliable; though they do not lead to the more active crimes, as cocaine may; except in so far as crime may be necessary for obtaining the drug.

The addicts of inherently good character, and who take the drug solely to ward off the intolerable depression, are not so seriously affected. They may appear and seem to lead a normal life, save for overindulgence, and the agony of drug-deprivation drives them to deception and more serious crimes when their supply is threatened; but outside of this, their character and mental faculties are said to remain practically normal. A large part of the traditional depravity of the addicts exists in the minds of the public, rather than in life. This pariah-like attitude makes it more difficult for the addicts to lead a normal life, and thus tends to drive them into the very vices of which they are accused (Bishop).

Physicians should look upon drug addicts as patients with a nervous disease. Like other nervous patients, they must be treated with firmness, but also with sympathy and kindness.

*Physical Phenomena of Opiate Addiction.*—These relate at first to the digestive tract: obstinate constipation, alternating later with equally obstinate diarrhea; loss of appetite alternating with voracious hunger and thirst, and polyuria. The patient loses weight rapidly and suffers from marasmus and cachexia. The skin becomes hard, pale, dry and rough; sometimes of a peculiar waxy appearance. The nails, teeth and hair are also diseased. The condition of the integument is rendered worse by the local effects of the injections when the drug is used hypodermically. The whole skin may be mottled with scars and marks of recent or older injections, and abscesses are often produced through want of cleanliness.

The pupils are usually contracted. The pupillary and accommodation movements are affected. The heart may become irregular. *Albuminuria*, *glycosuria* and *amaurosis* are frequent. The sexual functions are lessened (functional impotence, sterility), but usually return on withdrawal (Whooley, 1912). *Pneumonia* resembling simplex, intermittent, and typhoid are seen. The motor-nervous system shows considerable change: nervous tremors, increased reflex irritability, etc. These conditions sooner or later weaken the resisting powers of the patient, so that he falls an easy prey to some other ailment, and thus rarely reaches old age. However, the habit may persist for over thirty years (Mclver and Price).

**Withdrawal Symptoms.**—The withdrawal of morphin from those accustomed to its use leads to a train of very severe effects, the severity being proportional to the duration of the addiction, the dosage that has been used, the rapidity with which the drug is withdrawn, and the general resistance, vigor and will-power of the patient.\(^1\)

1 These are ill-defined terms. The former, marasmus, signifying a continued low condition of the nutrition and a wasting of the flesh without apparent organic cause. *Cachexia* also indicates a wasting of the body, with some striking change in the features, which are usually pinched and yellow.
In the early stages of addiction, withdrawal results in more or less restlessness, weakness and depression. These are endurable, and disappear in a few days, if the drug is withheld.

Uneasiness, restlessness, depression and weakness are also the earliest withdrawal symptoms in confirmed addicts. They become more and more intense, leading to almost uncontrollable craving for the drug, which may pass into real mania.

Other early symptoms are spasmodic yawning and sneezing; coryza and lachrymation; and hoarseness. The pupils dilate again. Most conspicuous are muscular twitchings and violent pains or "cramps," sometimes in the abdomen, more commonly in the legs; also headache and other neuralgias. The extremities are cold, the head congested. Insomnia is a very constant symptom; the patients are very irritable and excitable. This condition may culminate in delirium or acute mania, of tenuical nature. Women often have hysterical attacks. The digestion is profoundly disturbed, presenting the symptoms of a violent functional gastroenteritis. The most dangerous phenomenon is sudden collapse, ushered in by irregular and weak pulse, alternating between extremes of rapidity and slowness, cold sweat, and general prostration; and sometimes ending fatally by heart-failure. This collapse, if severe, demands the prompt injection of a moderate dose of morphin, which generally causes the symptoms to disappear.

The withdrawal symptoms are practically absent if the patient is rendered delirious by scopolamin (Wagner and Riewel, 1905). This suggests that they are mainly of psychic origin.

Talley, 1917, attributes the abstinence symptoms largely to acidosis. Further resistance would be needed.

Abstinence Symptoms in Animals.—According to Valento, 1914, these show circulatory disturbances, arrhythmia, tachycardia, low blood pressure, etc.; and he states that these effects are produced acutely when abstinence blood is injected into normal animals. He finds, further, that the blood retains this property long after the morphin has been stopped, which speaks rather against an analogy with the human abstinence symptoms.

Rats that have been habituated to large doses of morphin and its esters do not show conspicuous withdrawal symptoms (Soilman, 1914).

Treatment of Opium and Other Drug Habits.—The prime indication, as in all diseases, is the removal of the cause, the withdrawal of the drug. This must be done under medical supervision, best in special institutions, for the patients have neither the will power, nor the physical resistance to carry it through unaided; attempts at self-treatment are generally unsuccessful, and always dangerous. In fact, the closest surveillance of the patient is indispensable, both to prevent clandestine continuance of the drug, and to control the withdrawal symptoms. The main object, therefore, is to withdraw the drug without danger or too great agony to the patient. When the drug has been completely stopped, even for a few days, the intense craving for it disappears, and the patient may be considered cured, although still in need of tonic treatment.

Unfortunately, the cure is often not permanent. The experience of the morphin euphoria remains, and the patients are likely to succumb again, sooner or later; to resort to it for the relief of any stress or ailment; and the addiction develops very rapidly if the drug is resumed. It is therefore also necessary to be especially cautious in the therapeutic use of opiates on ex-addicts. Those who were treated against their full consent
naturally relapse on the first favorable occasion. These remarks apply equally to cocain and other serious drug habits; and the treatment of these is identical.

Methods of Withdrawal.—Attempts at "insensible withdrawal," by very gradual diminution of the dose, amounts to useless and protracted agony; the sensations of the patient gauge the dose with surprising accuracy, and their patience reaches its end long before the drug.

Ambulatory treatment is also so often inefficient, and is so liable to fraud, that it is rarely justifiable (S. D. Hubbard, 1920). Advertised Morphin-cures are generally thinly disguised solutions of morphin, and are used by addicts as a convenient source of supply of the drug.

Rapid and abrupt withdrawal, preferably under hospitalization, are by far the most effective methods. Either is successful under proper conditions. The preference depends mainly on the special experience of the physician. The abrupt method is simpler, but is likely to place a greater tax on the patient.

Preparation of Patient.—E. S. Bishop, 1920, points out that the suffering of the patient is much smaller, and the chances of permanent success are much greater, if the withdrawal is attempted only when the patient is in the best physical and mental condition, because his need for the drug is then less imperative, and because he can withstand the discomfort more bravely. This may require a preliminary period of training, to obtain the best possible health, and to establish the patient's confidence. Unless this is done, suffering and incompetence may, in advanced cases, persist for weeks and months.

Rapid withdrawal is generally preferable if the patient can be supervised. With this method, the drug is reduced as rapidly as can be borne by the patient without producing very violent reaction.

It is better to begin by reducing the number, rather than the size of the doses (Bishop). The withdrawal may be completed within ten to fourteen days. Very hot baths relieve the restlessness and insomnia; salicylates, or probably mecoinchophen, the "pains" (McIver and Price, 1916). The bowels should be kept loose. The treatment is effective and not excessively difficult (Drysdale, 1912).

Internal and Dosage.—E. S. Bishop, 1920, states that there is an almost mathematical relation between the size of the dose and the interval before craving sets in; that is, if the dosage is doubled, the number of administrations may be halved.

Abrupt Withdrawal.—Unless the patient is perfectly prepared, this entails severe suffering, and some danger. However, when skillfully managed, good results may be obtained in nearly all cases, without other medication than catharsis (S. D. Hubbard, 1920). The patient must be closely watched. If withdrawal symptoms become dangerous, they may be controlled by 0.015 to 0.03 Gm. of morphin.

Drug-adjuncts to Morphin Withdrawal.—The withdrawal symptoms of all drug addictions can be greatly diminished by diverting the attention, by cathartics or nauseants; or more effectively, by inducing a mild delirium and amnesia ("twilight sleep") by scopolamin or atropin, for 1 or 3 days (Wagner and Riewel, 1905).

Details.—The treatment consists in absolute withdrawal of the drug, and in administering hypodermically a mixture of scopolamin hydrobromid, 0.3 mg. (0.04 gr); atropin sulphate, 0.1 mg. (0.0004 gr.); and water 1.5 c.c. (25 minims). The first dose, 1 Fuller descriptions of the standard methods are found in the J.A.M.A., 94: 1022, 1915.
MORPHIN GROUP

which is usually without results, is repeated in one-half to two hours, and again in one
and one-half hours, and then every one-half to two hours, until the full scopo-lamin effect
is indicated by dry throat, flushed face, dilated pupils, restlessness, and mild dilatation.
The patient is maintained continuously in this state for three or four days, by repeating
the injection every two to six hours, reducing the individual dose to half, if possible.
Constant, careful and skilled watching of the patient is indispensable. If the pulse
(which remains ordinarily of normal character, with a rate of 60 to 70) should fall below
50 or rise above 110, the treatment is intermitted, and a very little morphin given.
The second day usually produces some abstinence symptoms (violent attacks of
sneezing and some gastro-intestinal phenomena), but these are rarely of sufficient
severity to require special attention.
The patient can be about the room throughout the treatment, and receives "leve
luncheon" consisting of coffee and bread, usually mild and buoy, the patient being mainly engaged in
picking imaginary insects, etc.
At the end of the third day the injections are stopped, to see whether craving for
the drug will return. Should this occur, the treatment is continued for another day.
This is rarely required.
The Lambert-Towns Method, described by A. Lambert, 1909 and 1913, involves the
use of principles, since it uses essentially hyoscymus and belladonna, together with
severe catharsis. (Details in J. A. M. A., 1915, v. 66, p. 503; v. 66, p. 1933.) Collapse
sometimes occurs (Wholey, 1915). Bishop considers the active catharsis as detrimental
to the patient.
Phosphorin has also been employed.
Sodeth, 1917, advises a method including scopoamin, pilocarpin and ethylmorphin.
Substitution of Other Habit-drugs.—Withdrawal of opiates may be made less dis-
tressing by substituting other habit-drugs; but this is rarely justifiable since the
end-result is usually merely to condemn the patient to an additional drug habit.
The After-treatment.—This is important with all methods. The patient should receive tonics, nutritious food, and rest for several weeks. Insom-
nia is rather troublesome at first, and should be relieved by giving chloral or aconite for two or three nights. The bowels should be kept clear, both
before and after the treatment.
The "recovered" patient must be protected as much as possible against
pain and other circumstances which would tempt him to the resumption of
the drug. Psychotherapy may be useful to prevent recurrence.
Legislation Against Drug Habit.—The real cure of drug habits lies in the enforce-
ment of appropriate legislation. The Harrison Law reduced the sale of opiates and
coke to half (Willibert, 1916); but there is a great deal of smuggling that is difficult to
suppress. This is partly caused by the inadequate provision for the proper treat-
ment of addicts.
Heroin is so particularly liable to abuse, and the medical need for it is so super-
fluous, that its manufacture and sale should be completely prohibited.
Therapeutic Uses.—Morphin and Opium are used mainly to lessen
pain, to procure sleep, to check peristalsis, to stop cough, to cause drowsiness,
to facilitate anesthesia, and to secure muscular quiet. These indications
are in a great variety of diseases; and since the action of the opiates is
certain and highly effective, their field of usefulness is extensive and
important. However, they must be used with discretion. It should be
remembered that the relief is generally only symptomatic and may some-
times interfere with the natural processes of repair, or obscure the observa-
tions of the progress of the disease. The danger of habit formation restricts their employment in neurotic individuals and in chronic diseases
(except when these are hopeless). The habit danger can be somewhat
avoided if the morphin is administered only by the physician, with some-
what impressive formalities of asepsis, and not intrusted to the patient

1 Cashon, 1914, rightly points out that the avoidance of opiates for fear of obscuring the diagnosis is a confession of deficient diagnostic technic; it should not be necessary to make the diagnosis at the expense of exhausting pain.
himself. The side actions (constipation, nausea, gastric disturbance, and occasional excitement) may also interfere with the usefulness. Even with these restrictions, however, the range of usefulness of the opiates is still very wide.

Pain.—Morphin surpasses in efficiency all other analgesics, particularly for persistent pain. Its use is generally aimed to dull, rather than to abolish the sensibility; and for this purpose relatively small doses suffice. Morphin by hypodermic injection is to be preferred, 5 to 15 mg. (1/12 to 1/4 gr.) according to severity, and repeated as necessary. Local application is irrational, although it is still somewhat used (H. C. Wood, Jr., 1910).

Insomnia.—Morphin should be avoided, if possible, especially in nervous insomnia and in psychic excitement. It may be needed if the insomnia is caused by pain, cough, or dyspnea; and small doses (5 mg. or 1/12 gr.) may be employed to reduce the dosage, and thus the side actions, of other hypnotics (i.e., the circulatory depression of chloral).

Diarrhea.—Opiates are very effective in arresting the excessive peristalsis in acute intestinal catarrh. If the intestines are first cleared of toxic and irritating material by a cathartic, the rest afforded by opiates favors the subsidence of the inflammation. Tincture of Opium by mouth (0.5 c.c. or 10 drops) deserves the preference. If the opiates are given while the materia morbi are still in the intestine, they may do harm, even when they give symptomatic relief.

Opium is also useful in the constipation and colic of lead poisoning, by relaxing the intestinal spasm. In peritonitis it relieves the pain, both directly and by lessening peristalsis; but the disguise of the symptoms may be surgically objectionable. In biliary and renal colic, Morphin (15 mg. or 1/4 gr.) is given hypodermically, to lessen the suffering (usually with 1 mg. atropin, which relaxes the ducts).

Cough.—The opiates check cough by lowering the reflex irritability of the respiratory center. Small doses suffice for this purpose—by mouth, Morphin 5 mg. or 1/12 gr.; Tr. Opit 1/5 c.c. or 10 drops; Codein 30 mg. or 1/4 gr.; Heroin 5 mg. or 1/12 gr. (children above one year, 1/4 mg. or 1/30 gr.; below one year, 1/16 mg. or 1/240 gr.); Dionin 15 mg. or 1/4 gr. Codein deserves preference, since it produces the desired effect with less side actions, and without habit formation.

The use of opiates as “sedative expectorants” in bronchitis and phthisis requires judgment. They are indicated when the cough is mainly irritative; and contraindicated when it is required for the expulsion of excessive mucus. Even then, however, they may be needed to produce sleep.

Asthma and Dyspnea.—Morphin (15 mg. or 1/4 gr., hypodermically, often relieves this condition, by quieting the patient, allaying the “air hunger” and perhaps by lessening reflex irritability. It should be avoided if possible. In nervous asthma, it tends to form a habit. In respiratory dyspnea, the reduction of respiration may be dangerous. In cardiac asthma, the increase of carbon dioxide in the blood may injure the cardiac function and establish a vicious circle. The use of caffeine or atropin would be preferable; but it may be justifiable to resort to morphin especially for relieving the anxiety.

Morphin in “Gassing” by Chlorin and Other Volatile Irritants.—Morphin not only dulls the agonizing “air-hunger,” but tends to save life by quieting the patient and thus diminishing the use of oxygen and the production of carbon dioxide. Hjort and Taylor, 1919, claim that it also prolongs the maintenance of alkali reserve.
MORPHIN GROUP

Cold.—The diaphoretic action is utilized for aborting colds; generally as Pulv. Ipecac et Opii, 0.5 Gm. or 7/4 gr.

Anesthesia.—Morphin in safe doses does not induce complete insensibility, but it is an efficient synergistic to other anaesthetics (10 mg. or 1/6 gr., hypodermically; see under "Ether," also under "Scopolamin"). Morphin is similarly useful for distracting the patient's attention from operations under local anesthesia.

Hemorrhage.—Morphin favors the arrest of hemorrhage by quieting the patient, thus keeping the blood pressure low, and permitting the formation of the clot. It is especially valuable when the hemorrhage is in an inaccessible situation, i.e., the pulmonary hemorrhage of phthisis. The depressant effect on the respiration enjoins caution in the use of larger doses, especially in severe hemorrhage, cardiac disease, and other debilitating conditions.

Convulsions.—Since morphin increases reflex excitability, it can not compare with ether, chloral or chloroform for suppressing tetaun or other spinal convulsions; but its analgesic effect may justify its use as an adjuvant. The depressant action on the respiratory center must be borne in mind (Dreyfus, 1914).

Edema.—Large doses of morphin have been recommended (15 mg. hypodermically, every hour until the respiration drops to 8 or 10 per minute). This generally arrests the convulsions; and it is claimed that labor often proceeds spontaneously (McPherson, 1917).

Psychic and motor excitations, e.g., delirium tremens or atropin poisoning, are controlled only by very large doses, the danger of which offsets the problematic benefit.

Emetic.—Morphin is employed as an ant-emetic, but the doses which can be safely prescribed are often ineffective.

Diabetes.—Large doses of opium, morphin or codein appear to benefit some otherwise intractable cases; but the ultimate results are not brilliant. The effects are probably indirect, by slowing the absorption of sugar from the alimentary tract.

Experimental Glycosuria.—The opium alkaloids have no effect on the hyperglycemia resulting from the conversion of hepatic glycogen (epinephrin or piqure); but they have an inhibitory action on alimentary hyperglycemia (Klierker, 1914). This indicates that the action is on the alimentary canal, presumably by the gastric delay slowing the digestion and absorption of the carbohydrates, and thus preventing the sudden flooding of the organism with sugar (Macleod, 1914). Morphin delays the disappearance of injected dextrose from the circulation of dogs, although it facilitates its excretion by the urine (Kleiner and Melzer, 1916). It must therefore hinder the passage of sugar from the blood into the tissues.

Clinical Evidence.—Good clinical observers claim that the thirst, polyuria, glycosuria, and itching of the skin are all markedly diminished. Part of this action must be attributed to the analgesic effect, while the influence on the glycosuria is probably due to its action on digestion, and is produced in the same way as by limitation of the diet by ammensnts. On the whole, opiothrophic diabetics die earlier than others. Codein has been used instead, but without any marked advantages.

Dosage of Opiates for Children.—This is best adjusted to the weight: with children above ten months, the weight (in pounds) is divided by 150; below ten months, by 300. The adult dose is multiplied by the fractions thus obtained (Doebeli, 1912).

Recapitulation of the Chief Differences of the Morphin Derivatives.

The actions of all morphin derivatives are quantitatively identical, so long as they involve only changes in the outlying side-chains (R. Stockman, 1891). Even the quantitative differences are not of very great practical importance.
Morphin produces the strongest narcotic, analgesic, hypnotic and intestinal effects, and the weakest stimulation. It causes the greatest derangement of digestion; and, with heroin, is most apt to induce addiction.

Codein (Methyl-morphin) is less narcotic, less constipating, and less apt to induce a habit or tolerance. It has some advantage in the treatment of cough. Bastedo uses 15 to 30 mg., but Fraenkel, 1899, claims that at least 40 to 60 mg. are required to affect cough. This dosage is somewhat quieting, but not narcotic, and scarcely analgesic. Larger dosage produces restlessness instead of quieting. The susceptibility is the same for all ages (Doebeli, 1911).

It increases the spinal reflexes more than morphin (v. Schroeder, 1884). Frankfurter and Hirschfeld, 1910, claim a greater dilatation of the cerebral vessels (without rise of blood pressure).

Dionin (Ethyl Morphin) seems to stand intermediate between morphin and codein, in all respects. Merin advises it in cough. Lindemann, 1912, uses it in colds, 0.05 Gm. before retiring. It sometimes causes itching of the skin (Seifert, Nebenwirk., 1915, p. 61). It has a special action on the conjunctiva (edema).

Heroin (Diacetylmorphin) approaches still more to morphin, of which it shares all the disadvantages, and over which it has no serious advantage. Bastedo finds it inferior to codein (Side actions, Seifert, Nebenwirk., 1915, p. 69).

Severe poisoning has been reported from 2 to 8 mg. (1/2 to 1/4 gr.). The government services are contemplating its abandonment; and prohibition of its manufacture is being agitated.

Thobain (dimethylmorphin) is so markedly convulsant that it may be placed in the strychnia group (Ch. Bernard; Stockman and Dott).

Structure of Opium Alkaloids.—These belong to two groups, those containing a phenanthren nucleus (morphin and its esters); and those derived from isoquinolin (papaverin, narcotin, narcein). The difference in the nuclei is shown in the diagram.

Structure of Morphin and Its Derivatives.—Morphin is a complex derivative of phenanthren. It contains two OH groups (one phenolic, the other alcoholic) in which substitutions can be made, either by alkyl or acid radicals.

The more important alkyl esters are the monomethyl (Codein), dimethyl (Thebain) and ethyl (Dionin). Heroin is the di-acetyl derivative.

The nature of the radicals—whether acid or alcoholic, aromatic or aliphatic—is not of great importance. Replacement of a single H (codein, dionin) diminishes the narcotic actions and increases the respiratory and tetanic action, and the toxicity for ani-
When both OH groups are replaced by acids (heroin) the narcotic action is stronger than for codein; the tetanic action is weaker than with morphin.

The constitution of the morphin group of alkaloids is discussed by M. Freund, 1919.

**Comparative Activity of the Two Groups.**—The alkaloids of both groups are more or less narcotic and convulsant. The essential differences are in the peripheral actions on all kinds of smooth muscle: Their contractions and tonus are stimulated by the phenanthren group (morphin and its esters), and depressed by the isoquinolin group (papaverin, etc.). This applies to the intestines, bile ducts vas deferens, bronchioles and blood vessels. Macht, 1918, attributes the stimulation to the pyridin radical of the phenanthren group; the depression to the benzyl radical of the isoquinolin group.

**Convulsant-narcotic Series.**—In general, the narcotic actions on the brain, on the end-land, and the stimulant action on the cord and medulla on the other, are in inverse ratio; morphin being the most narcotic and least convulsant, and thebain the most convulsant and least narcotic; the other morphin esters and the isoquinolin alkaloids being intermediate. Claude Bernard arranged them in the order of: Morphin, codein, papaverin, laudanum, thebain. Buerger, 1914, places them as: Morphin, papaverin, codein, narcein, narcein, thebain.

**Morphine.**—This has no effect in the doses which would be administered in opium. Larger doses produce nausea, muscular fibrillation; medullary convulsions; death; curare action (Barrh, 1902).

**Papaverin.**—This is discussed in a separate section.

**Narcotine.**—The peripheral actions appear to be similar to papaverin, but weaker (Pal, 1914). Macht, 1915, found, contrary to Straub, that it is quite toxic to the heart, respiration and other functions.

**Papaveren.**—The peripheral actions resemble narcotin (Pal, 1914).

**Differences between Morphin and Opium; Opium Alkaloid Mixtures.** While the actions of opium are essentially those of its principal alkaloid, morphin, there are various differences, especially quantitative. These are due partly to the mechanical action of the gums and resins, which delay absorption, and thus increase the local and diminish the central actions. In the main, however, the differences are due to the presence of the minor alkaloids, which modify the effects of morphin; for similar differences exist in mixtures of the alkaloids, natural (Papavine) and artificial (Narcopin, Laudanosin).

The precise differences between the actions of morphin, opium and the mixed alkaloids are still under dispute. The statements of different (and sometimes of the same) observers are so contradictory that it is often impossible to judge them (Litterature, E. Buerger, 1914).

**Claimed Therapeutic Advantages.**—It is asserted that opium and the alkaloid mixtures, for a given degree of analgesic and cough-sedative action, cause less depression of respiration and less nausea; that their action, though slower, is more prolonged. It is also claimed that opium and papavine are more efficient in checking diarrhoea; while at the same time, it is stated that papavine is not as constipating for normal individuals.

Before considering these actions in detail, it is necessary to describe the nature of the commercial products which have been largely used in the investigations.

**Papavine** (Papavine Hydrochloricum), N.N.R.—This consists of the isolated alkaloids of opium in their natural proportions. It was introduced by Sahli. Discounting the early extravagant claims, it has the advantage that the absence of gums and resins ensures prompter absorption and makes it much more suitable for hypodermic injection. The pharmacological data on papavine are reviewed by Barth, 1912; Schwenetz, 1912; Watkin-Thomas, 1913. Severe poisoning from 9-10 Gm. is reported by Voigt, 1917. The side actions are quoted by Selkett, Nebenwirk., 1915, p. 81.
Artificial Mixtures.—Since it is unlikely that all the alkaloids are therapeutically useful, and that they occur naturally in the optimal proportions, there exists a field for artificial mixtures. Faust, 1912, introduced mixtures of the principal opium alkaloids under the name of "lakualoids." The proportions appear to be merely arbitrary. A more scientific attempt has been made by W. Straub in the introduction of Narcopon.

Narcopon.—W. Straub and Caesar, 1912, investigated the modifications produced by a variety of mixtures of opium alkaloids. They found narcoin the most important alkaloid in the combination; claiming that doses of narcotin, which were ineffective alone, modified the actions of morphin, so as to increase the toxicity and narcotic effect, and at the same time diminish the respiratory depression; that a mixture of equal parts of the two alkaloids was the optimal proportion and fully represented the advantages of opium; that the other alkaloids of opium had less effect and introduced complex modifications which render them undesirable. These claims have been both confirmed and contradicted, clinically and experimentally. Meissner, 1913 and 1914, failed to confirm the synergism in the most important effects, viz., the respiratory and psychic; Straub's reply, 1915, is not quite convincing. Under the circumstances, judgment must be suspended.

Potentiation of Toxic Action.—Sassekutz, 1913, found that the toxicity of mixtures of morphin and its esters corresponds to simple addition, but that mixtures of these with the isooquinolin alkaloids shows marked potentiation. This has been confirmed by W. Straub and Caesar, 1913, who claim that doses of narcotin, which are in themselves inactive, double the toxicity of morphin for mice. This synergism may be considered as established; but it has little bearing on the therapeutic use.

Analogic Action.—The statements are contradictory, as might be expected from the difficulty of making quantitative observations on a subjective condition. As yet, the claims of superior analogic or narcotic action are not fully established. The sedative action on cough comes under the same category.

Straub claims a marked increase of narcotic action by narcotin, in that the morphin excitement of cats is prevented. (This, however, is a very variable condition, which is greatly influenced by external conditions.) Macht, Herman and Levy, 1916, also claim a synergistic decreased sensitiveness to cutaneous pain in human subjects; and Macht and Issacs, 1917, find a greater delay in the reaction-time. On the other hand, it is very surprising that the clinical doses of morphin and pantothen are strictly equi-active, to their morphin content. Zeelen, 1910 and 1911, found only simple summation in the narcotic (and tetanizing) action of the various opium alkaloids. Meissner also failed to confirm this.

Respiratory Action.—Straub asserts that the respiratory center in rabbits (as judged by response to CO2 stimulation) is much less depressed by narcotin than by morphin. This is contradicted by Meissner. Straub's statements appear self-contradictory, since he also claims that the toxicity, which generally depends on respiratory depression, is increased. However, Macht, 1915, confirms that the minor opium alkaloids stimulate respiration, and thus antagonize somewhat the morphin depression.

Circulation.—The data are scanty. Macht, 1915, finds that morphin-narcoin mixtures dilate the coronary vessels much less than either alkaloid alone; add that Paniso- pon and Laudanon have practically no effect on the coronary circulation.

Gastric Disturbance.—It is quite generally asserted that the combinations are less liable to produce nausea and vomiting; but quantitative differences of this kind are difficult to judge, clinically. It is possible, though not proven, that there may be a slight difference, since morphin itself stimulates the vomiting center more than any other opium alkaloid.

Constituting Action.—This has been discussed under morphin.

Urter and Gall-bladder.—The depressant action of the isooquinolin alkaloids would make the combined alkaloids more effective than morphin, in ureteral and biliary colic (Macht, et al.).

The synergism of morphin with isocapalamin and with the anesthetic and hypnotic will be discussed in connection with those drugs.

PREPARATIONS—OPiUM

* Opium, U.S.P., B.P. (Meconium, Thebaicum).—The dried milky juice exuding from the incised unripe seed-capsules of the poppy, Papaver somniferum. Brown masses or powder, of peculiar odor and bitter taste. Contains a number of alkaloids, the most important being morphin (about 10 per cent.). Dose, 0.06 Gm., 4 to 5. B.P. (equivalent to 6 mg. or ½ g. morphin); 0.03 to 0.12 Gm., ½ to 2 gr., B.P. Maximum dose, 0.2 Gm., 3 gr.
Opium was mentioned by Theophrastus, third century B.C. An interesting account of its history is given by Macti, 1913. The history of the opium preparations is also interesting (Wilbert, 1916). Laudanum is said to have been originated by Paracelsus (1493-1541), but as a solid aqueous extract; parapirc by La Mett of Leyden, early in the eighteenth century. Sydenham's laudanum (Vinum Opii) is derived from a formula of Sydenham (1624-1680). Tr. Opii Deodorati was originated by Robiquet (1750-1808), and Rob. Hater, 1827; Mist. Glycyrrh. Co. by Dr. B. J. Barton of Philadelphia, about 1812.

The opium poppy is cultivated in Asia and Egypt; it can be raised in the United States, but the cost of labor renders the production of opium unprofitable. The capsules (especially before ripening, Caesar and Loretz, 1902) and seed also contain the alkaloids.

They are not present in the fresh plant, but are produced by the action of oxidases on the latex (Stockberger, 1916).

The seeds yield 50 per cent. of a bland fixed oil which may be used like olive oil. The usual percentage of the other alkaloids in opium is: Codgin, 0.2 to 0.7 per cent.; Thebain, 0.15 per cent.; N-acet, 0.02 to 0.7 per cent.; N-acetin, 1.3 to 10 per cent.; Buter, 1 per cent. (absent in some sorts; Van Italie and Kerbosh, 1910). The development of these alkaloids in the growth of the plants is interesting (Kerbosh, 1910).

Opium also contains a number of other minor alkaloids; menthol (2.5 to 5.5 per cent.), lactic acid; gums, resins, fats, odorous principles. No starch or tannin.

* Opium Pulvis (Opil. Pulv.), U.S.P.; Powdered Opium. — Light brown powder, yielding 15 per cent. of anhydrous morphine. Dose, 0.08 Gm., 1 dram, U.S.P.

Opium Deodoratum (Opium Dec.), U.S.P.—Opium exhausted with petroleum ether, to remove some of the odorous principles. It is similar to the secret "improved" opium.

Opium Granulosum, U.S.P.—This is employed in manufacturing.

* Est. Opil. Lq. B.P.—0.03 per cent. of morphine, 0.75 per cent. of the Dry Extract, in 10 per cent. alcohol. Dose, 0.02 to 0.8 c.c., 5 to 30 minims, B.P.

* Est. Opil. U.S.P.; Est. Opil Sicc., B.P.—A powdered extract, 1 Gm. representing 1 Gm. of the drug, or 20 per cent. of morphin. Dose, 0.03 Gm., °2 gr., U.S.P.; 1 to 60 mg. B.P. Maximum dose, 0.25 Gm., 0.5 gr., U.S.P.; 1, B.P. Maximum dose, 1 Gm., 2 gr., U.S.P.

| Latin Opil Et Plumb. | N.F.; Lead and Opium Wash.—Lead acetate, 4.5 Gm.; Tinct. opil. 2 c.c.; Water, q.s., 200 c.c. | Mixture Glycyrrhiza Composita (Mist. Glycyrrh. Co.), U.S.P. (Brown Mixture).—The adult dose, 10 c.c., 23 gr. of the mixture contains 1.2 c.c. of Paregoric or 5 mg., °4 gr. of opium, and 2.5 mg., °2 gr. of Tartar Emetic; also a little Sp. Aether. Nat. It is a popular expectorant, but needlessly complex.

| Pl. Pium. C. Opio, see Index. |

| Pl. Pium. Co., B.P.—20 per cent. of Opium. Dose, 0.02 to 0.23 Gm., 2 to 4 gr., B.P. |

| Pl. Croat. Arom. C. Opio, B.P.—25 per cent. of Opium. Dose, 0.6 to 4 Gm., 10 to 20 gr., B.P. |

| Pl. Pium. Ipecacuanhae et Opil. (Pulv. Ipecac. et Opil. U.S.P.); Pulv. Ipecac. Co., B.P. (Dover's Powder; Opil et Ipecac. Pulv. Co., P.I.)—Contains 10 per cent. each of Opium and Ipecac with Milk-sugar, U.S.P., or Potass. Sulphate, B.P. (It was introduced by Thomas Dover, 1741, as a diaphoretic in gout.) Dose, 0.5 Gm., °2 gr., U.S.P.; 0.5 to 1 Gm., 5 to 15 gr., B.P. Maximum dose, 1.5 Gm., °20 gr. |

| Pl. Kino Co., see Index. |

| Pulv. Opii Co., B.P.—10 per cent. of Opium, with aromatics. Dose, 0.03 to 1 Gm., 0.05 to 15 gr., B.P. |

| Squ. Plumbii Co., B.P., see Index. |

| Tr. Opil. U.S.P.; Tincture of Opium (Laudanum)—10 per cent. of opium, or 1 per cent. of morphin, in diluted alcohol. Miscible with water or alcohol. Dose, 0.5 c.c., 8 minims. U.S.P.; 0.3 to 1 c.c., 5 to 15 minims, repeated; single, 1.2 to 1.5 c.c., 20 to 30 gr., B.P. Maximum dose, 1.5 c.c., 30 minims. |

| Tr. Opil. Ammon. B.P.—0.1 per cent. of Morphin, with Anise oil, Benzoic acid and Amylum. Dose, 2 to 4 c.c., °4 to 1 dram, B.P. |

| Tinctura Opil. Camphorata (Tr. Opil. Camph.), U.S.P.; Tr. Camphor. Co., B.P. (Paracetic; Opil Tinctura Benzoinica, P.I.)—0.4 per cent. each, of opium, benzoic acid, camphor, and anise oil, U.S.P. The B.P. contains the same ingredients with °4 per cent. of opium. The preparation is used especially for children. Dose, 4 c.c., °2 dram, U.S.P.; 2 to 4 c.c., °4 to 1 dram, B.P. 4 c.c. contains 10 mg., °2 gr., of opium or 1.6 mg., °4 gr. of morphin. U.S.P., °20 Gm., °20 gr. of opium or 2 mg., °2 gr. of morphin, B.P. |
* Tinct. Opio Deodorat., U.S.P.—Same strength and dose as the Tincture; 1 dr. odor, having been extracted by petroleum ether. Similar to McMunn's Elixir ad nostrum.

(Eng. Gail. C. Opio, B.P., see Index.)
(Eng. Myrrh. C. Opio, B.P., see Index.)

Penicillin (Penicillum Hydrochloricum), N.N.R.—A purified mixture of alkaloids, containing 50 per cent. of morphin. Sol. in water. Dose, 5 to 12 1/4 to 12 1/2 gr., by mouth or hypodermically.

Narcophrin; Morphin-narcotin meconate—About 33 per cent. of morphin in water. Dose, three times that of Morphin.

PREPARATIONS—MORPHIN

* Morphin and its salts occur as odorless, bitter white powders or colorless crystals. They are incompatible with alkalies, tannins, iodides and other precipitants of acids. Dose, 8 mg., 1/2 gr., U.S.P.; 8 to 30 mg., 1/4 to 1/2 gr., B.P. The rectal—same; the hypodermic about two-thirds of the oral. Maximal single dose, 2 1/2 gr. The actions begin in about five minutes on hypodermic administration. Doses are said to decompose rather readily when heated above 60°C. (Weilman, Morphine, U.S.P., C₉H₅NO₃ + H₂O.—Very slightly sol. in water (1; slightly sol. in alc. (1:20); sol. in lime-water (1:100).

Morph. Acet., B.P., C₉H₅NO₃C₂H₅OH = 3H₂O.—Freely sol. in water (Loses acetic acid on exposure to air).

* Morph. Sulph., U.S.P., (C₉H₅NO₃)₂S₂H₂O + 3H₂O.—Sol. in water (1 slightly sol. in alc. (1:56).

Morph. Tort. B.P., (C₉H₅NO₃)₂C₂H₅OH + 3H₂O.—Sol. in water (1:11).

Inj. Morph. Hyp., B.P.—2.5 per cent. of tartrate. Dose, 0.3 to 0.6 cc. 5 minims, B.P.

Liq. Morph. Acet., B.P.—1 per cent. Dose 0.6 to 3.6 cc., 10 to 60 minims, 1 liq. Morph. Tort., B.P.—1 per cent. Dose 0.6 to 3.6 cc., 10 to 60 minims.

Supp. Morph., B.P.—0.01 gm., 1/2 gr.

Dose, 0.3 to 1 cc., 5 to 15 minims, B.P. Used in colic.

Trach. Morph. B.P.—1 mg., 1/4 gr.

Trach. Morph. et Ipecac. B.P.—2 mg., 1/4 gr., of Morphin; 6 mg., 1/4 gr., of 1

PREPARATIONS—MORPHIN DERIVATIVES

These resemble the morphin salts in physical characters and u patabilities; they are further incompatible with strong acids or alkaline agents.

Diacetylethylnorphina, U.S.P. (Heroin), C₉H₅(C₂H₅O)₂NO.—Very slightly soluble in water (1:1,000); sol. in alc. (1:39). Dose, 5 mg., 1/5 gr., U.S.P.

Diacetylethylnorphin Hydrochlorid. Hydrochlor., U.S.P., Diacetylmorph. Hydrochlor., B.P. (Heroin Hydrochlor), C₉H₅(C₂H₅O)₂NOHCl + H₂O.—Freely sol. in water (1:2); sol. in alc. (1:3). Dose, 5 mg., 1/2 gr., U.S.P.; 5 to 10 mg., 5/4 to 1 gr., B.P. Maximum dose, 10 mg.

Codine, U.S.P., B.P., C₉H₅(C₂H₅O)₂NO + H₂O.—Slightly sol. in water (1 freely sol. in alc. (1:2). Dose, 30 mg., 1/2 gr., U.S.P.; 10 to 60 mg., 1/2 to 1 gr., B.P. Maximum dose, 0.1 gm., 25 mg.; Supp. Codine. Phosph., B.P.—0.5 per cent. Dose, 5 to 12 cc., 1/4 to 1/2 gr., B.P.

Codin Sulph., U.S.P., (C₉H₅NO₃)₂H₂SO₄ + 3H₂O.—Sol. in water (1:27). Dose, 5 mg., 1/4 gr., U.S.P.; 10 to 60 mg., 1/2 to 1 gr., B.P. Maximum dose, 0.1 gm., 25 mg.; Supp. Codine. Phosph., B.P.—0.5 per cent. Dose, 10 to 12 cc., 1/4 to 1/2 gr., B.P.

Papaverin. Sulph., N.N.R., (C₉H₅NO₃)₂H₂SO₄.—Sol. in water or alc. (1:30) slightly sol. in alc. (1:1,800). Dose, 30 mg., 1/4 gr., U.S.P.

PAPAVERIN

This was recommended as an analgesic by Baxt, 1800, and Macht, 1858; b central effects are insignificant (Pal.). Its toxicity is low. Bouchet claimed that produced no effects on man.
Its important peripheral actions have been investigated mainly by Pal, 1913, 1914. He found that it relaxes the tonus of all smooth muscle, especially when this has been spasmodically contracted, and this without paralyzing the contractility of the muscle; i.e., it lowers intestinal tonus without interfering with normal peristalsis or producing constipation; that small doses lower abnormally high blood pressure, while it requires much larger doses to lower the normal pressure. Mack, 1916, claimed that it lowers blood pressure, mainly by peripheral vasodilator action, especially in the splanchnic area. The coronary circulation is increased. Small doses slow the heart, with tendency to stronger contractions. Popper claims that the isquinolin alkaloids relax the longitudinal coat of the intestines; the pheochromus the circular coat.

Macht, Herman and Levy, 1916, found that 40 mg. hypodermically, in man, produces marked analgesia with some vasodilation, fall of blood pressure and slight constipation.

Therapeutic Use of Papaverin.—Pal advises its use in gastric and intestinal spasms of colics, and in spastic constipation (50 to 80 mg. by mouth or hypodermically; 5 to 30 mg. by vein). Stoerk, 1915, employs it against the tenesmus of bacterial dysentery (20 mg., three times daily, continued as long as required). It has also been tried, with less success, in hypertension, angina pectoris; vomiting, gastric crises; asthma and pertussis (Pal; Popper, 1914; L. Levy, 1914). It is a local anesthetic, and has been used on the cornea as solution of 4 to 10 per cent. Mack, 1916, finds that papaverin relaxes the tone of the ureter, without inhibiting the peristalsis. Gerathy and Mack, 1916, use its injection by ureteral catheter, against the colic of ureteric calculi (5 c.c. of a per cent. Papav. HCl). The gall-bladder and the seminal ducts are also relaxed (Macht, 1919).

Commercial papaverin contains considerable cryptopin, to which most of its chemical tests are due (Péret and Kramers, 1916). In general, however, the quality of commercial opium alkaloids is satisfactory (Warren, 1915).

For a Papaverin.—It is probably extensively destroyed in the body, since neither papaverin nor any immediate decomposition products have been recovered from the organs or excrta after its hypodermic administration (Zahn, 1914).

An extensive Bibliography of papaverin is given in Merck’s Reports, 1914, 28:74.

Tetra-hydro-papaverin.—Laidlaw, 1910, found that this inhibits the tone of unstripped muscle, dilates the bronchides and blood vessels, and lowers blood pressure, while retaining the heart stimulating the heart. It is relatively non-toxic. Marshall, 1912, tried it clinically in arteriosclerosis, but found it practically inefficient—probably because it is too easily oxidized.

PROTOTIN GROUP

The curare and muscular actions of the opiates were first described by v. Engel, 1899, for the prototin group—certain unimportant alkaloids (prototin, cryptopin, chelidonia, homochelidonia, and chelerythrin) which occur in opium, but especially in other Papaveraceous plants (Sanguinaria or Bloodroot; and Chelidonium or Celan- telle; Bocconia, etc.). These alkaloids share also the depressant morphin action on the heart (Hale). They are said to paralyze the sensory endings like cocaine. The respiration is stimulated.

CHELIDONIN

This is the most promising member of the prototin group. It is chemically related to papaverin, containing the benzyl-isquinolin group. It therefore depresses all smooth muscle and has a low toxicity. It deserves clinical trial against spasm and colic of smooth muscle, asthma, etc., i.e., in the same fields as benzyl codeine (Hanulik).

Central Actions.—H. Meyer, 1892, found that it produces, in frogs, descending depression of the central nervous system, similar to morphin, but without spinal stimulation. Mammals also respond by analgesia and sleep, without marked depression of respiration.

The respiration is unaffected by therapeutic doses; moderately slowed by large doses. Toxic doses cause coma, without nausea or vomiting; finally, the vasomotor center becomes paralyzed.

Peripheral Actions of Chelidox.—These have been investigated especially by Hanzi, 1915. Like other isquinolin alkaloids (narcotin, papaverin), it depresses all kinds of smooth muscle. The effect appears to be directly on the muscle substance, since it antagonizes not only pilocarpin, but also histamin, epinephrine, and adrenalin; while these do not remove chelidoxin depression.

Large doses depress cardiac muscle, slowing and dilating the heart. (Meyer commonly attributed this to vagus stimulation.)

Skeletal muscle is also depressed, and Meyer described paralysis of sensory and motor endings. It has no effect on nerve-trunks, even in high concentrations.
PREPARATIONS

Chelidonine Sulphate.—Freely soluble in water. Incompatible with chloroform.

Chelidonium Juice.—This is an acrid irritant, applied in folk-medicine to remedy warts. The acrid principle has not been isolated. Chelidonium also contains berberine.

SANGUINARIA (BLOODROOT)

This has been used as a nauseant, usually as the 10 per cent. acetylated tincture (dose, 1 c.c., 15 min.).

Sanguinaria contains sanguinarin (Reports, Council Pharm. and Chem., 1900) and other alkaloids (Kozlowski, 1910). It is irritant, but requires further pharmacological investigation.

BENZYL BENZOATE

The hypothesis that the benzyl radical is responsible for the toxic effects of smooth muscle by papaverine, suggested to Macht, 1918, to trial the simpler benzyl esters. Benzyl benzoate and acetate were found to relax excised smooth muscle from various organs. On this basis they were used clinically in colics or spasmodic conditions of smooth muscle, with apparent success (see below). However, Mason and Pies, 1920, find that doses considerably larger than those used in therapeutic even when injected directly into the blood stream, are insufficient to affect either resting or stimulated smooth muscle in those organs against whom activity the drug had been especially advised (uterus, intestine, stomach and bronchi); but produce only some cardiac depression. The clinical effects on the intestine may conceivably be caused by direct local action but apparently the claimed clinical actions on other organs, in so far they were not suggestive, may have been due to reflexes from the taste a gastro-intestinal irritation.

The toxicity of the benzyl esters is low since they are largely converted into hippuric acid.

Therapeutic Field.—Macht, 1916, cites the following conditions in which clinical improvement was noted; and these have been confirmed as noted:

- Excessive Peristalsis.—Chronic diarrhea; dysentery, including amebic. Intestinal colic; enteritis; spasm; Spastic Constipation, colitis, ureteral and renal vesical spasm.
- Uterine colic; dysmenorrhea. Litzemberg, 1910, endorses it in "vagotonic" or "essential" dysmenorrhea; as being effective in most cases, relieving the pain and headache.
- Arterial Hypertension.—It is said to lower the diastolic as well as the systolic pressure, and may succeed when nitrates fail. Damage to the kidneys has not been demonstrated.
- Angina pectoris.
- Bronchial spasm (asthma).—Many cases respond, but not all.
- Whooping Cough.—It is more or less palliative in most cases (Macht, 1920).

PREPARATIONS

Benzylis Benzoas, N.N.R., Benzyl Benzoate, C_{12}H_{2}OOCCH_{3}C_{6}H_{5}.—A colorless oily liquid, of faint odor and disagreeable, sharp taste. Insoluble in water or glycerine. Freely soluble in alcohol and fat solvents. Best prescribed as the commercial 20 per cent. alcoholic solutions or emulsions, usually flavored with aromatics (Spir. Anis. The dosage is 5 to 10 c.c. (1/2 to 2 teaspoons) of the 20 per cent. solution, in cold water 3 or 4 times daily.

Benzaldehyde, C_{6}H_{5}CHO.—This is also antispasmodic and anesthetic. A saturated solution (0.2 per cent.) relaxes the tonus and inhibits the contractions of smooth muscle. Small doses do not lower blood pressure.

As local anesthetic it is inferior to benzyl alcohol, since its solutions are rapid oxidized to benzoic acid (Macht, 1919).
HYDRASTIS

Hydrastis (Golden Seal) has few, if any, rational indications. It is employed empirically as a bitter stomachic; to check internal hemorrhage; and locally in catarrhal conditions, especially of the genito-urinary tract.

 Constituents.—Hydrastis contains at least three alkaloids: Berberin, 1.5 to 4 percent; Hydrastin, at least 2.5 percent (U.S.P.), and Canadin, a derivative of berberin.

 There is also some resinsous matter, etc.

 Hydrastin.—This is an inquisoquinine derivative, closely related to some of the minor opium alkaloids, Narotonin, Laudanosin and Papaverin. Narotonin is a methoxy-hydrastine, an H of hydrastin being replaced by OCH3.

 Hydrastin = C31H35NO7 + H(OCH3)6
 Narotonin = C31H35NO7 + OCH3

 By oxidation both give analogous artificial alkaloids, which are somewhat important:

 C31H35NO7 + H2O + O = C31H35O5 + C31H35NO6

 Hydrastin
 Oxidation
 Hydrastin
 Oxidation

 Berberis, C20H29NO5 (structure, Faltis, 1910) is an intensely yellow and bitter alkaloid, of wide occurrence, which gives the color and taste to a large number of "golden" roots and barks (Berberis, Zanthoxyllum, Coptis, etc.).

 Actions of Hydrastis.—An extensive study of hydrastis and its alkaloids was made by Bunge, 1895. This gives the literature to that time. Of later papers, mention may be made of those of Felner, 1906; Williams, 1908; and Laidlaw, 1910. The effects of the drug and of its different alkaloids are qualitatively similar.

 Central Nervous System.—Hydrastin produces convulsive effects analogous to those of strychnine. These are also obtained with the fluidextract. The derivatives of hydrastin and cotarin have a purely depressant action, producing death by respiratory paralysis (Laidlaw).

 There is no narcosis.

 Circulation.—From the experimental results, it seems that the effects of hydrastis and its alkaloids and derivatives on the circulation are too uncertain to be therapeutically useful. The clinical evidence also appears insufficient to establish their value. FREY, 1900, found that hydrastin had no effect on pulmonary hemorrhage; and HANDL, 1918, showed that hydrastis and its alkaloids, including hydrastin, are not toxic on ordinary wounds, either with local or systemic administration, but they rather tend to increase the bleeding. The effects of hydrastin on the circulation are variable, and the description of different investigators is discordant.

 Williams obtained no effects with hypodermic or oral administration, even with very large doses. Intravenously the fluidextract, hydrastin and berberin produced the same results; considerable fall of blood pressure, followed with small doses by a slight and abrupt rise. With large doses, the pressure remained low. These effects were predominately cardiac (myocardograms and encometer); this overshadowed any possible vasomotor changes.

 The vasomotor center is not directly affected by moderate doses of hydrastis, hydrastin, berberin, hydrastin or cotarin; but may be stimulated indirectly through respiratory depression, convulsive phenomena or cardiac arrest (Pilcher and Sollmann, 1904).

 With toxic doses, there is vasomotor paralysis, and paralysis of vagus endings. Excised organs show some vasodilation.

 On the scarified skin, hydrastin (1:1000) produces some blanching (Sollmann and Pilcher).

 Hydrastin is related to the prothrin group, and therefore depresses the cardiac and skeletal muscle, and has a weak local anesthetic action.

 Hydrastin also causes some primary fall but a larger rise (about 15 mm.) maintained for over fifteen minutes; the heart rate is slowed. This rise is also predominantly cardiac, but there is a stimulation of the arterial muscle, not prevented by paralyzing the nerve endings with ergotoxin. KURDINOVSKY, 1904, interprets its actions rather differently.
**Uterine Actions.**—Fellner, 1906; Kebrer, 1907, and Lieb, 1914, showed that hydrastis, hydrastin, and cotarin increase the tonus and excite rhythmic contractions of the uterus, both in the excised organ and in living animals. This has been confirmed by the subsequent workers; also for the surviving human uterus (Kuehsemann and Kliegerman, 1917). High concentrations relax (Wendling, 1915). Berberin has similar effects (Marck, 1911). La Torre, 1912, examined histologically the uterine animals treated with hydrastin. The muscular layers were contracted and thickened, compressing the larger vessels, and thereby probably decreasing the blood supply of the mucosa. Laidlaw found the stimulant action of hydrastin and cotarin constant in the excised organ, but varying with conditions during life. These actions resemble those of the pituitary and ergot principles; but hydrastis does not act on the intestines and very slightly on the bladder. Synthetic hydrastin appears to be rather more stimulant than the natural alkaloid (Wendling, 1914).

The bronchioles are not markedly affected in pithehc animals (D. E. Jackson, 1914).

**Actions of Berberin and Canadin.**—Berberin acts as a simple bitter in small doses. Its bitter taste and the yellow stain which it produces on linen, render it objectionable in the therapeutic use of hydrastis. Berberin is about seven times as active as hydrasin in the circulation; and as hydrastin contains about one and one-half times as much berberin, about 85 per cent. of the circulatory effect is due to this alkaloid. Large doses lower the temperature, increase peristalsis, and kill by central paralysis (Curi, 1892). It is not excreted, being probably oxidized completely (Berg).

Canadin resembles morphin somewhat in its action. It is present in too small a quantity to be of practical importance. It occurs also in saxthoxyxylum, where its action has been studied by Laidlaw, 1913.

**PREPARATIONS—HYDRASTIS**

Hydrastis, U.S.P.; Hydrast. Rhiz., B.P. (Golden Seal).—The dried rhizome and roots of Hydrastis canadensis, yielding not less than 2.5 per cent. of hydrastin, U.S.P. Dose, 2 gm., 30 gr., U.S.P.

Hydrastis was employed by the Indians, mainly as a pigment, but also as medicine. It was introduced by the electics about the end of the eighteenth century. The plant is becoming rare, but is easily cultivated (Herkel and Klugh, 1908).

Est. Hydrast., U.S.P.—A powdered extract with 10 per cent. of hydrastin, 1 gm. representing 4.6 gm. of drug. Dose, 0.5 gm., 8 gr., U.S.P.

*Equisetum Hydrastis, U.S.P.; Est. Hydrast. Liq., B.P.—2 per cent. of hydrastin; ⅔ alcohol, ⅓6 glicerin, U.S.P. Dose, ⅓ cc., 30 minims, U.S.P.; 0.3 to 1 cc., 5 to 15 minims, B.P.

Glycer. Hydrast., U.S.P.—About 1.35 per cent. of hydrastin. Dose, 2 cc., 30 minims, U.S.P.

**Tr. Hydrast., U.S.P.—** 20 per cent. Dose, 4 cc., 1 dram, U.S.P.

Tr. Hydrast., B.P.—10 per cent. Dose, 2 to 4 cc., ⅓ to 1 dram, B.P.

Hydrastina, U.S.P., C₁₅H₁₁NO₆—White prisms. Almost insol. in water. Dose, 10 mg., ⅓ gr., U.S.P.

Locally, for conjunctivitis, 0.1-0.5 per cent.; for gonorrhea, 0.25-0.5 per cent.

Hydrastin. Hydrochl., U.S.P., C₁₅H₁₀N₂O⁺HCl.—Light yellowish needles or powder. Very sol. in water or alc. Its aqueous solution, especially when highly diluted, shows a blue efflorescence. Dose, 50 mg., ⅓ gr., U.S.P.

**COTARNIN**

Cotarin salts (marketed under the name of stypticum and styplet) have been tried locally and systemically, to arrest bleeding, especially in menstrual disorders. Their employment was based on very weak clinical and experimental data, which do not stand critical examination. It has no rational use.

**Use Against Hemorrhage.**—The older data were discussed rather fully in the 1917 edition of this book. Since then, careful experiments by Hanulik, 1918, have demonstrated that cotarin is not a local hemostatic. Systemically, it tends to lower blood-pressure, and thus indirectly somewhat decreases bleeding.
COTARNIN

General Symptoms.—K. Mohr, 1905, found that 0.1 to 0.3 Gm. per kilogram, in rabbits, dogs or cats produced only some lacrimation, and inactivity. Larger doses had a pronounced sedative action, especially in cats and dogs. Ataxia was also pronounced. With fatal doses, these effects were followed by some excitement, then progressive paralysis till death. Toward the end, the respiration became very slow and shallow, sometimes interrupted by asphyxial convulsions.

Laidlaw, 1910, on guinea pigs, describes indefinite depression of the central nervous system and death by paralysis of the respiratory center. Relatively small doses slowed the respiration, without change of depth.

Fatal Dose.—This ranges from about 0.1 Gm. per kilogram for guinea pigs (Laidlaw) to 0.3 to 0.4 Gm. per kilogram for rabbits, and even higher for dogs and cats (Mohr).

Urine Contractions.—Kehrer, 1907, found that cotarnin stimulates the uterus, both excited and in situ, pregnant or non-pregnant; increasing the contractions and tones. This has been confirmed for the excised organ by all subsequent workers (Laidlaw, 1910; Ruebsamen and Kligermann, 1912; Lieb, 1914). The results in situ are contradictory. Kehrer's stimulant effects were obtained with cats. With a pregnant rabbit, Mohr, 1905, obtained no stimulation. Laidlaw, 1910, also found the results on living rabbits negative, whilst the excised organ responded. La Torre, 1912, observed no histologic evidence of contraction, such as is seen after ergot and hydralazine. Chiappe and Kavano found that the pregnancy of guinea pigs was not affected by toxic doses; and that even fatal doses produced no uterine abnormalities.

The clinical data are in harmony with these negative results. All reporters agree that cotarnin never provokes uterine pains, even in late pregnancy; that it does not hasten the involution of the uterus; and that it has no influence on postpartum hemorrhage.

Mohr claimed that cotarnin depresses the excitability of the uterus to hypogastric stimulation; but his conclusion appears to be based on a single very imperfect experiment with enormous doses, and must therefore be rejected.

It appears, from all this, that cotarnin stimulates the excited uterus, on local contact; but that, with systemic administration, the uterus does not respond, at least in rabbits, and certainly not with therapeutic doses in the human subject.

Other Smooth Muscles.—Offergeld quotes contraction of the intestines and bladder; but Laidlaw found the bladder insensible.

Systemic Circulation.—Intravenous injection produces variable changes in the blood pressure; sometimes a fall; or a momentary fall followed by a slight rise (Kehrer, 1907; Laidlaw, 1910; Lieb, 1914). If the vagi were divided, the rise is more prominent (Pichler and Sollmann, 1913). The vasomotor center is not affected directly, but may be stimulated by the slowed respiration (Pichler and Sollmann); and this probably accounts for the rise. The fall of pressure appears to be cardiac; for the Langendorff heart is slowed and weakened (Laidlaw). Kehrer and Heinz also consider the fall cardiac.

This diminished output of the heart has been credited with causing a hemostatic effect; but this is most improbable. There is no evidence that it occurs with therapeutic doses; and even with the experimental doses, it is too slight and especially too transient, to influence a persistent hemorrhage.

Direct Action on Systemic Arterioles.—All the earlier investigators (Falk, Marfori and Ronse) affirm that cotarnin has no effect on the arterioles, with systemic administration. This has been confirmed by the negative results of perfusion experiments (Laidlaw, loc.). The positive results of direct contact with strong solutions have no bearing on this. Cotarnin does not produce the gangrene changes characteristic of ergot (Mohr).

Coagulation of Blood.—This is not affected; whether the cotarnin is added directly to the blood, or injected into the animal (Laidlaw; Marfori).

Dosage and Administration.—The cotarnin salts were used by mouth or hypodermically. The intramuscular dose is 0.25 to 0.5 Gm., as 0.10 or 0.20 per cent. solution, repeated as needed. The injections are not irritating. By mouth, the dosage is from 0.05 to 0.1 Gm. four to five times daily.

Side Actions.—None have been reported from oral administration or from hypodermic injections of 0.5 Gm. Offergeld found some laxative with 0.5 Gm. and a single case of temporary collapse with 0.67 Gm. by intramuscular injection.

PREPARATIONS — COTARNIN

Cotarnin Hydrochloricum (Cotarn. Hydroch.), U.S.P. (Stypctin), C₁₅H₁₂O₇N·HCl Odorless, bitter, yellow, crystalline powder. Very sol. in water or alc., yielding yellow solutions. Dose, 0.06 Gm., 1 gr., U.S.P.
CANNABIS

The tops of the hemp plant are somewhat of a pharmacologic curiosity. They contain psychoactive compounds (cannabinoids) which produce various psychic effects. Cannabis is employed as an intoxicant in the Orient. Therapeutically, it is used empirically (Extract 0.01 Gm., ½ gr.) as an adjuvant to other drugs in nervous headaches, and as a coloring agent for corn remedies. The drug is of uncertain activity, and has no rational indication.

Intoxicant Action in Man.—The oriental use of Cannabis ("Hashish," Bhang, Charas, etc.) antedates history. It was introduced in Western medicine about the middle of the nineteenth century. When used as an intoxicant, the tops or resins are made into a confection or smoked with tobacco. Effective doses (2 gr. of solid extract of the Indian or American drug) produce after about an hour a state of partial incoherence and confusion, with happy and humorous tendencies. Ideas pass rapidly but disconnected, so that the time seems very long. The subject often has hallucinations of double personality. The exaltation, which seems to be much more marked in orientals, is succeeded by some irritability, dosing, and complete recovery in five or six hours. The effects are modified by individual disposition and surroundings (Hamilton, Lescoclier and Perkins, 1913). It is stated that the drug is not fatal even in very large doses, but experience on dogs certainly shows that it presents some danger. The habit to which it gives rise shows less effect upon the alimentary canal and less marasmus than does morphin, but more often psychic alterations, delusion, or mania. The clinical side actions are described by Seifert, Nebenwirk., 1913, p. 149.

Cannabis smoking is becoming prevalent in Mexico and is said to be a national menace in Brazil. "Smokers nearly always become imbecile in time" (T. S. Blair, 1910).

Effects on Animals.—Dogs (Dixon, 1899) exhibit a decided narcotic effect. After a preliminary ataxia, excitement, and nausea, the animals usually fall into a deep and prolonged sleep, during which the sensation of pain is much diminished, whilst the reflexes persist. Some animals show acute mania; a fatal ending is not rare. Narcotics which are ineffective in other animals, the same preparation being used. Considerable idiosyncrasy exists, and the action is fairly independent of the dose. The effects can not be obtained by hypodermic administration (on account of the non-absorption of the resin). Rabbits seem absolutely insusceptible to the narcotic action of cannabis.

PREPARATIONS—CANNABIS

Cannabis, U.S.P.; Cannabis Indica, B.P.; Cannabis, Indian Hemp (Hashish, Bhang, Guza, Gangja, Charas, Momca, etc.).—Dose, 0.05 Gm., 1 gr., U.S.P.

The dried flowering or fruiting tops of the pistillate plant of Cannabis sativa. The B.P. requires that it be grown in India; the U.S.P. permits any origin, but provides that the activity must be confirmed by testing its narcotic effects on dogs (Houghton and Hamilton, 1907; U.S.P. IX). This is necessary since different samples vary greatly, and are liable to deteriorate rapidly. If the Indian drug is preferred, Cannabis Indica may be specified; if the American, Cannabis Americana. American grown Cannabis produces identical effects (Houghton and Hamilton, 1907 and 1908), but is generally only half as active (Eckler and Miller, 1912). The preparations, however, are brought to the same degree of activity.

The active ingredient is a resin, cannabinol (Frakenel, 1903), C21H22O5, which presents the appearance of a thick reddish yellow oil, soluble in petrolatum ether, etc. (not identical with the commercial "cannabinol"). This changes by oxidation to an inactive black pitch. The change accounts for the deterioration which the drug and its preparations undergo in keeping. The deterioration can be prevented by excluding the air (Marshall, 1909).

However, there is some question as to the instability of the ordinary drug. H. C. Hamilton, 1915, claims that crude drug samples that had been on the shelves for at least 14 to 17 years still showed 20 per cent. of the bio-assay activity of the "standard" recent drugs; and that nine year old extract has apparently not lost in activity.

Cannabis also contains a volatile oil (terpenes), paraffin, pitch, etc., which are not concerned in its action. There is no specific alkaloid, but the extracts may give
alkaloid reaction from the formation of cholin and trimethylamin. These are not connected with the action. The fresh extract has a beautiful green color (if prepared without excessive heat), due to chlorophyl. The active principle is completely extracted by alcohol, but is insoluble in water.

The pretended Isolated Principles on the market under various names are generally quite inactive (S. A. Matthews, 1908).

Fist. Cannabis, U.S.P.—Dose, 0.05 cc., 1 minims, U.S.P.

Tr. Cannabis, U.S.P.—10 per cent. of drug. Dose, 0.5 cc., 8 minims, U.S.P. Maximum dose, 1.25 cc., 20 minims.

Tr. Canab. Ind., B.P.—5 per cent. of extract. Dose, 0.3 to 1 cc., 5 to 15 minims, B.P.

PISCIDIA (JAMAICA DOGWOOD)

This drug produces ataxia similar to cannabis (Pittenger and Ewe, 1909; bioassay), and was introduced as a sedative, hypnotic and analgesic (Ott, 1883; Nagle, 1881). However, it is practically useless (Tyrade and Nelson, 1900).

It contains a crystalline non-nitrogenous principle, "piscidin," but this does not seem to be the bearer of the ataxic action (Pittenger and Ewe).

LACTUCARIUM—DRIED LETTUCE JUICE

This was introduced by Dr. Cose of Philadelphia in 1799 as a sedative. Lettuce had some reputation as a hypnotic in ancient times, but it is probably undeserved. Kelterborn took 12 gm. of Lactucarium without any effects. No active principle has been determined.

PREPARATIONS—LACTUCARIUM

Lactucarium, U.S.P.—The dried milk juice of wild lettuce, Lactuca virosa. Dose, 1 gm., 15 gr., U.S.P.

Tr. Lactucar., U.S.P.—50 per cent. Dose, 1 cc., 50 minims, U.S.P.

LUPULIN AND HOPS

These act as bitters, and have some popular but exaggerated reputation as hypnotics. Hops are the dried pinnatulate flowers of Humulus Lupulus. The active principles are contained in small glands, which can be separated as a powder, and constitute the lupulin.

Two acids (α- and β-lupulinic acids) are present. They stimulate the respiratory and vagus centers; this is followed by depression. They also depress the cardiac muscle. Lupulin contains a further, unknown, constituent which is insoluble in water and a strong cardiac poison. Power, Tutt and Roper, 1913, also found a trace of alkaloid. All these, however, are not active when administered by the stomach, and are therefore not concerned in the action of the drug.

PREPARATIONS—HOPS

Humulus (Humul.), U.S.P.; Hops.—The dried strobiles of Humulus Lupulus. Dose, 1 gm., 30 gr., U.S.P.

Lupulin.—Dose, 0.5 Grm., 8 gr.

LOCO DISEASE

Horses, cattle and sheep on the Western stock ranches are subject to this peculiar disease, which bears some resemblance to drug habits. The symptoms consist in motor incoordination, forced movements, misjudgment of distance, stupidity, apparently hallucinations. In the chronic form there is emaciation. Death is preceded by coma and delirium.

The cause of these conditions is obscure. It is generally attributed to feeding on certain leguminous plants ("loco weeds"—especially Astragalus). C. D. Marsh, 1909, claims to have reproduced the condition (nervous symptoms, etc., with exudative meningitis, anemia, etc.) experimentally by very long-continued feeding with these plants; but H. T. Marshall, 1914, considers the results inconclusive, and believes that there is no distinct loco disease; and that the name covers a variety of conditions—malnutrition, parasitism, etc.—unconnected with the loco weed.
COCAIN GROUP; LOCAL ANESTHETICS

Actions and Uses.—The alkaloid cocaine is important mainly a local anesthetic, paralyzing the sensory nerve fibrils on direct application. With dilute solutions, its action may be confined to these; but higher concentrations paralyze all other nerve fibers, and, indeed, all protoplasm. It also causes local vaso-constriction. The pupils are dilated through stimulation of the sympathetic pupillo-dilator mechanism, both cen- and peripheral.

When cocaine is absorbed in sufficient quantity, it produces com- systemic actions, involving stimulation and paralyzation of various part the central nervous system. These are mainly of toxicologic and scien- interest. Its continued use leads to the formation of a habit, resemb- morphinism.

Analogous local anesthetics are produced by a variety of synth- bases, which may be used as substitutes for cocaine; such as Procain (or- cain), alpyin, beta-ecuain, apotesin, benzyl alcohol; phenylcarbinol, vain; also tropacocain and quinin-urea hydrochlorid. Potassium salts anesthetic under suitable conditions.

Historical.—Cocaine is derived from the leaves of Erythroxylon Coca, a tree indi- ous to Peru, Chili and Bolivia. The leaves were chewed from time immemor- the natives to relieve hunger and fatigue, and to produce a psychic stimulation, — what after the manner of caffeine. It is now cultivated in other tropical countries. In Europe, trials with the leaves gave disappointing results. The discoverers coca (Wohlert; Niemann and Lassen, 1860) incidentally described its benzoi action on the tongue, but without realizing its significance. As late as 1860, a Bt medical commission reported on the drug as merely a poor substitute for ca (further details, J. U. Lloyd, 1911, "History of Vegetable Drugs," and 1912, J. Pharm. Assoc., 2:1234). In the same year, Anrep subjected cocaine to a thor- pharmacologic investigation.

In 1884, the Vienna oculist, K. Koller was engaged in general pharmacol- experiments with cocaine, and it occurred to him that the numbing effect on the to- was really anesthesia. Being interested in ophthalmic anesthesia, he tried the immediately on the eyes of animals, and then in the clinic, and announced the disco to the German Ophthalmologic Society (Koller, 190). Its practical value w at generally recognized.

Peripheral Nerves.—Local Anesthesia.—Local contact with co- paralyzes all forms of nervous tissue, without preceding stimulation. susceibility of the various nerve fibers presents marked and cha- teristic quantitative differences. Sensory fibers are especially es- attacked, and, by using appropriate dilutions, the paralyzing action can be di- strictly to them. With sufficient concentration, the paralysis is as c plete as if the nerve fibers had been severed with a knife. If the alka- is washed away, or absorbed, the nerve recovers its functions prom- and completely (but very strong solutions may produce neuritis and manent paralysis).

Since these effects are strictly local it follows that the cocaine mus- applied in such a way that an effective concentration will reach the supply of the part which it is desired to affect. This may be accomplis- according to circumstances, by painting a solution on mucous mem- (from which it is very readily absorbed); or by injecting it into or ur- the skin (infiltration and subcutaneous anesthesia); or around or into nerve trunk (peri- or intraneural anesthesia); or around the spinal n roots (subdural or spinal anesthesia). The intact skin is practic
LOCAL ANESTHETICS

impermeable to cocaine, although it penetrates slightly if the skin has been
sucked (Macht et al, 1916).

Duration of Local Action.—The onset and duration of the anesthesia
vary with the concentration of the solution, and the method of its appli-
cation. Roughly speaking, it starts in a few minutes and lasts perhaps
ten to thirty minutes, with a single application.

Local Anemia.—As the cocaine is absorbed and thus removed from the
site of application, its local action ceases and its systemic and toxic effects
start. Since cocaine is rapidly destroyed in the body, the systemic toxicity
increases with the rapidity of absorption. It is therefore desirable and
often necessary to delay the absorption. This may be done by restricting
the local circulation. Cocaine itself tends to do this by producing a local
vasoconstriction—an action which is not shared by its substitutes.
This vasoconstriction should be reinforced by the addition of epinephrin.
In this way, more dilute solutions may be used, and the anesthetic effect is
much more prolonged. In suitable situations, the circulation may be
stowed by bandages, or arrested by temporarily clamping the arterial
blood supply.

 Interruption of the circulation was introduced by Corning in 1885. He showed
that this makes 1/4 of 1/5 per cent. cocaine solution more effective than the 2 to 10 per-
cent solutions that were then in vogue; and that it greatly diminishes the danger of
poisoning (H. Braun, 1914).

The anemia also favors anesthesia directly; ligation of a large artery in
itself produces anesthesia of the nervous end structures.

When a large quantity of dilute cocaine solution is injected under pres-
sure, as in the infiltration anesthesia, the cocaine action is reinforced by
anemia, pressure, and edema.

Comparison of Anesthetic Efficiency: This may be attempted by a
number of experimental methods. In transferring the results to clinical
problems, the conditions of the clinical use must be borne in mind (Soll-
man, 1915).

Intravenous Injection (the “wheel” or “quaddel” method of H. Braun), ob-
serving either the duration or better the threshold values of the anesthesia. This
represents practically the conditions of infusion and of injection anesthesia. When
mixed with epinephrin, it also measures absolute anesthetic efficiency. The ratio
by this method is as follows:

<table>

</tbody>
</table>

The susceptibility of different skin areas varies, even in the same neighborhood, so
that discordant results are sometimes obtained.
The solutions should be approximately isotonic (4.5 per cent. or higher, corresponding to 0.55 to 2.5 per cent. NaCl). Stronger and weaker solutions are first irritable, then anesthetic, even when indifferent salts are used (Bräun, 1914). More dilute solutions should have about 0.5 per cent. of KCl added (H. Bräun).

**Mucous Membranes.**—The skin of the frog’s foot is most convenient; but rabbit’s cornea corresponds more closely to clinical conditions. However, it must be remembered that the absorptivity, and therefore the ratios, would differ for various mucous membranes. The results on the cornea are as follows:

</table>
The Selective Action of Cocain on Motor and Sensory Fiber.—When a $\frac{1}{5}$ to 2 per cent solution of cocain is injected into a mixed nerve, or into the subdural canal, the selective action is very marked, so that there is complete anesthesia, without motor impairment. If the contact is prolonged, by stopping the circulation, or if stronger solutions are employed, the motor fibers become paralyzed, so that the difference is merely quantitative. A similar difference in the susceptibility of motor and sensory structures exists also for the alcohol group, acetin, phenol, hydrocyanic acid and for pressure (Haedvits); and even for the centrally acting narcotics, ether, etc. It is therefore a characteristic of nervous tissue rather than of cocain.

Cocain is Less Effective in Inflamed Tissues.—This may be explained by the hyperesthesia, resulting in more rapid absorption.

Peripheral Paralysis of Special Sense Nerves.—Cocain abolishes not only the sensation of pain, but other special sensations, if it is suitably applied. Here also there is some selection. In the skin, it paralyzes the sense of pain, temperature and tickling, before touch and pressure (Goldshneider). In the nose, it abolishes the olfactory sense. In the tongue, it destroys the taste for bitter substances, but has less effect on sweet and sour taste, and none on salty taste.

Selective Action on Other Nerves.—When cocain is applied to the appropriate nerves, it is found that the central vagus fibers are paralyzed before the centripetal, vasomotor fibers before vasodilator; bronchial constrictors before the dilators, etc. (Dunn, 1904).

Visceral Pain.—The abdominal viscera are sensitive to pain in normal animals; but the sensation is abolished by cocain, even when small doses (0.7 mg. per kilogram) are injected at a distance; for instance, into the pectoral muscles (Kast and Meltzer, 1906-1909). This special anesthesia lasts about half an hour. The insensitiveness of viscera in surgical operations under cocain anesthesia is thus explained. The effect is probably central, for the animals are greatly quieted, although general sensation is not impaired.

Nature of Action.—Of this, little is known, except that it is purely functional. No structural changes are discoverable in the nerve fibers.

Carbon Dioxide Production in Nerve.—Nisw. 1915, investigated this on frog's sciotic nerve by the Tashiro method. He found the same effects from cocain as from the morphine narcotics: Subanesthetic concentrations increased the production. With anesthetic concentrations, the increase was short or absent; the main phenomenon being decreased production.

Site of Action.—Cocain can paralyze the nerve fibers anywhere in their course, whenever it is brought into contact with them. When it is applied to mucous membranes or hypodermically, it doubtless selects the portions peripheral to the main trunk, the thinner sheath of the terminal filaments facilitating its penetration. It is therefore unnecessary to assume a selective action on the histological sensory endings.

Penetration.—It is quite possible that its selective action on different nerve fibers may also depend, in part, on differences in penetration.

Alkalization.—The addition of sodium bicarbonate increases the efficiency of the local anesthetics 2 to 4 times, for direct application or injection into nerve trunks, and probably for subdural injection and on application to mucous surfaces. This is due to the easier penetration of the free anesthetic bases, as compared with their salts (O. Gros, 1910; A. Lawen, 1910; 1912; Sollmann, 1918). This does not apply to hypodermic and intradermic injections, since these do not require penetration.

For all other purposes, the usual solutions of the anesthetic salts may be mixed with an equal volume of 0.5 per cent. sodium bicarbonate solution, without loss of efficiency, and with a saving of one half of the anesthetic, and correspondingly smaller danger of accidents. These mixtures, however, do not keep well, and must be made just before use (Sollmann, 1918).

Combination of Anesthetics.—The efficiency of mixtures of the local anesthetics corresponds to more or less complete summation without any potasium (not potassium, see below). That is, if solutions of different anesthetics are diluted until they are "just effective," then a mixture of any two of these solutions will also be "just effective," no more
and no-less (A. Schmidt, 1913; Sollmann, 1918). There would therefore be little or no practical advantage in such mixtures.

Potassium Synergism.—Potassium salts may give considerable potentiation with the other anesthetics (Hoffmann, A., and Kochmann, 1913, 1914). However, this seems to hold mainly for motor fibers, and not for sensory; and therefore has little practical importance (Sollmann, 1918). One per cent. potassium chloride could be used with some advantage in place of sodium chloride, for making up isotonic anesthetic solutions (H. Braun, 1913).

Epinephrin-Anesthetic Combinations.—H. Braun, 1903, confirmed that the anesthetic effect of cocain injections is greatly improved by the addition of epinephrin (about 1:50,000). The duration of the anesthesia is prolonged for over an hour and therefore the effective concentration can be considerably lowered, and the danger of poisoning almost abolished. These results are due to the vasoconstriction, which practically arrests absorption into the circulation. The greatest field for the epinephrin combination is in connection with operations involving bleeding. The epinephrin is useless on the intact cornea, and probably also for intravenous or subdural injections (Sollmann, 1918).

Epinephrin is similarly efficient with procain and apotheosis. Its effect is not as pronounced with stovain, and is practically absent with tropococain, since 1/4 per cent. of this destroys the vasoconstrictor effect of epinephrin (Smyth, 1911). Beta-eucain also counteracts epinephrin (Braun, 1914).

Cocain actually potentiates the epinephrin constriction (Braun, 1914) even with very small concentrations of cocain (Fischel, 1915). Cocain therefore increases the pressor effect of epinephrin. This applies also to the synthetic local anesthetics (Kutsky, 1916; Hotchkin, 1910).

Epinephrin is not directly anesthetic either alone or in combination with cocain; for it does not increase the anesthetic effect when the circulation has previously been arrested; nor does it lower the threshold concentration in vessels, although the duration of the anesthesia is greater for a given concentration (Sollmann, 1918).

Local Vasconstrictor Action.—The application of cocain to mucous membranes, particularly the inflamed conjunctiva, constricts the capillaries and small arterioles, resulting in blanching, astringent sensation, and actual contraction of vascular formations, such as polypi. The cocain substitutes do not possess this action; many of them dilate the vessels (alyplio, eucain, stovain); procain has no effect (Impens, 1913; Gross, 1910).

The analysis of the constrictor action of cocain has given contradictory results. Since the action is local, it must be peripheral. However, direct perfusion of the vessels is either ineffective or produces dilatation, never constriction; nor does cocain counteract the dilator effect of nitrates (Kuroda, 1912). The constriction can not be explained by anesthesia, since other local anesthetics do not constrict.

Effect on Capillary Hemorrhage.—Cocain is distinctly hemostatic; procain, apotheosis, and other synthetic anesthetics tend rather to increase bleeding. Anesthesia by Iechemia.—Persistent interruption of the blood supply of a part gradually induces anesthesia. However, this requires hours and therefore has no direct share in cocain anesthesia. Indirectly, limitation of circulation, including local cooling, is important by delaying absorption.

Effect of Temperature on Local Anesthesia.—With the frog's nerve, this differs for the various types of anesthetics; cocain, salicylamid and monacrin are more effective on cooled nerves; whilst alcohol and chloral are more effective on heated nerves. This is probably connected with differences in solubility, i.e., the "partition-coefficient" (H. Moral, 1918).

General Toxicity to Protoplasm.—Cocain is a typical, if rather weak, protoplasmic poison, paralyzing all sorts of cells, without producing any gross chemical changes. It is toxic to the lower forms of animal life (infusoria, etc.); but has little effect on bacteria, or on ferment.
LOCAL ANESTHETICS

Precipitation of Proteins and Astringency.—Neither cocaine nor the synthetic local anesthetics precipitate proteins; they are therefore not astringent in the ordinary sense, nor irritant (Sollmann, 1910; adalin, anesin, apothesin (slightly), cocain, cyclomol, holocain, orthoform, neurac, procaen, propaen). Anesthetic Action.—Benzyyl alcohol betaecuacain and holocain are antiseptic; cocain and procain are not (Macht and Satani, 1920). Yeast Growth.—This is inhibited by small quantities of cocain, whilst larger doses accelerate (Somogi, 1916).

Toxicity for Earthworm and Tadpoles.—This is not parallel to the toxicity for mammals (Sollmann, 1916).

ACTIONS OF COCAINE ON THE EYE

When cocain is applied to the conjunctiva, it produces local anesthesia (which may not extend to the iris); local anemia (which extends to the iris, but not to the retina); and submaximal dilation of the pupil by peripheral sympathetic stimulation. The mydriasis occurs also on systemic administration. The accommodation is impaired, but the light reflex is preserved; there is some exophthalmus. The intraocular pressure is usually lowered, but may be increased. The mydriasis and its associated phenomena are not produced by most of the cocain substitutes.

Injury.—Cloudiness and even ulcers of the cornea sometime follow the application of cocain; they are explainable by the drying, and the irritation of dust and other foreign matters which are not perceived on account of the anesthesia, and the abolition of the winking reflex. The protoplasmic toxicity may have a part in their production.

Relative Irritation of Conjugated by Various Anesthetics.—Experimental data are given by Closson, 1914. It is difficult, however, to estimate degrees of irritation on animals.

The Cocain Mydriasis.—This differs in important respects from the atropin mydriasis; with atropin, the dilation is greater; the light reflex is lost; the intracocular tension is always raised; exophthalmos is absent. The pupil does not react readily to pilocarpin or mescarin, whilst these constrict the cocain pupil easily.

These differences point to a different mode of action. In effect, atropin paralyses the oculomotor (constrictor) endings, whilst cocain stimulates the sympathetic (dilator) mechanism; for when the sympathetic fibers have degenerated (eight days after extirpation of the superior cervical ganglion) ordinary doses of cocain cease to be effective (Limbourg, 1891; Schutz, 1892). Dilation may still occur, however, with large doses or under special conditions. Simple (postganglionic) division of the sympathetic does not immediately abolish the cocain reaction; the stimulation must therefore involve the endings; but since the dilation is not as strong, it would seem that, ordinarily, the pupillo-dilator center is also concerned (Schultz, 1890).

Under ordinary conditions, the cocain pupil continues to respond to oculomotor stimulation, showing that the constrictor mechanism is not paralyzed. Prolonged application of a 5 per cent. solution, however, also paralyses the oculomotor endings in birds’ eyes cocain produces no dilation, whereas in frogs it is very marked.

Cycloplegia.—This begins in five or ten minutes. The maximum is reached in thirty minutes and lasts ten to fifteen minutes; the normal is restored in one and one-quarter to two hours. The accommodation is merely disturbed by a drop of 0.1 per cent.

Intracocular Pressure.—This may be unchanged, or raised or lowered (Tourniere, 1901). The reduction is probably due to the local vasocostruction, which would tend to lessen the lymph flow into the chambers. This is partly counteracted by the mydriasis, which leads to obstruction of the lymph channels by the relaxed ciliary masses (see “Atropin”). This obstruction may predominate, and the pressure may thus be increased, especially glaucoma (Miyashita, 1913).

Bacine and alypin act similarly. Holocain is said to have provoked acute glaucoma (Gunning, 1915). Tropococain and acin are probably inactive (Bollet and Curtil, 1911).
Reinal Vessels.—These are strongly constricted by cocaine (Hirschfelder, 1913). This may be responsible for the occasional occurrence of optic atrophy (Harnack, 1912).

Smooth Muscle.—This is generally first stimulated, then depressed by cocaine, regardless of innervation (constituting a fundamental distinction from epinephrin). The stimulation is therefore not through the sympathetic; nor is it parasympathetic, for it is not prevented by atropin. It must be exerted directly on the muscle. This applies also to the synthetic cocaine substitutes (Waddell, 1917).

The excised arteria is stimulated by both cocaine, and procain; excised intestine (rabbits) is stimulated by small doses of cocaine and depressed by large doses; it is depressed by procain in all concentrations (Roth, 1917).

The urinary bladder (excised) is stimulated by cocaine, less by the synthetic substitutes. Mixtures of these give simple summation. So does pituitary and epinephrin, the latter being depressant (Waddell, 1917).

Cardiac muscle and the salivary glands are not stimulated (Keroda, 1913).

Striated Muscle.—Rubats and Macht, 1919, investigated the effects of cocaine and most of the synthetic substances (allocain, salpin, apothosis, benzyl alcohol, beta-eucain, holocain, procain and tovalin). All depress the excitability and contractibility, and hasten fatigue. There was no stimulation, even with small doses.

Motor Endings.—Large doses of cocaine paralyze these in frogs. This curare action would not be seen in intact mammals.

Procor on Tetanus.—E. Meyer and Weiler, 1916 and 1917, discovered clinically that the intramuscular injection of procain relaxes traumatic tetanus. This has been further studied by G. Liljestrand and Magnus, 1919. They found that procain injections (½ c.c. of 3 per cent procain, per K.), locally relax various kinds of tonic tetani, although active and reflex movements are not affected. The relaxing effect does not occur, with these doses, if the posterior spinal roots have been cut. Apparently, therefore, the procain acts by abolishing the sensory impulses, which help to maintain tone and tetanus. With larger doses, there is a curare action.

SYSTEMIC ACTIONS

These are rather variable and complex, depending largely upon the dose. Whilst all structures are first stimulated and then paralyzed, the susceptibility to the poison is not uniform. Indeed, some portions of the nervous system show only stimulation, death occurring before the paralysis of these structures is reached.

Stimulation of Higher Functions.—The first effect is a stimulation of the higher parts of the brain (caffein action). This is shown in animals by increased movement (sometimes "circus movements"). In man there is some psychic stimulation and wakefulness. A greater endurance against fatique and hunger is also noticed.

How far this may be due to stimulation after the manner of caffein, or to narcosis, after the manner of morphin, cannot be stated. It is not at all unlikely that both play a part. In regard to the sensation of hunger, it is also probable that local anesthetisation of the stomach aids in the effect.

The resistance to fatigue can be demonstrated with the ergograph.

Another evidence of the stimulating action of cocaine furnished by the fact that animals to which it has been administered are more difficult to put and to keep under chloroform or other anesthetic. Mosso, 1887, and Airila, 1915, find that 10 to 40 mg. of cocaine, hypodermically, wakens dogs or rabbits from deep chloral sleep. The stimulation is greatest with excitable individuals, and may seriously interfere with operations.

Incoordination, Narcosis, Convulsions.—The stage of stimulation may be very short or even absent. With somewhat larger doses it is usually succeeded by depression, first of the coordinating functions. The movements lose their purposive type and become choreic. This is followed by a general narcosis; and then by convulsions. If the paralysis is rapid, the convulsive stage may not appear.

The Seat of the Convulsions.—This has not been exactly determined. They, like the other effects, are probably descending, and the different convulsive centers may be
affected in succession. In some stages at least they seem to reside exclusively in the hind brain. In dogs, they appear to be confined to the cerebral cortex, for Feinberg and Blumenthal, 1887, claim that they do not occur after ablation, nor in new-born animals, in which the cortical motor centers are not yet excitable. Rabbits deprived of the hemispheres do not show the tonic convulsions or respiratory effects; but they do exhibit tonic convulsions and "running movements." Their resistance to toxic doses is increased (Morita, 1915).

Central Phenomena in Frogs.—These show at first symptoms of stimulation by increase of the voluntary movements and exaggeration of the reflexes, sometimes leading to convulsions. This is followed by paralysis of the whole central nervous system. Spinal Cord.—In frogs from which the brain has been removed, cocaine causes at first an increase of the reflexes, then convulsions, and finally total paralysis. In intact animals this effect is obscured by the action on the higher centers of the nervous system. The results of applying cocain directly to the cord will be considered later.

Respiration.—This is at first accelerated. During the spasms it is irregular. The volume then diminishes. It may assume the Cheyne-Stokes type. Respiratory paralysis is the usual cause of death. This is also the first center to fail when the cocain is applied locally to the fourth ventricle.

Roth, 1917, found that small doses of procain also increased the respiration; large doses being depressant.

---

**Figure 9**—Diagram of the Actions of Cocain on Respiration and Circulation. (A rise of the curve signifies an increase or stimulation; a fall, the reverse.

Excised bronchial muscle is somewhat dilated (Trendelenburg, 1912).

Emesis.—The vomiting which frequently occurs in cocain poisoning is perhaps due to the medullary stimulation, but its mechanism has not been fully investigated.

Circulation.—The effects of cocain on the general circulation are partly central, partly peripheral. They vary according to the dose, as shown diagrammatically in Fig. 9. They are also influenced by individual susceptibility.

The typical effects are as follows:

Very small doses diminish the pulse rate, by stimulation of the vagus center (Vulpian, 1846). There is a quick rise of blood pressure from stimulation of the vasomotor center; this is followed by a temporary fall due to the slowing.

Moderate doses quicken the pulse, mainly by central and peripheral depression of the vagus (v. Anrep, 1886) with some stimulation of the accelerator center (Mosso, 1887).
The pressure rises (v. Anrep) from stimulation of the vasomotor center (Berthold, 1885) aided by the faster heart rate. The vasomotor factor is predominant, for the rise in pressure is much larger if the cord is cut and if the vagi have been cut, so that it is of central origin. The quickening from moderate doses is also less marked if the vagi have been divided, so that it is probably due in part to a depression of the vagus center. The vagus ganglia are also depressed, for electrical stimulation of the vagus trunk is only partly successful (v. Anrep, 1886). In the frog these ganglia can be paralyzed completely by the local application of cocaine, but in the intact mammal the paralysis is not complete. Some quickening occurs, however, even when the vagi have been divided, but none is seen if the accelerators have also been cut. The final slowing is due to direct paralysis of the muscle, for it is accompanied by weakening of the contraction, and it occurs after atropin, and in the excised heart.
Cocain also stimulates the cardio-inhibitory center when perfused through the medulla of the turtle (Bush, 1926).

The Excised (Langendorff) Mammalian Heart.—This has been investigated by Helboon, 1890; Kochmann and Dech, 1908; and Prus, 1913. Low concentrations slow and strengthen the contractions; higher concentrations cause slowing and weakening; fatal concentrations give diastolic arrest. Kuroda, 1915, observed no stimulation of excited hearts of mammals or frogs.

The excised frog’s heart is stimulated by small concentrations (Mosso, 1890), and depressed by high concentrations. The terrapin’s heart is similarly affected (H.G. Beyer, 1885).
Roth, 1917, describes decreased rate and diminished systolic excursions for both cocain and procain. Kuroda, 1915, on perfusing the heart with 150,000 of cocain observed typical block with 2:1 rhythm. This was prevented by atropin (0.000) or epinephrin (0.000000000).

The effects on blood pressure have been described mainly by Ott, 1874; v. Anrep, 1886; Vulpian, 1885; and Reichert, 1891. The comparative effects of cocain and procain have been investigated on dogs by Kamenovze, 1912. Roth (1917) found that both drugs increase the blood pressure in small doses, and lower it when given in large doses.

Splanchnic Circulation; Influence on “Shock.”—The intravenous injection of cocain has a very pronounced effect on the splanchnic circulation. The intestines appear unusually pale. Handling of the viscera and other measures of “shock” which cause a splanchnic dilatation and consequent fall of blood pressure in normal animals, have less or no effect after cocain. Burning and stimulation of the stigmatic, which cause a rise in pressure normally, are also ineffective (Crisle, 1901). Ford, 1906, on the other hand, claims that local anesthesia (by cocain, its substitutes, or freezing) does not abolish the depressant reflexes (decrease of muscular work, of sharpness of vision, etc.); these occur from procedures which would ordinarily be painful, even when the sensation of pain is eliminated.
Cerebral Circulation.—This is increased by cocain, and still more by procain (Frankfurter and Hirschfeld, 1910). The vessels of the retina and pia mater are constricted (Hirschfelder, 1913).
The urine flow is generally diminished, but sometimes increased, depending mainly on the vasomotor effect.

Temperature.—Cocain causes a rise of temperature, due essentially to increased heat production, and this largely from muscular excitement (see chapter on “Heat Regulation”).

Effects on Metabolism.—In rabbits, large doses of cocain cause rapid loss of weight. The quantity of urine, its specific gravity, and particularly the urea, are diminished, whilst the incompletely oxidized (extractive) nitrogen is increased. During recovery, the quantity of urine returns promptly to normal or above; the disturbances of the nitrogen metabolism persist for some time (Maestro, 1904).

The effects of repeated injection on dogs have been investigated by Underhill and Black (1912): Dosage of 10 mg. (per kilogram) produced no change in fat or nitrogen metabolism; 15 mg. gave a slight improvement of fat utilization, and considerable decrease of body weight; 20 mg. markedly decreased the nitrogen and fat utilization. The nitrogen balance may become negative. Lactic acid excretion was markedly increased in well
LOCAL ANESTHETICS

led dogs, but not in starvation—the increase being probably due to the muscular activity. The ammoniaceous output bore little relation to the lactic acid.

Blood-sugar.—This is not changed (cats, 15 to 35 mg. per kilogram), except as a result of excitement (Schaefer, 1913).

Sympathetic Stimulation.—The symptoms of cocaine poisoning correspond to stimulation of the sympathetic system; i.e., they are analogous to epinephrin, although the analogy is not perfect. The real synergism of the two drugs extends to these sympathetic effects.

The sympathetic symptoms consist, for instance, in the mydriasis and slight exophthalmos; constriction of the ear-vessels; erection of hair; relaxation of intestines. In rabbits, these are produced by the hypodermic injection of 35-50 mg. of cocaine, or by 10 mg. of cocain plus 1 mg. of epinephrin (Mills, 1910).

Fate of Cocain.—This is partly destroyed in the organism, but mainly excreted unchanged in the urine (contrary to the results of Wiechowski, 1912).

Rilwackshal, 1911, recovered 42 to 85 per cent. from the urine of rabbits after acute poisoning, and all in chronic poisoning. None was present as ecoin; but if ecoin itself was injected, 75 per cent. was recovered from the urine. Cocain left for several hours in a ligatured limb was not destroyed.

Persistence of Effect and Cumulative Action.—Most synthetic local anesthetics are destroyed so rapidly in the body, that the toxicity is much smaller when the drug is introduced slowly. Cocain and phenacain (holocain), however, are not destroyed nearly as promptly (Eggleston and Hatcher, 1910). Mills, 1910, obtained contradictory results with cocain according to the criteria: No cumulative effects were noted unless injections were repeated in less than 1½ hour, indicating rapid destruction. On the other hand, papillary effects could be demonstrated after 25 hours, so that the iris must retain the drug for longer periods.

 Destruction of Cocain in Vitro; Sterilization.—Long-continued boiling decomposes cocain into benzoil-econin and methyl alcohol. It was therefore believed that solutions could not be sterilized by boiling. In fact, however, the decomposition on boiling half an hour, is insignificant (Merck, 1907; Holbrook, 1912); and even longer boiling only decreases the activity, for the decomposition products are merely inactive and not toxic. Any decomposition on boiling is probably due to alkalinity from the glass (Baumestein, 1917).

Water solutions of basic cocain deteriorate rapidly, losing their anesthetic power within 7 hours; and still more rapidly when heated. Basic procaain and alypia are stable in solution (Gros, 1912).

Solutions of cocain salts are much more stable than basic solutions, but liable to mold. Procaain solutions are said to be difficult to sterilize (Esenr, 1917). They turn brown on keeping, and such changed solutions should not be used until their pharmacology has been established.

Resistance to Pseudohex.—Positive tests for cocain were obtained in cadavers even months after death (Pate, 1919).

Benzoil Ecoin.—This was found by Stockman, 1886, to resemble ecoin in its central and muscular action. It had no effect on sensory nerves or the pupil.

ACUTE COCAIN POISONING; ETIOLOGY

Toxicity.—This is of special importance, since cocaine poisoning is not a very uncommon occurrence in the therapeutic employment of the drug. Very large amounts are sometimes used in a most careless manner for local anesthesia; and since the absorption is fairly rapid, serious and even fatal results may follow. The susceptibility varies enormously, due partly to
the uncertainty of the absorption; partly to the rapidity of destruction and partly to the varying intensity of the effects.

There seems to be a very considerable psychic element (fright) in some of the "accidents."

Bibliography of Clinical Intoxications.—Egleston and Hatcher, 1912.

Frequency of Fatalities.—Reliable statistics are not available, but fatalities appear to be much more common than is ordinarily supposed (E. Mayer et al., 1910).

Mistakes in Drugs or Dosage.—A large proportion of the anesthetic accidents (25 per cent. in one series) are due to mistakes in the drugs, concentration and dosage (E. Mayer et al., 1910). These could probably be avoided almost entirely by employing the toxic drugs only as tablets, colored by a distinctive dye; so that the tint of the solution would inform the surgeon of the nature and concentration of the drug.

Safe and Toxic Dosage of Cocain.—This depends so largely on rapidity of absorption and idiosyncrasy, that absolute figures are rather misleading. The toxicity is greatly diminished by the addition of epinephrin.

The ordinary fatal dose of cocaine is considered to be about 1.5 Gm. (18 gr.) Kussik but death has been reported from 0.02 (½ grain) and severe poisoning from 2 drops of 4 per cent. solution (5 mg.) on the conjunctiva, and with three drops of ½ per cent. cocaine (2 mg.) in a tonsil operation (Mayer). In other cases, very large doses produce no effect (bibliography, Roth, 1917).

Propion proved fatal in a tonsil operation with 4 c.c. of ½ per cent. (0.025 Gm.) injected with epinephrin (Mayer).

"Safe Dose."—This has been placed by various writers between 0.05 and 0.4 Gm. (½ to 5 gr.). Strictly speaking, the "minimal fatal dose" would be obtained by intravenous injection of concentrated solutions. This would probably be less than 0.01 Gm.; i.e., a dosage that would often be insufficient for ordinary operations (Braun). Very much larger doses can be used with almost perfect safety, if systemic absorption is checked.

Dilution slows the absorption of cocaine and insures its thorough utilization, and thus economizes its use. Solutions above 1 per cent. should not be used for hypodermic injection. With solutions of ½ per cent. and proper precaution, Reclus considers 0.2 Gm. quite safe.

Safe Operations.—In open wounds or body cavities or other surfaces from which any excess will be removed when the operation is completed, the total quantity of cocaine is practically immaterial if dilute solutions (0.1 to 0.2 per cent.) are employed; for only a small fraction will be actually absorbed.

Dangerous Operations.—Cocaine is especially dangerous when 2 to 10 per cent. solutions are injected into closed mucous or serous cavities, such as the urethra, bladder, scrotal sac, etc. Very severe poisoning has repeatedly followed after urethral injection of 1 Gm. in 5 to 20 per cent. solution, in one case even after 7 c.c. of 1 per cent. (0.07 Gm.). Indeed, a fairly large number of toxic cases are reported from 0.05 to 0.025 Gm. in 20 to 20 per cent. solution (Weigand, H. Braun, 1914).

Tonsil operations, when cocaine is injected, show many more fatalities than operations on the nose (Mayer).

The toxicity is increased by severe hemorrhage, also by chloral narcosis; probably by interference with the activity of the liver (Egleston and Hatcher).

Symptoms with Slow Absorption.—The symptoms vary according to the rapidity of absorption. If this occurs relatively slowly, there is confusion, laughter, vertigo, motor excitement; quickened pulse and palpitation; irregular respiration; pallor, chill, with sweat and rise of internal temperature; dilated pupils and exophthalmos; nausea; vomiting and abdominal pain; great anxiety; disturbance of cutaneous sensation (worms under skin, etc.); finally delirium, dyspnea and Cheyne-Stokes respiration; convulsions, unconsciousness; and death by collapse and asphyxia.

However, if the death has not occurred within a few minutes, the patient will almost always recover. Unconsciousness and Cheyne-Stokes

\[1\] Fuller description in Selkirk, Noonan, 1915, p. 51.
respiration may persist for one or 2 hours. Recovery may be followed by more lasting psychic depression and melancholia.

With rapid absorption (especially from mucous membranes) severe symptoms may develop without warning: fainting, extreme pallor, brief convulsions, and death, generally in a few minutes.

Practically the same symptoms occur in fatalities with the synthetic substitutes (procain, apothezin, etc.; Mayer).

Symptoms in Animals.—These symptoms of acute clinical intoxications by the local anesthetics are closely paralleled by animals, especially cats (Eggleston and Hatcher, 1919).

Intravenous injection of fatal doses produces almost instant extensor spasm, fixation of the respiration, and sudden cessation of the heart.

Subcutaneous injections cause immediate stimulation of the respiration and abrupt fall of blood pressure of cardiac origin; the heart-rate being inconstant, but generally slowed. The respiration may be temporarily arrested.

Within a minute, the heart begins to improve and the blood pressure rises; the respiratory stimulation diminishes; there may be brief but severe clonic convulsions. Within five minutes the animals may be apparently normal.

As the doses approach the fatal, the convulsions are more prolonged, and recovery is slower; especially after cocaine (Eggleston and Hatcher, 1919).

Treatment of Poisoning by Local Anesthetics.—If the drug has been taken by mouth, evacuation and chemic antidotes are indicated. If the anesthetic was injected, absorption should be checked by ligation, epinephrin or cooling.

If symptoms have developed, the head should be lowered; collapse treated by aromatic ammonia and caffeine; convulsions allayed by ether or chloral; and artificial respiration applied as needed. Amyl nitrite has been recommended. Epinephrin and ouabain, intravenously, and cardiac massage are useful in animals (Eggleston and Hatcher, 1919), but have not been tried sufficiently in the clinic. Whatever delays death is likely to save the life, in view of the rapid destruction of these drugs.

As prophylaxis, the patient should be recumbent, if the operation permits. With nervous patients, it is advisable to inject morphin 15 minutes before the local anesthetic, and to delay the start of the operation till 30 minutes after the injection of the local anesthetic (Mayer et al, 1910).

CHRONIC COCAIN POISONING

This bears considerable resemblance to the morphin habit. It is unfortunately on the increase, especially amongst negroes, prostitutes, and the criminal classes (see under "Morphin Habit").

The immediate effects consist in a sense of elation and increased mental and physical vigor. The excitement may rise to delusions and mania. These stimulant effects are succeeded by depression, tremors, with pale face, pale sunken and unsteady eyes (Owens, 1912).

The chronic effects are similar to those of the morphin habit, with more severe psychic disturbance—insomnia, hallucinations, apathy, melancholia, suicidal mania. (For Cocain Psychoses, see Vallon and Besiere, 1914.) The pupils are inconstant. A very considerable tolerance is acquired, so that the daily hypodermic consumption often reaches 25 Gm., sometimes even 10 Gm. (Grose, 1917). Animals do not become tolerant (Grose, 1913). Chouppe, 1889, claims that morphinists are relatively tolerant to cocain. Sudden withdrawal leads to abstinence symptoms very similar to those of morphin.
With cocaine snuffing, where smaller amounts are used in intermittert debacles, the chronic effects, the craving and the abstinence symptoms are proportionately less marked. Such patients show characteristic ulceration of the nasal fosse (Owens; also present in heroin snuffing Phillips).

The treatment of cocaine habit coincides exactly with that of the morphin habit (which see); it is said to be more difficult to cure.

The prescribing of cocaine and tropococaine comes under the Harrison Anti-narcotic Law. This does not apply to the synthetic substitutes.

ADMINISTRATION OF LOCAL ANESTHETICS

Sensory nerves may be paralyzed at their periphery: terminal or surface anesthesia; or in their course: conduction or injection anesthesia. This "blocking" of the nerve fibers may be done by infiltrating the field of their peripheral distribution: infiltration-anesthesia; or by injection into or around the nerve-trunks: intraneural or perineural methods; or at the point of origin in the spinal canal: spinal or subdural anesthesia.

Surface Anesthesia.—Anesthesia from intact surfaces requires that the drug must be absorbable. This excludes the intact skin. Cocain and butyn are readily absorbed from mucous membranes, and are therefore efficient, but also correspondingly toxic. Procain and apothecaries are relatively inabsorbable and therefore less applicable. Alpyin and beta-eucaia are intermediate; but the order of absorbability varies for different mucos.

Eye.—For conjunctival application cocain (1 to 5 per cent.) is still the dominant anesthetic; perhaps mainly because it is not irritant. Phenacain (holocain) useschat 1 per cent. is equally efficient, but more irritant and toxic. Butyn, 2 to 4 per cent., appears promising. Tropococaine and beta-euacain require stronger solutions (3 to 5 per cent.). Procain is not suited to the conjunctiva, but may be used for deeper operations.

A single application of 2 per cent cocain produces complete anesthesia of the conjunctiva and cornea, starting in 2 minutes, and lasting 7 to 10 minutes. If 5 per cent. cocain is instilled every 3 minutes for half an hour, the anesthesia generally extends also to the iris. Epinephrin does not enhance the efficiency in the eye (Sollmann, 1913).

Cocain dilates the pupils, and contracts the vessels; the other anesthetics do not.

Urethra and Bladder.—The urethra is a good absorbing surface, and has therefore often given rise to poisoning. This danger is practically obviated by using dilute solutions. These are efficient if sufficient time is allowed. Braun, 1903, advocates cocain 0.1 to 0.2 per cent. for the bladder, 0.5 per cent. for the urethra; both with epinephrin (about three drops of 1:1000 for the entire injection).

Alpyin has been rather a favorite, since it is also readily absorbable, and is supposed to be less toxic. However, fatal accidents have occurred from the usual doses. It is used as 0.5 per cent. for the bladder; 5 c.c. of 1 per cent. for the urethra. Braun endorses the addition of epinephrin, as for cocain.

Absorption of the Hydrochloride from the Urethra.—Sollmann, 1918, found that alpyin and tropococaine were absorbed somewhat better than cocain; apothecaries, betaecain, and procain were absorbed somewhat less efficiently; but the differences were not great.

The rate of absorption increases with the dose and concentration. The absorption is more rapid during the first ten minutes, but continues quite markedly after this time. Alkalization does not increase the absorption.

Operations in Nerve.—Practically all operators prefer local anesthesia as being more convenient than general anesthesia and at least equally safe. The most common method is to swab the mucosa with epinephrin solution, 1:10,000, then to apply a little of the solution on the cutaneous part with an applicator; or a trace of powdered cocain at the point of a moistened probe. The strong cocain solutions are fairly safe in this case because only a small surface is covered. For more extensive operations, this is followed by the slow injection of procain solution (1/4 to 1/5 per cent.; generally 1/5 per cent.) in epinephrin 1:50,000 (Mayer et al, 1920).
Operations on Tonsils and Adenoids.—The majority of American operators favor local anesthesia, notwithstanding occasional accidents. The preferred practice consists in swabbing with 5 or 10 per cent. cocaine, followed by the slow injection of a synthetic anesthetic, i.e. ½ to 1 per cent. of procain in 1:50,000 epinephrin. Preliminary morphia is advisable (Mayer et al, 1920).

Operations on Larynx.—These require careful application of fairly strong (10 to 20 per cent.) cocaine solutions (Mayer et al, 1920).

Insoluble Anesthetics for Open Wound and Ulcers.—The soluble anesthetics are absorbed too rapidly to be of material use in persistent pain. The limited and slow solubility of some of the free synthetic bases renders them more adapted to these conditions. However, their practical usefulness is limited. They are employed for painful wounds, ulcers, etc., of the skin and accessible mucous membranes; for instance, after dental operations. They have also been used against the pain of gastric ulcer or cancer and other gastralgias; but here their efficiency is doubtful.

Anesthesia, cycloform, orthoform-new and propaesein are all about equally effective through intact mucous membranes (Sollmann, 1919). They are practically non-irritant and non-toxic.

They may be diluted with 10 parts of sterilized talcum.

Catarh, Hay Fever and Asthma.—Cocainization of the nasal mucous membrane may temporarily relieve attacks of hay fever and asthma. The astringent action makes it effective in acute coryza.

One per cent. cocaine ointment has been recommended in herpes noster; it is said not only to relieve the pain, but to put a stop to the disease.

Cocain locally relieves hemorrhoids, producing contraction and diminishing pain. It has been taken by the stomach to prevent vomiting and dyspeptic pain. The danger of the formation of the habit interferes with its use in these conditions; indeed many cases of cocaine habit were started by prostatytic catarh "cures."

Infiltration and Conduction Anesthesia.—None of the local anesthetics penetrate effectively through the intact skin. In most operations they must therefore be injected. Since any excess of the injected anesthetic is not easily removed, the greatest economy must be practiced by employing dilute solutions, placing these only where they are needed, and keeping them there by limiting the circulation by epinephrin or ligature. In view of its relatively low toxicity, procain (novocain) is preferred to cocain, aphiathin, benzyl alcohol, and saligenin are also successful.

It is not necessary to flood the entire field of operation, as in the earliest methods; nor even to infiltrate the whole line of incision, as in the "infiltration anesthesia" of Schleich (1892). It is now aimed to confine the anesthetic mainly to the nerves, by placing it where the nerves chiefly run, or injecting it into the nerves themselves (H. Braun).

For instance, one would start with a small wheal, produced by the intradermal (not hypodermic) injection of a few drops of 0.5 per cent. procain and 0.0005 per cent. epinephrin in normal saline. Through this anesthetized wheal, the needle is thrust forward into the subcutaneous tissue, and the same solution is injected, so as to outline the operative field. This blocks all the nerves of the area.

When feasible, the injection is made directly into the nerve trunk (intraneural method). For nonexposed large nerves, this requires 1 to 2 c.c. of 1 to 4 per cent. procain, or exposed nerves, 0.5 to 1 per cent. suffices (Braun). Epinephrin should be added in the proportion of 1 mg. per Gm. of procain.

If the injection is made quickly and directly into the nerve tissue, the procedure is quite painful. A few drops should first be injected under the nerve sheath. When these have caused a local anesthesia, the needle should be pushed deeper and more of the solution injected, until the anesthesia is complete. In this way the pain is relatively
slight. Anesthesia requires fifteen to twenty minutes, and is not always complete successful.

Anoxia association.—Crlie believes that the afferent impulses which reach the brain even in profound general anesthesia are distinctly harmful to the patient; and if therefore these impulses should be suppressed by blocking the nerve paths from the is of operation by the use of local anesthesia. It may at times be justifiable to operate without the knowledge of the patient which is quite feasible by the use of cocaine (Crlie).

Morphin in Local Anesthesia.—Nervous, fearful and excitable patients often suffer severely from apprehension that local anesthesia may not allay. This also disposes toward accidents. It may be at least somewhat quieted by morphin (0.015 Gm. hypodermically) half an hour before the operation.

Morphin and atropin, in moderate doses, do not materially alter the toxicity of cocaine or procain for cats. Large doses of morphin tend to relieve the convulsions, but increase slightly the toxicity of the anesthesia (Hatcher, quoted by Mayer).

Intravenous and Intraarterial Anesthesia.—These were introduced by Bier, 1910, and have a limited field. The limb, for instance, is ligated above and below the field of operation, and the solution is injected into a vein or artery of the ligated area.

Intravenous Injection of Cocain.—The action of cocaine is sufficiently selective so that a marked, though incomplete general analgesia, without disturbance of consciousness or motor functions, can be produced by intravenous (Ritter, 1900; Harrison, 1911) intra-arterial (Ransohoff, 1909) injection. However, these methods are both unsafe, factory and dangerous (Bevan, 1915).

Spinal Anesthesia.—The subdural injection of cocaine, or other local anesthetics, anesthetizes the sensory nerve roots at their emergence from the spinal cord. This abolishes sensation in their entire peripheral distribution, beginning in 2 to 10 minutes and lasting for about one and one-half hours (one-half to two hours), without loss of consciousness or motor functions. The anesthesia extends to the level of the nerve roots reached by the cocaine, the aim being to confine it to the lower half of the body. If it should extend to the fourth ventricle, it would paralyze the respiration. Alarming symptoms and fatalities from this cause are not infrequent (Seifert, Nebenwirkg., 1915, p. 105), and the method is more dangerous even than chloroform. The fatality is probably over 1:500 (Bevan). It has also been fatal to the fetus in utero (Jung, 1914). Minor accidents are not uncommon. Cord injuries are sometimes produced, severe headache may last for days or weeks. Further, the technique is difficult, disagreeable to the patient, and the anesthesia is often unsuccessful. Spinal anesthesia should therefore not be employed (Hohmeier and Koenig, 1910), unless inhalation anesthesia is directly contraindicated (Anesthesia Commission, Journ. Amer. Med. Assoc., 1908). It is especially useful in pulmonary disease, arteriosclerosis, bladder and rectal cases, impending uremia, and diabetes; emergencies after a full meal. It is not justifiable to use it for operations above the costal margin (F. L. Richardson, 1913). Bevan, 1915, can see no justification for spinal anesthesia under any conditions.

Technic of Spinal Anesthesia.—The method was demonstrated by Cornig of New York in 1865, and introduced into practice by Bier, 1899, but it was temporarily abandoned, and did not come into vogue until about 1904. The injection is performed by lumbar puncture, withdrawing a little cerebro-spinal fluid, and introducing 5 to 10 c.c. of 1 per cent. cocaine solution; or more commonly, corresponding quantities of its substitutes; Tropocain, 5 per cent., procain (not above 0.15 Gm.); stovain (not above 0.5 Gm.; beginning with one-half or two-thirds of these doses). Epinephrin and strychnin...
may be added. Glucose, 5 per cent., diminishes the spreading of the solution by lowering its specific gravity. E. Erbhardt, 1905 and 1912, proposed with the same object, to increase the viscosity by acacia. Bulk of solution (dilution) favors spreading (Smith and Porter, 1913).

**Phenomena of Spinal Anesthesia.**—These occur in the following order: Loss of knee-jerk; of plantar and cremasteric reflex; ascending analgesia; later, ascending loss of motor power. The upper limit is usually quite abrupt. Subjectively, there is an ascending feeling of warmth, swelling and heaviness. Occasional toxic effects are pallor, nausea, vomiting, sweating, feeble pulse, relaxation of sphincters, dyspnea. The most frequent side-effects are headache and insomnia.

**Fall of Blood Pressure.**—This is a very common phenomenon of spinal anesthesia. Smith and Porter, 1915, found that it is due to paralysis of the splanchic fibers in the cord, not in the medulla. Epinephrin with tropacocain or procain caused even a greater fall. Measures to restore the pressure were only temporarily successful. As the effects of the anesthetic began to wear off, sciatic stimulation produced a fall, in- stead of the normal rise.

The combined action of stovain and strychnin on the cord has been investigated by Ann and Rothman, 1909; and Simon, 1915. The two drugs are not antagonistic; and strychnin does not render stovain any safer.

**USE OF COCAIN AS CEREBRAL STIMULANT**

Cocain has been employed to combat fatigue, and as a general tonic. It has no advantages and many disadvantages as compared with other stimulants, especially cafalin. The danger of habit formation should suffice to condemn it. That the harm has not been greater may be attributed to the unreliability of the coca preparations which are generally employed.

**Comparison of Cocain and its Substitutes.**—Cocain is very satisfactory from the standpoint of efficiency, penetration, and practical absence of tissue-injury. However, its rather high toxicity has led to the use of substitutes wherever practical. Some of these present advantages in special fields, although they lack the general applicability of cocaine. These special fields were pointed out in discussing the applications of local anesthetics.

Structure of Cocain.—Cocain is the methyl-benzoyl ester of ecgonin, a base closely related to tropin, the corresponding base of atropin, both being ptyroldin derivatives.

**Relation of Structure to Actions.**—Ecgonin itself produces only the least important of the actions of cocain, viz., the hepatic degeneration. The other actions are only induced by the entrance of both radicals. The methyl may be replaced by any other aliphatic radical, without changing the actions of cocain. The benzoyl radical, however, may not be replaced by other aromatic acids (possibly with a few exceptions) nor by fatty acids without great impairment of the local anesthetic action. Indeed, the presence of the benzoyl group gives the anesthetic properties to other alkaloids, and may be considered as the hook by which the molecule attaches itself to the protoplasma of the sensory cell. It is present in most of the coca subsitutes. The required conditions for the development of a local anesthetic action seem therefore to be: a base with a structure analogous to ecgonin, containing a benzoyl and an aliphatic radical in certain relations.

**Principal Differences between Cocain and its Substitutes.**—These concern especially the following points:

**Toxicity.**—It is generally believed that cocain has the highest toxicity. This conclusion was based primarily on animal experiments, which, however, yield equivocal results. Nevertheless, it seems in harmony with clinical experience.

**Toxicity-comparisons on Animals.**—Extensive series of experiments have been published, for instance by Kochmann, 1914, Closson, 1914, Le Brocq, 1909. These show that cocain is perhaps three times as toxic to guinea-pig, on hypodermic injection,
than are most of the substitutes. This result has very generally been transferred to man, but without real justification. Rodents depart widely from man in their quantitative response to many poisons. The rate of penetration and absorption is a highly important factor in poisoning. Obviously, the hypodermic injection into guinea pigs does not reproduce the absorptive conditions, for instance, of the human urethra.

**Intravenous Toxicity for Cats.**—This would be a more definite index of absolute toxicity, but its clinical application would also be limited. Eggleston and Hatchett, 1918 and 1919, found the M.F.D. as follows:

<table>
<thead>
<tr>

</table>

Combinations of any two of these local anesthetics produce simple summation of the effects, so that they would not offer any advantages from this standpoint. The systemic actions of all are similar, death occurring by combined cardiac and respiratory paralysis.

Procaic, apopain and stovain and probably also the other synthetic anesthetics are rapidly destroyed in the liver.

The hypodermic fatal doses are therefore more than five times greater than the intravenous, except with the relatively indestructible cocain and phencain.

**Irritation and Tissue-injury.**—In ordinary concentrations, cocain, procaic and apopain are practically non-irritant. Eucaic, alypin, phencain (holocain), and benzyl alcohol produce smarting and some pain, but no permanent injury. Tropacain raises wheals on the scarlet skin. Stovain and quinin-urea cause more pain, and lead to induration or gangrene if the ordinary concentrations are exceeded.

The irritative phenomena have been compared for the intracutaneous injection by Brocas, 1905. Procaic up to 5 per cent. produced no pain or hyperemia. Stovain caused strong local irritation, even with dilute solutions; and gangrene with 10 per cent. Alypin, as dilute as 0.1 per cent. gave pain and hyperemia, but less than stovain; 1 per cent. produced persistent irritation; and 5 per cent., gangrene. Cocain is practically non-irritant.

The irritative phenomena have also been studied by Le Broc, 1919; Kochmann, 1914, and Closson, 1914.

**Combination with Epinephrin.**—The vasoconstrictor effect is produced perfectly in the presence of cocain, procaic, benzyl alcohol, apopain and probably alypin. The other interfere more or less; tropacain completely.

**Penetration of Mucous Membranes.**—This probably varies in different situations. Generally cocain, alypin, benzyl alcohol, eucain and holocain are effective; whereas procaic and apopain are relatively ineffective.

**Stability of Solutions.**—Cocain solutions should be freshly made, although their deterioration is not so rapid as was formerly supposed. Alypin solutions also should not be kept longer than a week (Impms, 1905). The others keep for a considerable time. Phencain (holocain) solutions must be slightly acid and are therefore irritant. Procaic solutions become discolored.

**Sterilization.**—This was formerly considered a material advantage of the substitutes; but it is now conceded that cocain solutions can be safely brought to boiling.

**Habit-formation.**—This has not been described for any of the cocain substitutes.
LOCAL ANESTHETICS

Incompatibilities. — The substitutes have in general the same incompatibilities as cocaine.

Solubility of the Bases in Oils. — This is in descending order: Alpyin (all proportions), cocain, procain, cocain (Gros, 1910).

PREPARATIONS — COCAIN

Coca Folia. — The dried leaves of Erythroxylum Coca and E. truxillense, shrubs indigenous to Peru and Bolivia, and cultivated in tropical countries. Ceylon coca contains mainly cocain; Java coca contains only other echogon derivatives (Jong, 1911).

Cocaine, U.S.P., B.P., C₈H₁₇NO₄. — Colorless prisms or crystalline powder, of slightly bitter taste followed by anesthesia. Slightly sol. in water (1:600); freely sol. in alc. (1:2.5), chloroform, eth.; sol. in oils (1:12 olive oil). Used especially in ointments. Dose, 15 mg., 1/4 gr.

*Coacín. Hydrochlorid. U.S.P.; B.P., C₈H₁₇NO₄.HCl. — Colorless, transparent prisms; or flaky, histruscent leaflets, or white, crystalline powder. Very sol. in water (1:2.4); freely sol. in alc. (1:1.3); sol. in glyc. ; practically insol. in oils. Incompatible with alkales, sodium borate (not boric acid), silver nitrate and calomel. Solutions decompose on keeping (a 15 per cent. solution in Dilute Alcohol is said to be permanent; Wintersteiner, 1906). Contrary to older statements, they are not materially decomposed by boiling. Dose, 15 mg., 1/4 gr. U.S.P.; 5 to 10 mg., 1/50 to 1/50 gr. B.P. Maximum dose, 50 mg., 1/4 gr.

Inject. Cocain. B.P.— 5 per cent. Dose, 0.3 to 0.5 c.c. 5 to 10 minims, B.P.

Trach. Kramer et Cocain. B.P.—60 mg. of Krameria; 3 mg. of cocain.

PREPARATIONS — SOLUBLE SYNTHETIC ANESTHETICS

Alococin S. — This is a complex benzoil derivative. Kubota, 1919, claims that it is somewhat less toxic and more anesthetic than procain, but rather more irritant. It does not appear to have any real advantage.

Alypin. N.N.R. — Benzozxydimethylaminomethylmethylaminobutane hydrochlorid. — This is efficient on mucous membranes, and is used especially in the urethra. Its structure resembles strovan.

It is more irritant than cocain. Several cases of sudden collapse and asphyxia, due its injection, have been reported (Kitter, 1912; Lichtenstein, 1914; Inbar, Hebern, 1915, p. 194). The maximal dose of 0.25 Gm. must not be exceeded. Alypin solutions should not be kept longer than a week (Impens, 1905). They are not readily precipitated by alkales and the base is very soluble in oils.

Apnoeth. — Diethylaminomethylpropylcinnamate hydrochlorid. Properties and uses resemble procain.

Douage, for Injection anesthestic, 1 to 2 per cent., with epinephrin 1:100,000. On cerat. 2 to 4 per cent. Spinal anaesthesia, 2 c.c. of 4 per cent.

Apopthésis is relatively safe; but severe collapse has been reported from the injection of 1 in 2 per cent. solutions in throat work (Mayer et al., 1920); and death has occurred from spinal injection (Ireland, Duboff, 1920).

Benzyl Alcohol, N.N.R. (Phenylmethyl) C₆H₅CH₂OH. — This was introduced by Matz, 1918, as an effective local anesthetic of low toxicity (being largely converted into acetic acid). Intravenous injection causes vasoconstriction. The pure substance is irritable and somewhat corrosive; but the watery solutions, which contain up to 4 per cent., are not irritant.

Hirschfelder, 1920, claims that injections of benzyl alcohol solutions in man are satisfactory; that the anesthesia is uncertain; and that it is often followed by subcutaneous edema and local pain.

It is somewhat antispetic (Macht and Nelson, 1948); but ordinary concentrations act too slowly to be efficient in wounds.

It is used for injection anesthestic, generally as 1 per cent. solution. This is also anesthetic on mucous membrane, but the action is rather brief (Sollmann, 1919).

Benzyl alcohol is effective against the itching of dermatitis; for instance in the older grades of "mustard gas" poisoning. It is used as a 10 per cent. ointment in fest; or as a mixture of equal volumes of benzyl alcohol, alcohol and water (Hess).

Spinal anesthesia has been produced in dogs by 2 to 4 per cent. solutions in oil or saline (Voegtlin and Livingston, 1918). Benzyl alcohol is soluble in all proportions in oil.
Benzyl Carbinol (Rose-Oil), C₇H₅C₂H₅OH.—Hjort and Eagan, 1919, find the anesthetic action more powerful than that of benzyl alcohol. Its toxicity is about the same but is more stable and sufficiently soluble for therapeutic use.

Its isomer, phenyl-methyl-carbinol, is even more effective, but also more toxic. It is unstable, and therefore not practical (Hjort and Kaufmann, 1920).

Buteoin Base. Hydrochloride (Eucain, Hyochol). U.S.P. (trimethyl-benzoyl piperidine), C₁₈H₁₉NO₂·HCl.—White, crystalline powder; odorless. Sol. in hot water (1:75) and alc. (1:55). Dose, locally, one to two times that of cocaine. The anesthetic effect is perhaps slightly slower and weaker, and the irritation considerably greater than with the same concentration of cocaine. The pupils are not dilated; the tissues a rendered hyperemic. The toxicity is four to ten times that of cocaine. Toxic doses cause convulsions, central vagus stimulation, and direct cardiac depression, with fall of blood pressure (Seifert, Nebenwirk., 1917. p. 62. case and bibliography, Ddr. 1940).

Benzoquin. Lact., B.P. (Beta-eucain Lactate). C₂₀H₂₄O₇·C₂H₅OH.—Freese in water (1:100) and alc. (1:18). Dose, 8 to 10 mg. i. e. to 15 gr. R. P.

Carbinols.—A series of phenyl-carbinols was investigated by Hirschfelder et al. 1920 (See below, Saligenin). All are anesthetic.

Phenocain (Holocain), N.N.R. (phenethyl-acacetophetanid hydrochloride). Colorless crystals, soluble in 50 parts water. Dose, for eye, 1 per cent. Anesthetic action about as strong as cocaine, but more rapid (anesthesia in half a minute); more toxic. N. effect on vessels has been reported (Gessing 1912).

*Procaïn (Novocain), N.N.R. (aminobenzoyl-diethyl-amino-ethanol hydrochloride).—Colorless needles, sol. in equal weight of water, or 50 parts alcohol. The solution is compatible with silver salts. Doseage, locally, one to three times that of cocaine. Anesthetic and irritant action perhaps slightly less. No effect on pupil.

Procaïn is safer than cocaine. Occasionally, however, toxic effects occur even with small doses (0.01 to 0.13 Gm.); while in other cases up to 3 Gm. have been used safely. There is no definite ratio between the toxicity of procaïn and cocaine, since this depends enormously on the rate with which they enter the circulation; especially in the case of procaïn. This is due to the rapidity with which procaïn leaves the circulation, being fixed and probably destroyed in the liver. Epinephrin diminishes the toxicity, even by intravenous injection, probably by cardiac stimulation (Hatcher and Eggelston, 1916).

Both, 1917, found that the heart toxicity ratio of (procaïn: cocaine) varies for different animals from 1:4 to 10 for frogs to 1:10 for rats and guinea pigs. By intrabular injection, the effect was not so distinct. The effects on pulmonary and renal circulation were unimportant.

After subduial injection, the excretion reaches its maximum rate in 2 hours, and is completed in 6 hours (Achard, 1910).

The details of the clinical toxic effects are described by Seifert, Nebenwirk., 1917. p. 78, hembar, p. 107. Renal irritation is not uncommon after local use of 5 to 10 per cent; but disappear in a few days (Morian, 1917).

Procaïn-derivatives.—A series of aromatic analogs have been studied by J. Braun and Hirschbaum, 1929.

Saligenin (Salicyl alcohol, saligenin). N.N.R., C₁₁H₁₄OHCH₂OH.—Hirschfelder et al. found this the most effective, and the least toxic and irritant, of the phenyl-carbinols as far studied. Its toxicity is much lower than that of the procaïn-apothesynyte. It is transilluminating, 2 per cent, saligenin appeared as effective as procaïn.

Stevan, N.N.R. (benzoyl-ethylmethylaminopropanol hydrochloride).—Colorless scales, extremely soluble in water, or in 5 parts alcohol. Doseage, locally, as for cocaine. Anesthetic action slightly stronger, irritant action (hyperemia) much greater, toxicity two-thirds that of cocaine. No effect on pupil.

It has been used especially for spinal anesthesia, in combination with strychnin (T. Fonseca, 1909). The immediate danger may be somewhat less than with cocain, although it is not negligible. The local injury is much greater. Spliller and Leopold, 1910, and Connolly, 1913, have observed degenerations in the nerve roots and cells, after subduial injection of stevan. The immediate paralysis is more extensive than with cocaine, involving muscular movements (Santessnot, 1906) and spinal reflexes (Adler, 1906). On the circulation, it causes in dogs, quickened pulse and fall of blood pressure (Kamenzovse, 1911). The kidneys are also rather irritated, especially if albuminuria was previously present (Schwartz, 1907; Chialie, 1913). The liver is not affected (side actions, Seifert, Nebenwirk., 1917. p. 91, hembar, p. 106). A comparative study of the local anesthetic actions of stevan and its homologues has been made by Syosse and Velely, 1917.

The literature of accidents is reviewed by M. J. Smith and R. A. Hatcher, 1917 Jour. Pharm. Exp. Ther., 9: 231. Even with intravenous injection or perfusion, it appears to have no direct action on the blood vessels, but toxic doses depress the heart.
PERIPHERAL AUTONOMIC SYSTEM

Death occurs by simultaneous and independent paralysis of the heart and respiration. Stovain disappears rapidly after injection into the blood stream, but little is excreted. It is removed and presumably destroyed by the liver. It is more toxic than procain by corresponding methods of administration.

Trichocain (Hydrochord, N.N.R., (benzoyl-pseudo-tropin); occurs in Javaneseoca, but the commercial is synthetic. Colorless needles, readily soluble in water. It destroys the vasocostrictor action of epinephrin. Dose, locally, one or two times

Yohimbine, C_{20}H_{29}N_{3}O_{5}HCl.—An alkaloid isolated by Spiegel, 1896, from the bark of Yohimbe bush (Apocynacea; West Africa). Forneau and Page, 1911, consider it identical with quebrachin. Local anesthetic, about same strength but more lasting than cocaine. Less toxic, but much more irritant. Mydriasis, without loss of accommodation. Vessels dilated. Intraocular, excised or in situ, and bladder stimulated by small, depressed by large, doses (A. Loewy and Rosenburg, 1914). Solutions are unstable.

When it is given by the mouth or hypodermically in moderate doses, it produces a general vasodilatation in the skin, mucous membranes, and particularly in the vessel organs. In consequence of the latter, and perhaps by a direct action of the spinal centers, it produces erection. It does not seem to stimulate the production of spermatoma or sexual desire. It does not increase the rate of reproduction in mice (Kumry, 1915).

The effect is not produced by therapeutic doses in man (5 mg. or 51.5 mg.), although it has been promoted as an aphrodisiac. The reports of clinical improvement after several weeks are probably explainable by suggestion. Yohimbine has also been proposed for lowering abnormally high blood pressure; but Lawrence, 1912, found that it may produce further rise, with dangerous symptoms.

Larger doses produce psychic excitement, cerebral congestion, vertigo, gastric disturbance, and in rabbits, marked injury of the renal epithelium (Huebner, 1912). It produces general stimulation and subsequent paralysis of the nervous centers, particularly in the medulla; and complex effects on the cardiac muscle (F. Mueller, 1917; J. Tait, 1910). The coronary vessels are not affected (Rabe, 1912); or they are stained (F. Meyer, 1912). Death occurs by respiratory paralysis (for literature, see Shibill, 1906).

Difficulty Soluble Local Anesthetics.—These are used locally as dusting powders, much or diluted with 1 to 20 parts of talc or ointment. The internal dosage and the side effects are stated under each substance.

Anethesin, N.N.R.; ethyl amino-benzoate. Dose, 0.3 to 0.5 Gm., 5 to 8 grains. Side actions, Sefert, Nenebwirk, 1915, page 30.

Cetylform, N.N.R.; isobutyl para-amino benzoate. Dose, 0.1 to 0.2 grains, 1 to 3 grains.

Orthoform, N.N.R.; methyl amino oxybenzoate. Dose, 0.5 to 1 gram, 8 to 15 grains. Sometimes produces inflammatory reaction (Sefert, Nenebwirk, 1915, page 172).

Propamin, N.N.R.; Propyl amino-benzoate. Dose, 0.25 to 0.5 grains, 4 to 8 grains.

DRUGS ACTING PERIPHERALLY ON THE AUTONOMIC-SYM-PATHETIC SYSTEM

A variety of poisons act peripherally upon the several portions of the involuntary or "vegetative" nervous system, in a more or less specific manner. It appears advisable to premise their individual consideration by a more general exposition, so as to obtain an intelligent grasp upon their various relations, and an insight into what is known of their action. Much light has been thrown upon these recent years, and our conceptions have been largely revolutionized.
Anatomic and Physiologic Relations.—The "autonomic" system (in the wider sense in which the term was introduced by Langley) has certain physiologic and anatomic peculiarities. Physiologically, it includes all the functions which are subject to involuntary nervous control—the smooth and cardiac muscles and the glands. Their relation to the central nervous system is peculiar, in that they are capable of functioning automatically, and by local neuro-muscular reflexes, when all connections with the cerebrospinal axis are severed (hence "Autonomic"). On the other hand, their functions are normally regulated, augmented or inhibited, by central tonic impulses of varying intensity.

The chief anatomic peculiarity of these automatic nerves is, that they all pass through relay ganglionic cells, situated outside of the central nervous axis. These cells are partly scattered but mostly collected into the "sympathetic ganglia." A given nerve fiber has but a single relay cell, although it may pass through a number of ganglia.

Receptor, Connector and Excitor Elements.—These together constitute every reflex path of the voluntary system. The essential anatomic difference between the two systems is that the cells of the effector nerves of the involuntary system have wandered from the central nervous system to the periphery, as ganglion relay cells (Gaskell, 1916).

The receptor part comprises the sensory end-organ, the sensory nerve fiber, and the cells in the posterior root ganglion.

The "connector part" for voluntary muscle, is entirely within the central nervous system. Its cells lie in the posterior horn, and are connected with the excitatory cells of the pyramidal tract.

The connector part of the involuntary system also has its cells in the central nervous system (the lateral horn of the cord); but the connector fibers run out by the anterior roots as fine medullated "preganglionic" sympathetic (autonomic) fibers.

The "excitor part" of the involuntary system consists of the motor cells in the anterior horn, and their fibers, constituting the motor trunks.

The excitor part of the involuntary system has its cells always outside of the central nervous system, as the "sympathetic ganglia." Its fibers are non-medullated.

The sympathetic ganglia (including not only the spinal ganglionic chain, but also the peripheral ganglionic pleurons—the coeliac, auerbach's, etc.) are therefore homologous to the motor cells of the anterior horn; they are simply the cells of the excitatory neurons (Gaskell).

The "autonomic system" consists purely of connector and excitor neurons. It does not contain any receptor neurons; these all run to the posterior root ganglia.

Connector Elements.—These can not properly be called either sensory or motor (receptor or excitor). They are not confined to one segment of the cord, but may communicate with other segments, near or distant. They need not communicate directly with the excitor neuron, but may connect with other connector neurons, within the central nervous system, thus forming a series of relays between the receptor and excitor elements. However, such relays do not occur outside of the central nervous system. The autonomic nerves therefore do not have relays, and each spinal sympathetic ganglion is therefore strictly segmental. However, the preganglionic fibers form collaterals, through which a connector cell innervates more than one excitor neuron, when important for securing coordination.

THE PARASYMPATHETIC AND SYMPATHETIC SYSTEMS

Physiologically, and especially pharmacologically, as also in its embryologic development, the autonomic system as a whole has two fairly sharply defined divisions, which correspond, anatomically, on the one hand, to the nerves having their origin in the roots of the midbrain, medulla oblongata, and sacral cord (the cranio-sacral or parasympathetic system, also often called the autonomic system in the restricted sense); and on the other hand, those arising from the dorsal and down to the fourth or fifth lumbar nerve roots (the sympathetic system).

"Outflows" of Autonomic (Connector) Fibers.—These leave the central nervous system mainly in two regions (partly interrupted by the outflows of the voluntary motor fibers of the extremities, i.e., of the brachial and of the lumbar-sacral plexus). The three autonomic outflows are the bulbar, the thoracoico-lumbar, and the sacra-
PERIPHERAL AUTONOMIC SYSTEM

317

There are also some fibers from the midbrain (the presomatic system) innervating the olfactory region.

The Sympathetic System Proper.—This corresponds to the dorso-lumbar outflow, the nerves arising from the second dorsal to the third lumbar division. Their-excitatory cells constitute the entire spinal “ganglion chain,” including also the cervical and thoracic ganglia.

The Parasympathetic System.—This includes the cranio-bulbar and the sacral outflow. The connective fibers of these run directly to the periphery, the excitator or relay ganglion cells being situated in or near the end organs (the vagus and pelvic trunks, therefore, are considered connective fibers).

Distribution and Function.—The two divisions are usually antagonistic, a given organ as a rule receiving its innervation from both divisions, one being augmentor, the other inhibitory.

The sympathetic division is generally augmentor to the blood vessels and to the organs derived from the ectoderm; whereas the parasympathetic system is augmentor to the organs derived from the endoderm. Gaskell therefore calls the sympathetic the modern system, and the bulbo-sacral he calls the endodermal or enteric system. The inhibiting innervation is generally just the converse. (Circular and longitudinal coats always have the same—not reciprocal—innervation; Gaskell.) The innervation of the sweat glands occupies a peculiar position; anatomically, it is purely sympathetic, but it reacts pharmacologically as if it were purely parasympathetic. The uterus is also exceptional; its sympathetic innervation responding to both classes of poisons. It must be remembered, however, that the anatomic evidence of the origin of the autonomic nerves is in some respects inconclusive.

The following tabulations are adapted mainly from Gaskell:

Augmentor Motor Functions of the Sympathetic (Vasodermal) Division.—These may be grouped as:

- Vascular System.—All blood vessels, and including the heart and the spleen. The excitatory fibers are in the lateral sympathetic chain.
- Intramural Skin muscles.—Excitatory cells also in the lateral sympathetic chain; includes the sweat glands, pilomotor, anus and vaginal orifices, retractor penis, extrinsic ocular, nictitating membrane, pupillodilator.
- Segmental Duct (by hypogastric nerves; excitatory cells in organs). Ureret, uterus, fallopian, prostate, urethra.
- Intestinal sphincter (excitatory cells in mesenteric ganglion).—Ileocecal and internal rectal, perhaps also pyloric, vesical, trigone (in some animals spreading over the entire bladder as an additional coat), and urethra.

Augmentor Motor Functions of the Parasympathetic (Enteric or Efermal) System.—The vagus supplies the lungs, gall-bladder, and small intestines; the pelvic supplies the dorsal region, i.e., the large intestines, rectum and bladder. The excitatory cells are situated at the periphery; those of the pelvic nerves form the pelvic plexus (formerly known as the hypogastric plexus) on the surface of the bladder and rectum. Gaskell considers the cells of Auerbach’s plexus as the motor-cells of the vagus.

Augmentor Motor Functions of the Pneumatic System.—The excitatory cells are in the ciliary ganglion, and supply the sphincter of the iris by the short ciliary. This innervation does not properly belong to the sympathetic or parasympathetic. The structure of the sphincter is also unique, being intermediate between the voluntary and involuntary muscles. The dilator of the pupil is strictly sympathetic.

Inhibitory Nerves.—With the voluntary system, inhibition occurs within the central nervous system. With the involuntary system, special inhibitory fibers exist, both excitator and inhibitor. (It is conceivable that, in addition, a single excitatory element may transmit both augmentor and inhibitory impulses.)

Distribution of Augmentory and Inhibitory Innervations.—The most important are:

- Vasodermal System.—Augmentor sympathetic; inhibitory (so far as they exist), sacral.
- Genital System.—(Uterus and Ureter). Augmentor and inhibitory, both sympathetic.
- Ischiadic Sphincters.—Augmentor, sympathetic; inhibitory, sacral.
- Rectal Muscles.—Augmentor, voluntary, rectal; inhibitory, sympathetic. Esophagus and Cardial Sphincters.—Augmentor and inhibitory; both vagal.
Heart and Vessels.—Augmentory, sympathetic; inhibitory, parasympathetic.

Innervation of Glands.—This corresponds to the same laws as the muscular innervation; the glands derived from the epidermis (sweat) receive their augmentor supply from the sympathetic; whereas the parasympathetic augments the endodermal glands (pancreas, gastric, mucus, etc.). The salivary glands probably have cells derived from explain innervated from both systems.

Stripped Muscle.—It has been suggested that the sympathetic controls the tone of the striated muscle. This appears to be incorrect, for S. Cobb, 1918, finds that section of the abdominal sympathetic chain in cats has no effect of decerebrate rigidity; on hypotonicity of the hind legs or tail, or on tendon reflexes; nor does stimulation of the chain produce tonic contraction of the ipsilateral hind leg.

PHARMACOLOGIC REACTIONS OF THE AUTONOMIC SYSTEM

Nicotin.—Pharmacologically, the most prominent characteristic of the whole autonomic system is its reaction to nicotin: this alkaloid paralyzes all the ganglionic synapses of both the parasympathetic and the sympathetic nerves (often after a fleeting primary stimulation). This paralysis is so specific, that it has proved of great value, especially in the hands of Langley, for locating the site of these synapses. Nicotin, whether it is applied locally or systemically, abolishes the response to stimulation of the preganglionic fibers, whereas the post-ganglionic fibers respond normally.

Small doses of Nicotin at first stimulate these preganglionic nerves.

Cures, Strychnin and Brucin.—These also depress or paralyze all preganglionic nerves, analogous to nicotin; and they are antagonized by stimulant doses of nicotin. The susceptibility to paralysis is in the following order: First, Cardenolitibitor, Second, chorda-secretory, sweat, pilomotor, pupil-dilator and constrictor, probably also bulbar and sacral vasodilators; Third, nictitating membrane and cutaneous vasodilators. Fourth, epinephrin-secretors and abdominal sacroconstrictors.

Most of the other drugs which affect the autonomic system restrict their action exclusively to one or the other of the two divisions: Epinephrin, ergotoxin and cocain act exclusively on the sympathetic division; atropin, pilocarpin, muscarin, cholin, and physostigmin act exclusively on the parasympathetic division; the action of acetylcholin on the parasympathetic system being almost as specific as that of epinephrin on the sympathetic (Gaskell).

There are other drugs that act only on certain parts of one or of both divisions.

Antineuritic Chlorin apparently also belongs to the group of parasympathetic stimulants, and its favorable effect on nutrition has been attributed to stimulation of the digestive glands (Uhlmann, 1918).

Deprivation of Calcium.—This increases the excitability of both divisions to augmentor impulses.

Anisotonic Solutions.—Hypertonic solutions (Ringer's) inhibit the tone of smooth muscle, increase the response to inhibitory drugs, and lessen the response to stimulants. Hypotonic solutions have the opposite effect (Dale, 1913).

PHARMACOLOGY OF THE SYMPATHETIC DIVISION

Epinephrin, the alkaloid of the suprarenal gland, produces a pure peripheral stimulation, restricted exclusively to the sympathetic system, but involving the entire distribution of this system (with the exception of the sweat glands). In other words, the effects of typical doses of epinephrin on a given organ correspond precisely to the stimulation
of its sympathetic nerve supply (Lewandowsky, 1899; Langley, 1901; Elliott, 1905). This has been aptly described by the term "sympatho-mimetic action" (Barger and Dale, 1910). The action of epinephrin is therefore augmentory or inhibitory, according to whether the sympathetic impulses are augmentory or inhibitory, as follows:

The Principal Sympathetic Reactions (e.g., the Effects of Epinephrin). The augmentory reactions consist in constriction of most of the arteries and consequent rise of blood pressure; stimulation of the cardiac accelerator; dilatation of the pupil; contraction of the plain muscle of the orbit; flow of sympathetic saliva and of tears, not readily abolished by atropin; erection of hair, etc.

Inhibitory Reactions concern the tone and rhythm of the contractions of the stomach, intestine, biliary and urinary bladder (cat), and of the virgin uterus of the cat.

Peculiarities of Species.—Certain of the sympathetic reactions vary with the species of animals, being augmentory in some, and inhibitory in others (urinary bladder, anal sphincter). The sympathetic reaction of the uterus varies according to its physiological state; in the cat, the virgin uterus is inhibited, whilst the pregnant uterus is stimulated. All these peculiarities are reproduced exactly in the reaction to epinephrin, thus furnishing the most striking illustrations of its sympathomimetic action.

Other Drugs with Sympathomimetic Action.—Similar actions are possessed by a large number of primary and secondary amines, the simplest being the primary fatty amines, anilin, etc.). There are quantitative differences between these. The relations of the different sympathomimetic distributions does not go parallel; nor is there any parallelism between augmentory or inhibitory innervations. The intensity and specificity increase as the amines approach the structure of epinephrin (Barger and Dale, 1910).

Cocain increases the peripheral excitability of the sympathetic system without being directly stimulant.

Peripheral Sympathetic Paralysis: Ergotoxin.—The active alkaloid of ergot (in large doses) destroys the response of the augmentory sympathetic impulses, but does not affect the inhibitory sympathetic impulses (Dale, 1906). It therefore prevents, etc., the vasoonstricctor action of epinephrin, that does not abolish the inhibitory action of epinephrin on the intestine or uterus.

PHARMACOLOGY OF THE PARASYMPATHETIC CRANIO-SACRAL (OR RESTRICTED) AUTONOMIC DIVISION

The action of drugs on this system is confined mainly to its augmentory functions (with the important exception of the vagus). These, in their entire peripheral distribution, are paralyzed by atropin; and stimulated by pilocarpin, muscarin, cholin and anaphylotoxin. Physostigmin heightens their irritability, perhaps without being directly stimulant. (These statements must be restricted to typical doses.)

Atropin is therefore antagonistic to all the other drugs named. If a sacro-cranial function is exposed simultaneously to the depressant action of atropin and to the stimulant action of one of the other drugs, the end result depends on the nature and quantity of the drug, and upon other conditions. Physostigmin, for instance, is a more powerful antagonist of atropin than is pilocarpin; however, larger doses of the stimulants tend to become depressant, so that the atropin action tends to appear predominant.

The centers of the parasympathetic system are stimulated by microtoxin.
Principal Results of Parasympathetic Stimulation (Pilocarpin, etc.).—These consist in: slowing of the heart; constriction of the pupil; bronchial spasm; contraction of intestine and uterus; increase of practically all centrally innervated secretions (sweat, saliva, mucus, gastric, pancreatic, etc.; not urine, bile, milk, nor the internal secretions). These are the main effects of pilocarpin, muscarin and physostigmin.

Cranioscelar depression (atropin) produces precisely the opposite results.

DRUGS WITH PARTIAL AUTONOMIC REACTIONS

The preceding presentation is schematic, and includes only the typical effects, as they are currently conceived. When the doses and other conditions are varied, many of these drugs depart more or less from the schematic as will be described later. This indicates that the physiological divisions which are the basis of the pharmacologic divisions, are not as absolute the schema would imply. In accordance with this, there are a number of drugs (for instance, apocodein and pituitary extract; the latter, however, is probably a mixture), which do not fit anywhere in the schema, but whose actions involve isolated functions of one or both divisions.

LOCATION OF ACTION

The precise site of action of the autonomic drugs is not yet satisfactorily decided. It is currently assumed that they act on the "myoneural junction," or upon a "receptive substance" (Langley, 1895), which is believed to be interpolated between the anatomical nerve-endings and the reactive substance of the cell (the contractile elements of the muscle, or the secretory elements of the gland cells). It would perhaps be equally or more exact to say that they act upon that property of the cells which excites or initiates their peculiar functions.

The essential evidence for this view is the fact that these poisons preserve their action after severance and anatomic degeneration of the postganglionic nerve fibers, showing that their action is peripheral to the nervous structure. On the other hand, the specificity of the reactions, and their correspondence with the physiologic innervation, indicates that the action is not directly on the contractile or secretory substance. If epinephrin, for instance, acted directly upon the contractile elements of smooth muscle, it would be difficult to understand why it should throw them into contraction in some situations, relax them in others, or in others again, leave them entirely unaffected. Anatomically, these muscles are all alike; their physiologic properties are also identical, they respond alike to muscular poisons, such as barium; the only difference between them lies in their innervation. This difference of innervation is reproduced exactly by epinephrin; and since the degeneration-experiments show that the poison does not act upon the nervous elements themselves, it follows that both the nervous impulse and epinephrin must act upon the same substance or property of the muscle.

It is idle to speculate upon the nature of this receptive substance, or receptive property, until we know somewhat more of the real nature of the nervous impulse, of simulation, and of excitability. The term "myo-neural junction" has the advantage that it does not commit one to any unproven hypothesis.

Phenomena observed by Edmunds, 1920, on the retractor penis muscle of the dog indicate that in this case, and probably also with the bladder, the action of the drugs is directly on the muscle substance. This does not invalidate the conception of the myoneural junction for other smooth muscle (bronchi, uterus, iris, etc.); but it cautions against unwarranted generalizations.
Anatomic Localization of Depressant Effects.—The anatomic methods of localization are quite simple, since the problem concerns a purely effector path. The nerve would be stimulated in various sites in its course; the paralysis would be located just central to the highest point which gave a positive response.

For instance, after nicotin, stimulation of the preganglionic fibers of the vagus (say in the neck), does not slow the heart; stimulation of the postganglionic fibers (in the sinus) causes slowing. Nicotin has therefore paralyzed the ganglia.

After atropin, stimulation of the sinus is also ineffective; the paralysis must therefore be peripheral; the heart-muscle is evidently not paralyzed, since it is beating vigorously. The paralysis must therefore be just central to the muscle, i.e., in the endings or myo-neural junction. It must be remembered, however, that this does not exclude the possibility of an additional more centrally located paralysis; for instance, so far as this evidence goes, atropin might have paralyzed the vagus ganglia in addition to the "myo-neural" junction. Further, the precaution must be taken to employ a sufficient dose of the poison, for a slight paralysis may often be overcome by a powerful stimulation.

Anatomic Localization of Stimulant Effects.—This would also be very simple, involving the division of the nerve (or its equivalent, the application of the drug to excised organs or structures). For instance, pilocarpin and muscarin contract the pupil of the excised eye, and physostigmin increases its excitability to stimulation of the postganglionic oculomotor. Their action is therefore postganglionic. It is again possible that the drug may stimulate an additional, more centrally located structure.

To distinguish between anatomic endings, myo-neural junction, and muscle substance, the nerve is allowed to degenerate, as just described.

Pilocarpin, for instance, remains effective after the anatomic endings are degenerated, and then therefore electric stimulation of the nerve is ineffective. However, if a still shorter time elapses after the division of the nerve, pilocarpin also becomes ineffective. It is therefore generally assumed that the myo-neural junction also degenerates, but very slowly than the anatomic endings. However, it is also conceivable that pilocarpin acts on the anatomic nerve-endings, and that the degenerating endings remain excitable to pilocarpin longer than they do to electro stimulation. This proof of myo-neural action is therefore not conclusive.

The evidence from degeneration may also mislead if the drug, instead of stimulating, represses the excitability of the reacting cell. In this case, the drug would produce no visible effect after degeneration of the endings, for this would exclude extraneous stimulation, and the increased excitability would therefore not be apparent. This increased excitability of the myo-neural junction is supposed to be the action of physostigmin on the autonomic mechanism.

Localization by Antagonistic Action.—The anatomic localization, although simple in theory, is often technically difficult, and it is beset with the limitations which have just been pointed out. It has therefore been attempted to supplement and extend it by pharmacologic evidence, based on antagonistic actions. The matter was at first conceived as very simple, namely as strictly analogous to anatomic localization; a drug paralysis being considered as equivalent to anatomic division or excision; and a drug stimulation as the equivalent of electric stimulation. The action of a few drugs having been localized (with more or less probability) by anatomic means, it was thought that the actions of others could be localized by simply "matching" them against these standards. In
localizing action by antagonism, a stimulant poison was paired with a depressant poison of known action, i.e., atropin. If stimulation resulted (as with physostigmin) it was concluded that the action must be peripheral to that of the atropin; if there was no stimulation (as with pilocarpin), it was assumed that it must be central to that of atropin.

However, there has been a good deal of cumulative evidence (well summarized by Magnus, 1908) that matters are not so simple, and that localization by antagonism has limitations so serious that it can be utilized only in relatively few cases. The difficulty is that the pharmacologic stimulation and paralysis are not strictly equivalent to the anatomic. In pharmacologic antagonism, the tissue is still in the body and exposed to both poisons; and the resultant effect is rarely, if ever, the simple algebraic sum of their separate actions. One drug may modify the effect of another qualitatively, as well as quantitatively. Moreover, a drug paralysis is not an irreversible process, as is anatomic division or excision. The numerous instances of mutual antagonism prove that a function which has been completely abolished (paralyzed) by one drug may be revived by another. For instance atropin can abolish the physostigmin miosis; but physostigmin can also remove an atropin mydriasis—the result depending upon the relative dosage.

Localisation by antagonism is therefore conclusive only if the antagonism is not mutual and if it involves absolutely distinct structures; for instance, atropin abolishes the action of cevadin (veratrin) on the cardiac vagus; while cevadin does not interfere with the atropin action. Evidently, the cevadin action must be central to that of atropin.

Mutual Antagonism.—When two drugs are mutually antagonistic, it is natural to assume that they act on the same structure. This is doubtless often the case; but there are instances in which this simple assumption offers difficulties; for in some cases, the point of attack of a drug appears to be different in the presence of an antagonist. This is practically important; for it is probable that disease may produce similar modifications.

The following instances are adduced mainly by Magnus, 1908:

Atropin—Pilocarpin—Physostigmin on the Pupil.—When the pupil has been dilated by atropin, stimulation of the short ciliary, i.e., of the postganglionic fibers of the oculomotor nerve, is ineffective, while direct electric stimulation of the iris sphincter contracts the pupil. Atropin therefore paralyzes either the nerve-endings or the myoneural junction. Pilocarpin and physostigmin both constrict the normal pupil. When the endings of the short ciliary are made to degenerate, pilocarpin is still effective (Anderson), but physostigmin is now ineffective. The pilocarpin therefore acts on the receptive substance or muscle; the physostigmin would be supposed to act on the extracellular nerve-endings.

From this, one might suppose that pilocarpin should be a more powerful antagonist of atropin than is physostigmin. In fact, however, the opposite is the case, so that the point of attack of atropin seems to be shifted more centrally by the physostigmin, as if it were determined by its antagonist.

However, another explanation is possible, perhaps more probable. The weak point in the argument is the localization of the physostigmin action. There is some evidence that physostigmin acts by increasing the excitability of the oculomotor mechanism, and not by direct stimulation; for it lowers the threshold for stimulation when it does not stimulate directly. If this be true, the failure of physostigmin after
nerve degeneration would not argue against its action being on the receptive substance; for degeneration of the nerve endings might interfere with the physostigmin action simply by eliminating the possibility of extraneous stimulation. (If this view is correct, physostigmin should be rendered active through the presence of pilocarpin even after nerve degeneration; but the experiment has not been tried.)

Conflict of Sympathetic and Parasympathetic Actions.—Langley and Dickinson, 1899, showed that the effects of nicotine on the pupil and nictitating membrane are the result of simultaneous stimulation of the sympathetic and cranial innervation. In cats, the sympathetic usually predominates (dilation of pupil and retraction of membrane). Pilocarpin, on the other hand, causes constriction (oculomotor stimulation), which is also unaffected by complete denervation (Anderson). However, it acts also on the sympathetic, for the nictitating membrane retracts. Both drugs therefore act on both systems.

Both drugs act after degeneration of the nerves, in the body; but with the excised iris, only the augmentor (oculomotor) response persists. To explain this contradiction, Dale and Laidlaw, 1912, assume that the sympathetic stimulation in denervated animals is brought about by increased secretion of epinephrin, to which the denervated sympathetic endings are especially susceptible.

Pilocarpin and Atropin on Intestine.—Magnus worked out an anatomic method for localizing the action of poisons on the intestinal movements, as will be explained presently. He could thus show that the ordinary atropin action is located in Auerbach’s plexus, while the pilocarpin stimulation is peripheral to this plexus. Nevertheless, the two drugs are mutual antagonists. Moreover, the pilocarpin stimulation is prevented by atropin, with concentrations but one-hundredth as large as the minimum dose which has any effect on the unpoisoned gut.

Apparently, therefore, the point of attack of atropin is shifted by the presence of pilocarpin. There is another possibility, however; for it is conceivable that atropin might inhibit the pilocarpin action, not by depressing the cells, but by preventing their combination with pilocarpin in some way. This seems to be nearer the truth, for Bayliss and Starling, 1901, showed that atropin, while it completely inhibits the pilocarpin stimulation, does not prevent the response to stimulation of the extrinsic motor or inhibitory nerves of the intestine, or to the pinching reflex.

Threshold of Sympathetic Stimulation.—It is also possible, however, that the differences are only quantitative; for there exist considerable differences in the threshold of the different functional fibers of sympathetic nerves (Gruner, 1915).

Physostigmin Against Curare, Bic., Antagonism on Excised Intestine.—Physostigmin presents a mutual antagonism with curare, nicotine, strychnin and gelasminene; i.e., the physostigmin contractions are relaxed by these drugs; and further addition of physostigmin restores the periodic contractions (Ikedra, 1910).

Atropin and Pilocarpin on the Vasomotor Mechanism.—This furnishes an analogous simple. Brodie and Dixon found that atropin removes the pilocarpin vasoconstriction, without impairing the response to electric or other stimulation of the vasconstrictor nerves.

Barium Against Curare and Nicotin Antagonism on Arterial Muscle.—Barium produces a rise of blood pressure; this is inhibited by nicotine, but is restored by curare. This suggests that barium does not act directly on the contractile substance, as is ordinarily supposed; but on a receptor mechanism distinct from that of epinephrin (Cutbick and Clark, 1915).

In these experiments, curare removes a nicotine paralysis. Conversely, the peripheral vasomotor paralysis of large doses of curare, strychnin and brucin is located in the cells that are stimulated by nicotine (Langley, 1916).

Epidemic Contraction of Arteries.—These may occur in isolated rabbits’ ear, in main coronary vessels, gills, etc. These are not markedly altered by drugs that act on arterial muscle. Their function is probably unimportant (Krausov, 1917).
Physostigmin, Curare and Nicotin on Striped Voluntary Muscle.—Physostigmin produces fibrillary twitchings of the voluntary muscles. These persist after section of the motor nerve (sciatric). They are therefore peripheral (Harnack and Witkowski, 1876). They are suppressed by curare, which paralyses the endings; on the other hand, physostigmin removes the curare paralysis (Pal and Rothberger).

Magnus and Langley and Kato, 1913, found that the physostigmin fibrillations can not be produced when the motor nerve has been cut and allowed to degenerate completely (but while the muscle fibers still respond to direct stimulation). This would seem to localize the physostigmin action strictly in the endings; and the case would be a typical instance of mutual antagonism, both poisons acting on the nerve-endings.

This conclusion appeared to be opposed by the antagonism of nicotin and curare on striped muscle. Langley, 1906, showed that certain muscles of the fowl are thrown into tonic contraction by nicotin, and that this is removed by curare. This peculiar nicotin action, however, persists after degeneration of the nerve; hence nicotin, and therefore also curare, must act upon the intramuscular "receptive substance." But if curare paralyzes an intramuscular structure, its action could not be removed by physostigmin, which stimulates an extramuscular structure.

The two phenomena are reconcilable by the assumption that the curare attacks the receptive substance in the presence of nicotin, and that it attacks the nerve-endings in the presence of physostigmin; in other words, that the point of attack of curare is determined by its antagonist; so that we would be dealing with two distinct and perhaps unrelated paralytic actions of curare, manifested under different conditions, one on the extramuscular, the other on the intramuscular structure. The nicotin-tonus effect appears to be a distinctive reaction, which has probably nothing to do with ordinary muscular contraction; so that the curare block, i.e., with ordinary sciatric stimulation is probably the same in all animals (i.e., in the nerve-endings).

Langley, 1913 and 1914, investigated the nicotin effects on frogs' muscle. He found the nicotin-tonus action quite distinct from the nicotin-twitchings. The twitchings, i.e., are prevented by a definite concentration of curare, whatever the concentration of the nicotin; whereas, to prevent the nicotin-tonus, the concentrations of the two drugs must be kept proportional.

Peculiarities of Fowl's Muscle.—The tonus action is particularly characteristic in fowl's muscle, which also shows other associated peculiarities (Edmunds and Roth, 1908). In these animals, not only the nicotin, but also the physostigmin actions persist after degeneration of the nerve; the physostigmin action is not removed by atropin, while it is so removed in mammals. Barium produces only an increase of muscular tone in normal fowl's leg; but in a denervated leg, or after nicotin, barium causes a strong contraction.

MUSCLES OF GENITO-URINARY TRACT

The responses of these to autonomic poisons present some interesting anomalies.

Responses of Uterus.—They show peculiarities of innervation and response that are of scientific and practical importance.

Nerve Supply of Uterus.—The uterus is innervated from the sympathetic, chiefly through the hypogastric; and from the parasympathetic through the pelvic nerve. Of these, the hypogastric is by far the more important.

Variation of Response According to Species and Functional State.—The response to hypogastric stimulation and to drugs differs according to the animal and pregnancy. Rabbits respond by contraction; so also do pregnant or recently pregnant cats; in non-pregnant cats, the same stimulation inhibits contraction and lessens the muscular tone. There are occasional exceptions to this; but in any case, it may be assumed that the augmentor or inhibitory response is due to the different functional condition of the muscle.

Quagliarollo, 1916, attributes the difference in the reaction of virgin and pregnant uteri to the development of new muscular fibers with predominant motor innervation.

Spontaneous Movements of Excised Uterus.—These present interesting problems of antagonism, especially in the cat (Cushny, 1910). The
PERIPHERAL AUTONOMIC SYSTEM

Uterus, when placed in oxygenated Ringer's fluid, continues in rhythmic movements for hours (Kehrer, 1908). These vary: physiologic condition of the organ, being most lively in early pregnancy. In advanced pregnancy they are slower and separated by pauses; but they are extensive. They can be influenced through the nerves and by the drugs which act upon these (Cushny, 1906).

**d Human Uterus.**—This responds to female remedies exactly as that of guinea pig that more concentrated solutions are required for equivalent effects (Pitcher, 1916).

**on Excised Uterus.**—Voegtlin and Lake, 1917, state that the addition of 4 per cent to the Ringer's solution in which an excised uterus is suspended causes inflammation, probably osmotic. Therefore, to avoid confusion, drugs, etc., to be used should be dissolved in Ringer's fluid.

**Control of the Uterus.**—This is relatively unimportant. The motor center for the cord is stimulated by anemia and asphyxia.

**Increase of Uterine Movements.**—This is secured by irritation of the intestine (1910), especially by drastic cathartics and irritants volatile oils. These should be avoided in pregnancy. They are reputed abortifacient, but are highly toxic.

**n of Autonomic Poisons on the Uterus.**—Pilocarpin, Nicotin, and Amyloid.—These always produce the same effect on the cat's uterus in gastric stimulation: augmentation in the pregnant; inhibition in the non-pregnant. Their reaction to atropin, however, is different:

- By itself stimulates the movements in small doses; while larger doses inhibit them. Its main interest lies in the antagonism: Atropin abolishes the pilocarpin effect; when the reaction is to epinephrin, or to electric stimulation of the hypogastric nerve. This is contrary to the specific predilection of atropin against pilocarpin, of which several have been given.

- Amyloid, on the other hand, abolishes the augmenting effects, both of pilocarpin naphthia; it therefore appears to differentiate between the effects, rather than the drugs.

Another phenomenon is presented by the physostigmin and atropin antagonism: The latter has a purely augmentor action, whatever the state of the muscle; this is by atropin, but the antagonism is one-sided (contrary to the experience in vivo): further quantities of physostigmin remain ineffective.

Uterus is an instance in which physostigmin, pilocarpin, and amyl nitrite act on the same nervous path as epinephrin, and is, in addition, to the sympathetic innervation and to the craniocutaneous pains, and apparently not to the sym pathetic epi-epinephrin.

**on of Different Uteri to Epinephrin.**—The response to this drug, and to sympathetic stimulation, varies in different animals and functional states, as shown in the table (adapted from Gann and Gann, 1914):

<table>

Pregnant guinea pig uterus may respond by contraction (Quaglia, 1916).

**Drugs Acting Peripherally on the Uterus.**—Infundibular extract produces contraction (Frankl-Hochwart and Froehlich, 1909), in all animals, pregnant...
or non-pregnant; also in human uterus, but not in the tubes (although these are contracted by epinephrin (Gunth). *Quinin* increases the contractions (Kurdinowski-Kehrer, 1906). Cincenixin and cinchonidine and quinidin contract even more powerfully than quinin (Hake, 1913).

*Morphin* has no effect.

*Seppolamin* has no effect.

Histamin or beta-imidazol-ethylamin (a constituent of ergot, also formed by the action of bacteria on histidin) is powerfully stimulating (Barger and Dale, 1910). Other related amines, *pepsine*, and *anaphylotoxin* act similarly. *Hydrastin*, *hydrastinina* and *cotarin* are stimulant (Kehrer, 1907). The actions of a number of other drugs and described by Pichler, 1916.

**Colloids on Uterus and Intestine.**—The following responses were found by Hanell, 1910:

Stimulation: “peptone,” rabbit’s serum, congo red.

Depression: acacia, dextrin, gelatin, glycerin, starch, human and horse serum, mucin.

No effect: Agar.

Bromide gave the same response, except to congo red.

**Prosthetic Excerise.**—This stimulates all excited genito-urinary muscle, the uterus being especially sensitive (Macht, 1920).

**Purified Organ Extracts.**—Fawcett, et al., 1915, examined aqueous extracts, after removal of the nucleo-proteins and coagulable proteins. Pituitary, pineal, thyroid, parathyroid, thymus, adrenal glands, pancreas and spleen were found to contain substances that stimulate cat’s uterus. The stimulation was inhibited by epinephrin. The effects on intestinal muscle differed; when stimulated, it was also inhibited by epinephrin.

**Correspondence of Uterus and Intestine.**—There is a general correspondence in the responses to most poisons (Sugimoto, 1915; Debell et al., 1915), but the correspondence is not universal; for instance it does not apply to the contractor effect of epinephrin.

**Dissimilarity between Uterus and in Excited.**—With non-pregnant cats, the uterus is inhibited by nicotine, cotarin, histamin, isodethylamin and pilocarpin. Excised uteri, on the other hand, are generally stimulated by these drugs. It seems from this that there is both sympathetic (inhibitory) and parasympathetic (excitatory) stimulation. The sympathetic effect predominates during life, but does not survive excision. Dale and Laidlaw, 1912, believe that the sympathetic stimulation is not direct, but through increased epinephrin secretion.

**Practical Importance of the Uterine Actions.**—The stimulation of uterine contractions is useful for arresting postpartum hemorrhage. Ergot particularly is employed for this purpose; hydrastis and cotarin have also been used, but they seem to be less effective. Pituitary extract is used to initiate or strengthen uterine contraction.

Nicotine (tobacco infusion), pilocarpin and quinin are sometimes used by the laity as abortifacients; effective doses, however, are dangerous.

**Vagina.**—Waddell, 1917, found that both the circular and longitudinal muscular coats of various animals make spontaneous rhythmical contractions, when excited. Both respond to autonomic drugs, generally like the uterus of the same animals.

**Male Genital Organs.**—The smooth muscle has motor sympathetic and parasympathetic innervation, and the excised organs behave generally like the uterus.

**Uterus Masculinus.**—In rabbits the tone of this organ is increased by epinephrin, nicotin, pituitary, pilocarpin, arecolin, ergot, hydrastin and barium. This is accompanied by decreased amplitude in the case of epinephrin, nicotin, pituitary and barium (Waddell, 1916).

**Prostate.**—This also reacts generally in the same manner as the uterus (Waddell, 1916).

**Vas Deferens.**—The movements are stimulated by epinephrin, ergot, hydrastin, pilocarpin, nicotin and barium. Pituitary is not effective. Atropin antagonizes the pilocarpin stimulation. Ergotoxin reverses the epinephrin stimulation. Strychnin, coca and quinin stimulate, even when the nervous apparatus has been paralyzed by atropin and ergotoxin. Their action is presumably directly on the muscular substance (Waddell, 1916 and 1917).
PERIPHERAL AUTONOMIC SYSTEM

work of Macht is discussed under Morphin.

nal Vessels.—These also behave similarly to the vas deferens (Waddell, 1921).

ter.—This receives augmentor impulses from both the sympathetic

tasympathetic systems. Accordingly, its contractions are aug-

both by epinephrin and by physostigmin, etc.; and these are

ized respectively by ergotoxin and atropin; but epinephrin con-

as are not removed by atropin, nor physostigmin contractions by

. Both are antagonized by papaverin, benzyl benzoate or cheli-

for these depress the smooth muscle directly. With unpoisoned

these drugs relax the tone, without inhibiting the peristalsis

 (-- 1916). They have therefore been suggested for the treatment of

ulation of the spinal and pelvic nerves both start ureteral contrac-

pathetic innervation is more active in the upper portion of the ureter, and the

the lower (Satani, 1916).

The contractions of the excised ureter are first stimulated, then arrested

so that they probably depend on the intactness of the ganglion cells (Satani).

effects of other substances on the contractions of the excised ureter are as

im: stimulates tonic, rate and amplitude, similar to epinephrin.

oden: first stimulates, then depresses. Counteracts epinephrin, but not

in and Procan: stimulate.

by: depresses.

ity: stimulates.

Alkaloids.—Phenantherin derivatives (morphin, etc.) increase

tractions and tonus. Isoquinolin derivatives (papaverin, narcotic,

also hydastin and emetine, inhibit contractions and relax tonus,

1926, 1917, believes that the inhibitory action of the papaverin

is due to the benzyl radicle; the stimulation of the morphins

piperidin. Piperidin, arecolin and conin all increase the con-

tons and tonus of the ureter.

local Lesions.—In general, the levo-alkaloids are stimulant, the

and inhibitory or indifferent. This has been ascertained for

oscyamins, hyoscyains, epinephrin and camphor (Macht, 1918).

plies also to the bladder.

ary Bladder.—This also has complicated innervations and responses to the

ac poisons (Langley, 1912; Edmunds and Roth, 1920). In cats, sympathetic

on (hypogastric) produces rapid contraction, followed by marked relaxation,

pathetic stimulation (erigantes) produces contraction. Epinephrin acts like

etic stimulation, i.e., it is mainly inhibitory. With the atropin-pilocarpin

localization is confusing (Edmunds and Roth). Probably these poisons act

muscle directly (Edmunds, 1920). Pituitary stimulates very powerfully;

is said not to stimulate (Abelin, 1919).

bladder.—Lieb and McWhorter, 1913, found that this is augmented by vagus

ited by sympathetic stimulation. Epinephrin therefore relaxes, while physos-

pilocarpin stimulate, and this stimulation is removed by atropin. It is

ated by stryphanthin and barium; relaxed by bile salts and nitrates.

its and its cisterns either have no effect on the tonus and contractions, or else

stimulate. Papaverin and other isoquinolin alkaloids tend to decrease the

contractions. This inhibitory effect predominates in opium. Atropin in

apeutic doses does not relax the gall-bladder (Macht, 1917). 

, 1915, states that the normal rhythmic movements are greatly increased

, and by the introduction of acids into the duodenum.
Melanophores.—Barbour and Spathe, 1917 found that the pigment cells of fish respond to autonomic drugs like smooth muscle. They are generally constricted by sympathetic stimulants (epinephrin). This reaction is “reversed” by ergotoxin. Atropin relaxes; pilocarpin and physostigmin also apparently relax.

**Autonomic Poisons on White Cells.**—The proportion of these cells is changed, the significance being obscure. Pilocarpin and colchicine, atropin diminishes the eosinophiles and lymphocytes. Epinephrin increases the lymphocytes but diminishes the eosinophiles. Histamin also diminishes the eosinophiles (Port and Brunow, 1914.)

**Yeast Formation.**—This is affected by some of the autonomic drugs, although not in accordance with their autonomic affinities (Somogyi, 1910):

- Atropin and quinina: small quantities accelerate; larger inhibit.
- Pilocarpin and cocaine: small quantities inhibit; larger accelerate.
- Acid dyes (methylene blue): dilute solutions stimulate; moderate concentrations inhibit.
- Basic dyes: very little effect.

**AUTONOMIC PHENOMENA OF INTESTINES**

**Peripheral Ganglion Cells of Auerbach’s and Meissner’s Plexus.**—These cells have been interpreted in two very different ways. Gaskell believes that the intestines conform completely to the ordinary type of involuntary innervation, the Auerbach cells being merely the ganglion (excitor) cells of the vagus.

**Enteric System.**—On the other hand, Langley, 1913, and many others believe that these ganglion cells constitute an additional link, interpolated between the ordinary (extrinsic) innervation and the muscle. They suppose that the Auerbach ganglia are independent local nerve-centers, presiding directly over peripheral reflexes, viz., segmentation and peristalsis; but that the extrinsic nerves can also initiate, augment and abolish these movements. As this plan is quite different from the general plan of the autonomic system, Langley distinguished the intestines as the “enteric system.”

These peripheral nerve centers and their connections react to the usual autonomic poisons; but the nature of the reaction is distinctive and cannot be deduced from the ordinary schema. The extrinsic nerve ganglia respond to nicotine in the usual manner. The effects on the Auerbach ganglia can also be located; these are stimulated by atropin and nicotine; these and the other autonomic poisons also act more peripherally.

**Peripheral Reflexes in Other Organs.**—The intestines are the most prominent, but by no means the only, example of reflex response in the absence of central innervation. In fishes and amphibians, for instance, the iris of the excited eye responds to light, even after removal of the retina (Steinach, 1902); blood vessels regain their tone when their nervous connections have degenerated, etc. These reflexes do not even involve the presence of peripheral nerve cells. They may be considered as survivals of the reflex mechanism of the lower invertebrates (Parker, 1909). This conception may help to elucidate some obscure pharmacologic phenomena.

**Extrinsic Innervation of the Intestine.**—**Sympathetic nerves, running through the superior and inferior mesenteric and mesenteric ganglia, supply the whole tract, from the cardia to the anus, mainly with inhibitory fibers.**

The parasympathetic supply consists of the augmentory ergens and pelvic nerves to the anus, rectum and colon; and the vagus fibers, distributed from the esophagus to the end of the ileum. The vagus innervation causes a short primary inhibition, followed by marked stimulation. It is not known whether the extrinsic nerves connect with the local nerve cells; or whether they act independently on the muscle; or both. The bulbocavernous innervation seems useful mainly for initiating tone, which is then maintained by the local mechanism. The initial inhibition favors the ingress of the chyme (Cannon, 1917). The “roll movements” which propel the contents for long distances, are of extrinsic origin, due to vagus stimulation with simultaneous depression of sympathetic inhibition (Meltzer and Auer, 1907).
PERIPHERAL AUTONOMIC SYSTEM

Differences of Rhythm at Various Levels.—In intact animals, the rhythm is faster toward the two ends of the intestine than toward the middle. In excised intestine, the rate decreases with the distance from the pylorus; the rate of the duodenum in rabbits being about 50 per cent. faster than in the lower ileum. The oral end is more irritable and therefore acts as pacemaker. It is also less subject to epinephrin relaxation and its tone is higher. On the other hand, the slower rate of the aboral end is accompanied by greater excursions (Alvarez, 1914, 1915).

The different rates are perhaps based on intrinsic differences in the intensity of metabolism. Cyaanid or cyanide, for instance, or shutting off the oxygen supply, interferes more with segments from the higher portions of the intestine (Alvarez, 1918).

Alvarez and Starkweather, 1918, believe that this gradient of excitability is mainly concerned in regulating the physiologic rate of propulsion of the food through the various levels of the intestinal tract. They point out that there is really no good evidence that the Starling-Bayliss Law or Cannon's myenteric reflex are concerned in the normal propulsion of food.

Drugs on Intestinal Rhythm.—The effects have been studied by Alvarez, 1918. The changes in rhythm are not necessarily parallel to those of the tone and amplitude of the contractions. This has also been found by Pilcher for the uterus.

The Intrinsic Neuro-muscular Mechanism.—The segmentation (pendulum) movements and the ordinary peristaltic movements are entirely of peripheral origin, since they are observed also in the excised intestine even when the mucosa and submucosa are removed. They are originated peripheral to the ganglia; for they persist, under suitable conditions, for five days after death, when the ganglia must be dead, and they can also be evoked in preparations from which the ganglia have been removed anatomically (Gunn and Underhill, 1916). The rhythmic segmentation movements are automatic; the peristaltic movements are evoked reflexly (as in the Bayliss-Starling reflex; a pinch causes the intestine to constrict for 1 or 2 cm. above, and to relax for some 30 cm. below the stimulus). The local nerve-muscle mechanism for these reflexes consists of the longitudinal and circular muscular coats, innervated by Auerbach's plexus of nerve cells and fibers, which lies between them. This communicates also with Meissner's plexus in the submucosa, which innervates the glands, muscularis mucosae, etc., but which is not concerned in the intestinal movements.

Isolation of Intestinal Coats.—Magnus, 1904, found that the muscular coats of the cat's intestine could be separated into layers, so as either to retain or eliminate Auerbach's plexus.

The "plexus preparations" contain the peripheral nerve cells, and respond to continued stimulation by rhythmic contractions.

The plexus-free preparations (which contain only the nerve-endings and muscle) ordinarily respond to continued stimulation by a single tetanic contraction, like ordinary smooth muscle; but if the preparations are carefully protected against injury, they also resume spontaneous rhythmic movements after a time (Gunn and Underhill, 1914).

With the disappearance of spontaneous movements by exposure, the reaction to all contractions is abolished. The response to pilocarpin and atropin disappears before that for epinephrin or barium, indicating that the parasympathetic innervation dies before the sympathetic (Gunn and Underhill).

The muscle coat muscles also contracts, especially in the diagonal direction. Its rhythm is slow, rather similar to that of the spleen. Its tone and rhythm are increased by epinephrin. Barium causes marked tonic contraction, abolishing the rhythm (Gunn and Underhill).

Localization of the Action of Poisons on the Intestine.—The use of excised intestine, and of plexus and plexus-free preparations, aids in the localization of the action of poisons.

If a given action occurs in the excised intestine, the point of attack must be local. If the action occurs in plexus preparations, and not in plexus-free strips, it is probably on the ganglion cells. If it occurs in the plexus-free preparations, it must be on the endings or muscle. No reliable method has been found to distinguish between the nerve-endings and muscle; or between the endings of the extrinsic and intrinsic system, if the two be distinct. All conclusions as to these are based on the insecure ground of analogy.
This general method as outlined only discovers the most peripheral point of attack which is of course the most important; but it does not exclude that the poison may also affect more central structures at the same time. This possibility is not merely theoretical; for even this method shows that the same drug may attack different structures according to the dose and other conditions. The conditions have not been fully analyzed, and until this has been done, the localization of the intestinal phenomena must be rather unsatisfactory.

The following exposition is mainly along the lines laid down by Magnus (Ergebnisse der Physiologie, vol. 7, 1908, and vol. 2, 1909), and by Hax Mayer (Meyer and Gottlieb’s Lehrbuch).

Nicotin Group.—The effects of nicotin are complex. With excise intestines, small doses stimulate the muscle and produce a slight increase of tone. With larger doses, the stimulation is violent, proceeding to intense spasmodic contracture, but soon followed by inhibition of the movements and relaxation of the tone (Ikeda, 1916).

The stimulation is probably ganglionic, for it occurs with excised intestines, but not with plexus-free preparations. The inhibition has also been attributed to stimulation of the ganglia (Ikeda).

The paralysis of the ganglia renders stimulation of the extrinsic nerves, both of the vagus and sympathetic, ineffective. Curare and coniin also stimulate the muscle and produce slight increase of tone. Spartein and colonin lower the tone and gradually diminish the movements (Ikeda).

These four drugs and nicotin are mutually antagonistic with physostigmin (Ikeda).

Parasympathetic Stimulants.—Physostigmin, Pilocarpin, Muscarin, Cholin and Carbicin produce violent irregular contractions, and also tetanic contraction of plexus-free preparations. Their action must be postganglionic, presumably stimulation of the vagus endings.

The stimulation of these drugs is abolished by small doses of atropin; pilocarpin is antagonized by extremely minute doses; physostigmin requires relatively the largest amount.

Pilocarpin-atropin Ratio.—The antagonism of these drugs on the excised intestine is not in simple ratio to their concentration, for while the pilocarpin, physostigmin and muscarin stimulation depends on the concentration of the drug in the fluid, the atropin inhibition depends on the absolute dosage. The antagonism is not materially influenced by temperature or H-ion concentration (van Liith de Jende, 1918).

Cholin as Periodic Hormone.—Watery or saline extracts from the serous side of surviving intestines contain a substance that stimulates the movements of excised stomach and intestines (Welland). This consists mainly of cholin, which is evidently present in the intestinal walls, and is perhaps essential for the automatic function of the Auerbach plexus (Le Heux, 1918).

Atropin.—The effects and their localization differ according to conditions: very small doses have no effect on the normal intestine, but remove intestinal spasm, due to peripheral vagus stimulation (physostigmin, pilocarpin, etc.; lead colic, anemia of intestine, etc.). The motor response to stimulation of the vagus trunk is lessened, but not abolished. This dosage does not affect the contraction on direct muscular irritation (baryum, strophanthin, cathartica). The action consists presumably in depression of the augmentory vagus endings.

Intermediate doses of atropin (from therapeutic to fatal) seem to act differently, according to conditions and species. In man (Katsch, 1913) in rabbits, and in some cats (Hirz, 1913), they cause further depression and relaxation of the intestinal tone.

In typical cats (Magnus) they increase the movements of the normal intestines (i.e., unless there is vagus-spasm). This occurs also in the
excised intestine, but not in plexus-free preparations. The segmentation movements also become more regular. The action consists apparently in stimulation of the Auerbach ganglion cells. Larger doses also paralyze the inhibitory splanchnic endings.

Excised doses of atropin (so large that they can not be brought into action by systemic application, but only locally and in the excised intestine) paralyze successively the ganglion cells, the endings, and the muscle, thus destroying the response to the muscular poisons such as barium.

In the excised intestine, the relative doses of atropin are as follows: 0.1 per cent. is required to produce depression; 0.025 to produce stimulation; and 0.005 to antagonize pilocarpin.

Cholin Influence on Atropin Response.—The variable and contradictory responses to atropin depend perhaps largely on the cholin content of the intestines. Small and medium doses of atropin are always inhibitory to freshly excised intestines, in which the cholin content is relatively high. After the intestine has been soaked in saline solutions for some time, the cholin gradually leaches out. Medium doses of atropin then become stimulant; and small doses are ineffective (Le Heux, 1910).

The optical isomers of atropin act quantitatively alike on excised intestine (Lilge-stand, 1910).

Sympathetic Stimulants.—Epinephrin inhibits the normal intestinal movements; as also those produced by atropin, nicotine, pilocarpin, and strophantin, but not those of barium. This inhibition occurs in plexus-free preparations, and after degeneration of the postganglionic fibers, and is therefore located in the myoneural junction.

Muscular Stimulants.—Barium citrate provoke very violent contraction; the effect occurs in plexus-free preparations and is presumably (from analogy) exerted directly on the contractile substance. It is abolished only by the very large doses of atropin which paralyze the muscle substance.

Strophantin (and presumably the other digitaloid drugs) stimulate in small doses and inhibit in large doses. The effects occur in plexus-free preparations, and hence involve the endings or muscle, presumably the latter. The stimulation is abolished only by the extreme doses of atropin.

Miscellaneous Poisons.—A procain paralyzes the sympathetic ganglia, thus abolishing the inhibition on splanchnic stimulation. In the isolated intestine, it first stimulates the Auerbach cells, and then paralyzes the endings or muscle.

Amino-acids.—Glutamic acid, aspartic acid, histidin, glycocoll, tyrosin and cystin were tried in a 1/1,000 solution on excised intestines of cats and rabbits, without effect.

Apergolin appeared to produce slight stimulation (Hirschlfeider and Cantwell, 1918).

Hydrogen Peroxid.—Very weak concentrations (sometimes 1:1,000,000) increase the tone of excised intestine temporarily. Shortly this returns to normal, and further pendant is then ineffective. Larger doses inhibit the movements (H. J. Hamburger and Brown). Female Romélie on Excised Intestines.—Debelle, Burman and Fletcher, 1916, found the effects on rabbit's intestine practically the same as on the guinea-pig uterus. Caesalpinium, however, leaves the tone almost unchanged, while the amplitude is lowered. Hiestan (oil) depresses the contractions. The vibratums are inactive.

Stomach.—Preparations of excised mammalian stomach were found by M. Smith, 1917, to react as follows:

Pilocarpin: Contraction of all regions.

Atropin: Counteracts pilocarpin and produces relaxation.

Nicotin: Contraction with most species; relaxation with a few.

Epinephrin: Relaxes with most species; contraction with some. Phosphates are always contracted.

Endotoxin: Relaxes epinephrin contractions.

Dr-elicie Sphyngist.—Elliott, 1904, showed that this differs from ordinary intestine, for splanchnic stimulation and epinephrin produce contraction. No inhibitory nerve is known. Kuroda, 1916, confirms this on excised intestine; but finds further that the parasympathetic poisons (pilocarpin and atropin) as also nicotin and cocain, produce the same effects as on small intestine. This sphincter therefore belongs to the same class as the skin and the uterus.

Conclusion.—Excised segments have little tendency to rhythmic contraction. This corresponds to their normal inertia in the body (Alvarez and Starkweather, 1918).
Colon Peristalsis.—In dogs and cats Alvarez and Starkweather, 1918, often found the gradient of irritability reversed. This probably protects against too frequent defecation. They suggest that excessively reversed gradient may be a cause of constipation.

THE NATURE OF ANTAGONISM

Until there is a clearer understanding of the chemical and physical changes which condition the actions of the antagonistic poisons, we can conceive the nature of their antagonism only in terms of crude analogies.

1. We may suppose that the stimulant and depressant drugs each act upon different chemic constituents. In this case, the combined effect would be a simple summation of their separate actions. This might be the explanation of the action of atropin and physostigmin on the oculomotor junction.

2. Both poisons may act upon the same constituent. In this case the end result would depend upon the relative affinity of the two poisons for this constituent. This offers several possibilities.

(a) The two drugs may have approximately the same affinity—in this case the ratio of effect would depend purely upon the relative quantity.

(b) One drug may have a much greater affinity than the other; this might apply, for instance, in the case of atropin and pilocarpin on the pupil, where a small quantity of atropin suffices to abolish the effects of a large quantity of pilocarpin; while a large quantity of pilocarpin is needed to overcome even a trace of atropin. The case may be somewhat analogous to the combination of oxygen and carbon monoxide with hemoglobin.

(c) The efficiency of the one may be so much greater than that of the other, that the antagonism is practically irreversible. Atropin, for instance, completely prevents the action of physostigmin on the uterus.

3. One poison might influence the penetration of another, and in this way alter its distribution, and thus again entirely change its point of attack. This has been shown by Ehrlich for certain dyes; and similar conditions have been shown to prevail for muscarin and atropin, by Straub; and for morphin and chloroform by Fuehrer.

With these possibilities in mind and remembering that they are based merely on crude analogies, it is clear, at least, that antagonism is a highly complex subject. We must be content, for the present, with the empiric facts: That the point of attack of the poisons is not absolutely specific; that it may shift according to conditions, dose, time of action, etc.; that the effect of the same drug on different structures, and even on the same structure, may be augmentory or inhibitory, or both; that a poison may present mutual antagonism to two poisons which act on different structures; that the antagonistic dose may be much smaller than the minimal effective dose under ordinary conditions; that the removal of a drug (pilocarpin) stimulation by a depressant (atropin) need not be accompanied by paralysis to electric stimulation, while in other cases they go hand in hand. The schematic presentation which has been given may serve as the thread of Ariadne through this labyrinth; but after all, it is still more important to grasp the individual facts which have a practical application.

Quantitative Antagonism of Atropin and Pilocarpin on Salivary Secretion.—This has been investigated by Cushny, 1916, on dogs with salivary fistulas. It was found that the antagonistic dose was the same for different dogs. The ratio also remained the same (about 1 part of atropin to 9.5 of pilocarpin) whether the two drugs were injected simultaneously or some time apart; and it remained unaltered whatever total dose was injected. This agrees with the laws of mass action, rather than with those of chemical combination.

Relation of Action to Intracellular Penetration, Storage, and Destruction.—According to W. Straub, 1907, the effect of most alkaloids is proportional to their concentration within the cell. With muscarin, however, he found the relation quite different: Here the effect appears to depend upon the concentration outside the cell; or rather, on there being a higher concentration outside than inside the cell. The experiments were made by placing the frog's heart into a muscarin solution.
PERIPHERAL AUTONOMIC SYSTEM

The quantity of poison remaining in solution, and the quantity which could be extracted from the heart were then tested on aplysia-hearts. Hearts laid in a muscarin solution show a primary diastolic standstill, followed by spontaneous recovery in a few hours. The maximal diastolic action occurs when very little muscarin has passed into the muscle; while at the time of "recovery," all the muscarin has passed into the heart. If now the recovered heart is placed into a fresh muscarin solution, it is again arrested, with spontaneous recovery. This may be done repeatedly; but the action becomes shorter and shorter, and finally nil. That is, the heart becomes completely refractory to even the highest concentrations of muscarin. If the muscarin concentration is increased very slowly, the heart does not respond. The presence of atropin appears to delay the penetration somewhat. Any explanation of these phenomena would have to be too hypothetical. (O. Loewi, 1912, considers the resumption of the beat under muscarin as analogous to escape from vagus stimulation, and attributes both to increased excitability of the cardiac muscle.)

Incidentally, this furnishes an interesting example of antagonism. The effects of muscarin are exactly the same in animals which have no vagus mechanism; but atropin is only antagonistic in animals in which a vagus mechanism is developed.

With Ephedrine the action is also proportional to the concentration outside the cells. A still more striking example is described by Freudenberg, 1912, for bronchial muscle. This constricts strongly in solutions of muscarin, pilocarpin or arecolin. Washing the poisoned solution with pure Ringer's fluid does not remove the constriction; on the contrary, this often causes a further contraction. The same phenomenon was observed by Kuyer and Wijnenbeck, 1913, on excised intestine and uterus. Transferring the poisoned tissues into pure saline again brought on the typical augmentory or inhibitory effect of the poison; while transfer from the old to a fresh solution of the poison produced no result. This is taken to indicate that the effect occurs only during the passage of the poison through the cell membrane, into or out of the cell.

Cell Permeability—Ascher and Gannus, 1911, found that the gland cells of the nictitating membrane of frogs take up much more of vital stains when they are stimulated by pilocarpin than when depressed by atropin.

OPTICAL ISOMERS

Most if not all the autonomic poisons are optically active (or racemic); and the chemical reactions which determine their specificity depend on their stereochemic configuration. The stereoisomers have an identical composition and radicals; but owing to the presence of one or more asymmetric carbon atoms, these groups are arranged differently in space (Van't Hoff and Le Bel, 1874). This is indicated by the optical activity, so that these isomers are levo-rotatory, dextro-rotatory, or by the combination of the two, racemic. Our knowledge of these phenomena dates from the classic discovery of Pasteur, that racemic tartaric acid is separated into its optical constituents by mould fungi. Since then, very numerous instances have been worked out on higher animals; such as atropin and hyoscynamin; atrocin and scopolamin; the ephedrine, muscarin, nocin, conina, cinchona alkaloids, camphors, etc. (Fräenkel, Arzneimittel-synthese). Cells and ferments distinguish sharply between these stereoisomers, so that they invariably differ, at least quantitatively, in their pharmacologic effects, the racemic being intermediate between the active forms. This indicates that the reactive substance of the cells must also be optically active, and it is suggested that the effects of the l-active hyoscynamin and lepincrphrin are antagonistic to those of the d-pilocarpin and esgotoxin (Cushny, 1898). In higher animals, the l-alkaloids usually have more powerful peripheral effects. It is probable that the cells can either attack or destroy the one isomer more readily than the other (Poulson, 1910). The asymmetric nitrogen atom also modifies the pharmacologic actions, as shown by Hildebrandt, 1905, for conina; and Laidlaw, 1913, for canadina. The curare action of the ammonium bases (Brown and Fraser, 1869) also depends upon the peculiar orientation of the pentavalent atom of nitrogen or similar elements.
ATROPIN

Summary of Actions.—Atropin and other closely related alkaloids (hyoscynam, scopolamin, etc.) produce a variety of peripheral and central effects, namely:

1. Complete paralysis of the peripheral distribution (myoneural junction) of the parasympathetic (cranio-sacral autonomic) nerves (oculomotor secretory, bronchial musculature, cardiac and intestinal vagues, uterus etc.).

2. Consequently, antagonism to pilocarpin, muscarin, physostigmin etc.

3. Slight stimulation and, in large doses, subsequent paralysis of smooth and cardiac muscle and other cells.

4. Slight peripheral sensory paralysis, on local application.

5. Excitation and then paralysis of certain cerebral and medullary centers.

These actions find varied application in therapeutics, and are of great scientific interest.

Specificity of the Autonomic Actions.—The peripheral actions of atropin are confined mainly to the augmentory nerves of the cranio-sacral division of the autonomic system. To this there are a few exceptions; for it affects also inhibitory cranial nerve (cardiac vagues) and a few augmentory and inhibitory sympathetic nerves (uterus and sweat glands) (Cushny, 1910).

Occurrence.—Atropin occurs in a number of drugs (Belladonna Stramonium, Hyoscyamus, Scopolia, Mandragora, Duboisia, etc.) derived from plants belonging to the order Solanaceae (the potato family). The also contain varying proportions of other alkaloids (hyoscynam, scopolamin, etc.) which are closely related to atropin in structure and in action.

The alkaloids, as first isolated, were mixtures; consequently, the properties appeared to vary with the origin, and these mixtures were given specific names (Daturin, Duboisin, etc.). The pretended difference between scopolamin and “hyoscin” is a survival of this tradition.

Historical.—Belladonna received but little medical notice, and seems to have been first introduced into practice, as an anodyne, about 1800. The first indisputable notice of belladonna occurs in 1504, but it then came quick into use for poisoning and cosmetic purposes. The name Atropos, which Linne gave the plant, is from the oldest of the Three Fates, who cuts the thread of life. Belladonna comes from the Italian “handsome woman,” as it was used to give luster to the eyes. On account of the slow course and the obscure symptoms, belladonna was a favor with professional poisoners in the middle ages, and this abuse in regard to several species of Datura (Stramonium) has existed in India since remote ages. The name itself Sanskrit (Dhatuara).

Hyoscyamus was mentioned by Dioscorides in the first century, and has been used continuously in domestic medicine. It was introduced into practice by Stoerck in the middle of the eighteenth century. He also introduced Stramonium Mandragora (Mandrake) was the subject of some interesting medieval myths. The “herbarium” of Apuleius (eleventh century) quotes its use, externally, for headache and insomnia and internally for mania.

Chemical Structure and Relations.—These alkaloids are ester-like combinations of certain bases with organic acids of the aromatic series.

Atropin, (C₁₇H₂₄NO₃), is the tropic acid ester of a base, tropin, and is isomeric with Hyoscyamin; hyoscyamin being levorotatory, while atropin is racemic. The esters of tropin are called tropeins. Homatropin is the
mandelic ester of tropin; and other tropeins occur naturally or may be prepared synthetically. Tropin itself is closely related to Ecgonin, the basic constituent of coca. The osceins are analogous esters of the base oscin. The tropeic acid ester constitutes the important alkaloid Scopolamin or hyoscin, (C₁₅H₂₄NO₄). This also occurs in isomeric forms: Atropin (racemic, corresponding to Atropin); and Scopolamin proper (levorotary, corresponding to Hyoscyamin). Atropin and Atrosin are the more stable products: Alkalies and many other agents convert hyoscyamin into atropin, scopolamin into atrosin.

Chemical Constitution.—Tropin has the formula

\[
\begin{align*}
\text{CH}_3 & \quad \text{CH} \quad \text{CH}_3 \quad (a) \\
& \quad \text{N.CH}_3 \quad \text{CHOH} \quad (b) \\
\text{CH}_3 & \quad \text{CH} \quad \text{CH}_3
\end{align*}
\]

Ecgonin (the base of coca) is the beta carbo-acid of tropin, one H at (a) being replaced by COOH.

Atropin is the tropic ester of tropin, the H at (b) being replaced by the radical

\[
\text{CO} \quad \text{CH} \quad \text{CHOH}
\]

The sulphuric ester of atropin is nearly devoid of peripheral actions, while the central effects, especially the respiratory stimulation, are preserved. Scopolamin-sulphuric ester does not share this respiratory action (Trendelenburg, 1913).

Bellerodane and Atroparin are isomeric alkaloids (belladonanic acid tropelins). Their formula differs from atropin by the absence of a molecule of H₂O. They are present in the plants in very small amount, and it is possible that they are only formed during the extraction.

Constitution and Action.—The relation between this has been investigated by Cashen, 1919, 1920; using as criterion the antagonism of the pilocarpin salivation. The atropin effect is absent from tropin itself; but is produced by many of its compounds, especially those with the benzene nucleus. It is greatly intensified by the presence of hydroxyl and of asymmetric carbon in the side-chains. The greatest activity is only reached when these are in the form of an aromatic acid.

The asymmetric carbon is very important. The β-hyoscyamin is 40 times more active than the d-hyoscyamin; but even this is more active than the nearest homologues that do not contain asymmetric carbon. This is not indispensable, however, for some activity exists in tropins without asymmetric carbon and without hydroxyls. These therefore probably do not act as anchoring groups; but more likely by affecting some physical property.

Distribution of Alkaloids.—Bellerodane and Stramonium contain mainly atropin and scopolamin; one or the other alkaloid may predominate. The hyoscyamin is the most widely distributed of these alkaloids, and is especially abundant in young parts of the plants, whereas older parts contain more atropin. It appears therefore that the hyoscyamin is the original alkaloid, and that it is partly transformed into atropin in the plant itself, and also during extraction. These plants also contain small traces of scopolamin and atrosin, but the latter alkaloids are relatively more abundant in Hyoscyamus and Sopola, taking the principal part in the actions of these plants. The distribution and variation of the alkaloids in individual plants has been studied by Sievers, 1913 and 1914. This suggests the feasibility of improving the alkaloidal content by selective breeding (Sievers, 1915).

Effects on Psychic Functions.—Therapeutic doses of atropia have no perceptible effects on the psychic functions; but overdoses produce symptoms (see "Toxicology") superficially resembling alcoholic inebriation. However, the excitement and stimulation are more prominent, passing
from mere restlessness to hallucinations and delirium, and even mani
and the effects are much more lasting. Similar symptoms are seen
animals. With toxic doses the stimulation passes into coma, convulsion
and asphyxia.

The convulsions are not entirely asphyxial, for they are not abolished by artif
respiration.
The vision is disturbed more than can be explained by loss of accommodation.
The motor areas in dogs are stated by some observers to be more excitable, but oth
deny this.
In frogs, atropin first increases the reflexes; this is followed by general paralysis, a
this again by late tetanus.

Respiration.—Therapeutic doses, in man (1 mg. hypodermically)
stimulate respiration, increasing somewhat the rate and minute volume
and sometimes the depth of the respiration. The excitability of
respiratory center is not increased directly, however; for the alveol
CO₂ tension is unchanged, whereas it would be found lower if the thresho
of the center were lowered. The stimulation is therefore indirect; bein
due partly to increased CO₂ production (increased gaseous metabolism
partly to increased "dead space" in the lungs by bronchial dilation (Eds
and Means, 1914; Higgins and Means, 1915). Toxic doses produce
late depression of the center (Binz, 1856), which is the usual cause of
death in atropin poisoning.

Respiration in Animal Experiments.—The results have been rather contradictor
Heinz, 1890, found no appreciable change in the respiratory volume of rabbits; Wo
and Cerna, 1942, increased rate and minute volume in dogs. According to most o
servers atropin countersacts respiratory depression from chloral (Husemann, 1877)
morphin (Henbach, 1878; Binz, 1887; Vollmer, 1892); but others found that it augme
the morphin depression (Oberwiski, 1891; Unverricht, 1892 and 1896).
Voegtlin and Wiggers, 1918, using an improved method on anaesthetized dog
find that moderate doses of atropin stimulate slightly after morphin.

Atropin was ineffective against depression of the respiration by cerebral compressi
(Loevenhart et al., 1918).

With larger doses, the psychic excitement and muscular activity would increas
respiration indirectly. Toxic doses depress respiration, producing slowing, Cheys
Stokes type, and finally cessation. Artificial respiration may enable an animal
to survive six times the ordinary fatal dose.

Therapeutic Uses of Respiratory Stimulation.—The mechanism of this respirat
action in man would render its usefulness doubtful. On the basis of the animal expe
ments (which, however, involve larger doses) it has been used against poisoning by po
phin, and as a preliminary to anesthesia, or even as a restorative in anesthetic fatalik
(Webster, 1908). It is also often used in whooping cough, but is of doubtful effic
(child of one year, ½ to ½ gr. of Extr. Belladonna, or 8 to 10 drops of Tr. Balle
three times daily, doubling the dose in a week if tolerance is acquired (A. Jacobii, 190

BRONCHIAL MUSCLES AND GLANDS

Atropin paralyzes the innervation of these structures, and therefor
dilates and dries the bronchial tubes. The dilation is obtained in excisi
rings of bronchial musculature (Trendelenburg, 1912), and is therefor
peripheral. These effects are especially important for relieving attac
of bronchial asthma.

Pharmacology of Bronchial Muscle.—This also has an important bearing on th
explanation and treatment of asthma. The bronchi are innervated by the vag,
wild being mainly constrictor, but also dilator fibers. The response to drugs has been studi
in intact animals by Dixon and Brodie, 1903, and by Sanoz, 1912, by recording th
excursions of the lungs under uniform artificial respiration. D. E. Jackson, 1913, in
controlled their work with the extra precaution of keeping the blood pressure level. Tremblay and Proctor, 1898; Fleisch and Pick, 1913, and Titone, 1913, have also checked it on excised bronchial muscle.

**Bronchial Constriction** is produced by the drugs which stimulate the vagus endings, such as physostigmine, pilocarpin, muscarin, cholin, anaphylatoxin, peptone, ergotoxin, tyramin, histamin, pituitary, aspidospermin, etc.; by those which stimulate smooth muscle, such as barium, veratrin, the salts of many metals (vanadium), quinin and several other alkaloids, bromin vapor, etc. It may also be produced by direct stimulation of the mediastinal centers, as by carbon dioxide; or reflexly by irritation of the mucosa of the nose, larynx or bronchial walls. Nicotin, lobelia, and curare and small doses of pilocarpin produce an initial constriction, followed by dilation. Jackson attributes this secondary dilation to stimulation of the subparenchymal. Muscarin and pilocarpin also contract the excised muscle; physostigmin and veratrin do not. (E. Weber, 1914, claims that the bronchus-constrictor action of muscarin, histamin, etc., is largely central.) Agar solutions perfused through the lungs of guinea pigs produce prompt and marked distention of the lung and arrest of perfusion flow. The effect is antagonized by papaverin or atropin, and is due to agar emboli in the pulmonary vessels. These arrest the circulation and shut off the bronchi by mechanical compression (Hanzlík and Karner, 1920).

**Bronchial Dilation.**—This is produced by drugs which paralyze the vagus endings, especially atropin and its related alkaloids (Dreser, 1890; Elsthooven, 1892; Beer, 1892) large doses of atropin also depress the dilator endings; by epinephrin, which stimulates the dilator endings; and by cholin, apericrin, chloroform and ether. Morphin dilates is small doses but contracts in large doses. The excited muscle is also relaxed by atro- pin (after a brief constriction), and by epinephrin. The vapors of ether and chloroform, in concentrations even smaller than those used in anesthesis, affect the excised bronchial muscle, ether (0.3 per cent.) producing dilation, and chloroform (0.6 per cent.) contric- tions. Amyl nitrite and sodium nitrate give a temporary dilation; ammonium salts produce a slight dilation. Sodium iodid and camphoric acid have no effect in living animals. In man, with 1 mg. of atropin, the increase of dead space amounts to 7 to 10 per cent. (Hering and Means, 1914).

**Pulmonary Nerves in Tortoise.**—These respond to drugs somewhat differently than in mammals. Nicotin, pituitary, lobelin and veratrin produce strong contraction of the tortoises lungs, which is not observed in dogs. Codetin and pilocarpin act as in mam- mals (D. E. Jackson and Pels, 1918).

**Therapeutic Application to Asthma.**—Bronchial asthma is commonly due to spasmodic constriction of the bronchioles, produced in some cases reflexly, in others probably analogous to anaphylactic reaction. The tubes of the bronchi may be further narrowed by catarrhal swelling of their mucosa.

The constricted passages offer an insurmountable resistance to expiration. This is easily overcome by inspiration, (Cloeckaert, 1913), so that the lungs become overdistended; but the respiratory exchange is greatly hindered.

Such cases may be promptly relieved by atropin or ephinephrin. The atropin acts on both the constriction and the hypersecretion. It is also effective against experimental bronchial constriction (Dixon and Lee, 1914); and with proper dosage against anaphylaxis (Auer, 1912; Kersner and Nutt, 1911). It could not be effective in cardiac, renal, or emphysemaus "asthma." Unfortunately, it seems to lose its effects, even in what would appear to be suitable cases. Ephinephrin is often much more active.

**Administration.**—Atropin (½ to 1 mg., ½ to ½ gr.) or the drugs containing it may be administered by any channel; but inhalation is most effective since it brings the drug directly to the site of its action. This is accomplished by inhaling the smoke of burning stramonium leaves.

**Asthma Powders** consist of atropin-containing drugs, mixed with sufficient saltpeter to insure their combustion; e.g., Powdered Stramonium, 3 Gm.; Lobelia, ½; Atise, ½;
CIRCULATION

Single therapeutic doses of atropin do not usually affect the pulse rate materially; but ordinary experimental doses greatly increase the heart rate by paralyzing the vagus endings. All vagus inhibitions are thus abolished. The blood pressure rises moderately, mainly through the quickened rate, but partly through central vasomotor stimulation. If the blood pressure has been abnormally lowered by excessive vagus stimulation, the atropin rise will appear correspondingly greater. The cutaneous vessels are actively dilated by atropin, the skin assuming a more or less scarlet color. Toxic doses paralyze the vasomotor center and eventually also the arterial and cardiac muscle, so that the blood pressure falls profoundly.

Action on the Vagus.—Atropin stimulates the vagus center in common with the other medullary centers. It may therefore cause a slight primary slowing; but this is soon overcome by the peripheral paralysis. This vagus paralysis results in quickened heart rate in all animals in which the vagus is tonically active (in man, the cat, dog, etc.). In completely atropinized dogs and cats, the rate is about 140 to 240 per minute. The vagus tone being small in rabbits and in frogs, these animals show little or no quickening; but in these the vagus is also paralysed, for its stimulation does not slow the heart. In man, the vagus tone is greatest in middle life, less in old age, and least in infancy, and the response of the heart rate to atropin varies accordingly.

The inotropic as well as the chronotropic functions of the vagus are paralyzed in frogs (Kansoan, 1917).

In the auricles of terrapin, atropin is said to increase the tonus, without affecting the periodic tonus waves (Gruber and Markel, 1918).

The duration of the paralysis varies with the dose, and also with the species. It lasts only a few minutes in rabbits (Rosenbach, 1874), longer in gopherous rabbits (Fleischmann, 1912). In dogs and cats, a partial effect persists for hours (Pilcher and Sollmann).

The dosage required to paralyze the vagus has been studied by Pilcher and Sollmann, 1914. It is always small, but varies somewhat in different animals, even of the same species, and even for the two vagi of the same animal; the left vagus being more susceptible. Low blood pressure also increases the susceptibility. In every respect the susceptibility to atropin is inverse to the natural excitability of the vagi. In the dog, about 0.01 mg. per kilogram lessens the response to vagus stimulation perceptibly and about two or four times this dose abolishes the response completely. When the paralysis is incomplete, a slight further slowing may be secured by strengthening the stimulus; but with the larger dosage even the strongest stimulus remains ineffective.

The vagus paralysis is located in the termination of the vagus (or in the receptive substance); for stimulation of the postganglionic fibers (at the sinus-auricular junction of the frog) fails to slow the heart.

Atropin abolishes cardiac inhibition by all drugs which act through the vagus mechanism, whether they stimulate this reflexly (ammonia or chloroform inhalation); centrally (picrotoxin or veratrum), or peripherally in the ganglia (nicotin), or in the endings (pilocarpin, muscarin, physostigmina).

Results of Vagus Stimulation After Atropin.—In dogs, when the atropin action has gone just so far that stimulation of the divided vagus trunk causes no perceptible slowing, this still produces a slight fall of blood pressure; larger doses abolish this response also, so that the inotropic properties of the vagus terminations seem to be somewhat more resistant then the chronotropic.

When the intact vagus is stimulated in atropinized mammals, the blood pressure may fall or rise by stimulation of the afferent vasodilator or constrictor fibers which run in the vagus.

In atropinized frogs, stimulation of the vagus trunk quickens the heart, since this carries the accelerator fibers, which are not affected by atropin.

Atrio-ventricular Rhythm.—This may occur in man from doses of 1 mg. It sets in within 8 to 10 minutes, and soon reaches a maximum, and then disappears. Wilson.
Assumes that atropin releases the A-V tissue from vagus control somewhat before it releases the sinus.

Electrocardiogram.—In dogs, small doses of atropin usually produce auriculo-ventricular block. With larger doses, this is followed by increased sinus rate. At the same time, it abolishes any existing blocks, sinus arrhythmias or ectopic beats (as with digitalis). In this last respect, atropin is more efficient than nitrite.

The A-V conduction is usually slowed by small and quickened by large doses. The P wave at first tends to negative, then to more positive (Halsey, 1917).

Perfusion of Tortoise’s Medulla.—Atropin, 0.02 per cent, has practically no effect on the heart rate or rhythm (Bush, 1919).

Therapeutic Use of Vagus Action.—The paralysis of the vagus endings indicates atropin (1 to 2 mg., 1/50 to 1/50 gr., hypodermically, repeated as needed) in conditions of excessive vagus stimulation, such as cerebral pressure; the reflex vagus inhibition of colic; of angina; of chloroform anesthesia; operations about the vagus trunks, etc. Atropin also abolishes such cardiac irregularities as are due to heightened vagus excitability (pulsus responsus), and it may be used to diagnose whether a cardiac slowing is due to vagus stimulation.

In fact, however, response to atropin (or amyl nitrite) merely shows that the heart is still under vagus tone—not that the bradycardia was of vagus origin (Fredericq, 1916).

In the atrioventricular block, the rate responds to atropin or nitrite (Fredericq, 1916). It has been found clinically effective in sino-atrial block (N. W. Brown, 1919, 0.5 to 1 mg.). It has no effect in complete heart-block (van Egmond, 1913).

Atropin Test for Typhoid Fever.—In fever, when the vagus control is weak, atropin does not produce much further quickening. This was suggested as a test for typhoid fever, but of course is not specific.

The “test” was introduced by F. A. Marris, 1916. It consists in injecting 2 mg. of atropin hypodermically into the upper arm. In normal subjects this gives in 15 to 20 minutes a maximal increase of 20 to 40 beats per minute (often preceded by a slight slowing of 2 to 4 beats per minute). This returns to normal in about 2 hours (Friedlander and McCord, 1916).

In typhoid patients, between the 10th and 21st day, the increase is not more than 15 per minute.

Marris, 1916, and E. H. Mason, 1918, considered this specific for typhoid, occurring in about 80 per cent. of the cases, independently of initial heart rate, and absent in non-typhoid fevers. However, Friedlander and McCord found the test “positive” in a third of patients with miscellaneous non-typhoid conditions.

Matsuz and Murakami, 1918, have expanded the test to comprise other drugs, as disturbed under vagotonia and sympathicotonia.

Vagotonia and Sympathicotonia.—Eppinger and Hess, 1909, assumed a normal equilibrium between the sympathetic and parasympathetic innervation of organs. In disease the system could acquire an abnormal tone, so as to become hyperexcitable, either to stimulants and pilocarpin in vagotonia; or to epinephrin in sympathicotonia. Later it was found that both conditions may co-exist in one patient.

Later Hess conceived vagotonia as a manifestation of “disturbed hormone equilibrium.” This conception is purely speculative (Vincent, 1917).
These tests were applied systematically to typhoid patients by Matsua and Murakami, 1913, with the following results:

**Atropin**, 1 mg. hypodermically, acted strongly in bradycardia, but was almost inactive in its absence. The most marked feature was the increase of pulse rate; the heart's rhythm; and lastly palpitation.

**Epinephrin**, 1 mg. hypodermically; many patients responded with increased pulse rate, rise of blood pressure, increased respiratory rate; rise of temperature; some also with tremor and glycosuria.

**Pilocarpin**, 1 mg. hypodermically; most patients responded with salivation, sweating, nausea, vomiting, singultus; slowing of pulse was exceptional.

Altogether, those typhoid patients with bradycardia generally were hypersensitive to the vagus poisons; those without bradycardia were generally hypersensitive to epinephrin. These latter presented a larger mortality.

**Atropin-response in "Effort Syndrome" with Irriable Heart.**—The pulse rate respond with the normal incipient slowing, followed by an increase which is generally greater than normal, i.e., 6 to 30 per minute. The respiratory quotient is slightly lowered. The basal metabolism remains unaffected (Sturges et al., 1919).

**Action on Cardiac Muscles.**—Atropin has a slight direct effect on the cardiac muscle which can be observed in the isolated heart, and also on the nerve-free heart of the embryonal chick. Small doses stimulate the muscle, causing an increased tonus, greater excursions, and some slowing. An exhausted frog's heart may be made to beat again. Large doses diminish the tonus and may slow or quicken the rate. Finally the heart is paralyzed, but only after the vasomotor center. Indeed, the effects on the heart muscle are not of any importance in the sytemic action of the drug, being overshadowed by the other effects.

In the excised mammalian heart (Langendorff method) atropin provokes rhythm contractions of the apex after the base is clamped. This requires larger doses than are needed for paralyzing the vagus. These large doses may also restore the beat when it has been arrested by muscular poisons (Luchsinger, 1881).

In intact animals, atropin increases the auricular, but decreases the ventricular efficiency (Wiggers, 1912).

**Vasomotor Center.**—Sollmann and Pilcher, 1910, have shown by their perfusion method, that this is moderately stimulated. The stimulation is not sufficiently marked to produce a rise of pressure when ordinary doses are injected after dividing the vagi.

**Cholin-Antagonism.**—Large doses of atropin prevent the vasodilator effect of cholin. Since atropin does not counteract other vasodilator reactions, this must be a peculiar mechanism, probably peripheral (Hunt, 1918).

**Pulmonary Vessels.**—Atropin has no effect on the normal vessels, but removes the constriction of plicaripin or histamin (Hare in, 1914).

**Cerebral Vessels.**—These are dilated (Benzain, 1912).

**Cutaneous Circulation and Skin Eruptions.**—Atropin produces intense flushing of the skin, particularly of the face and chest, occurring in extensive erythematous spots, or as a continuous erythema which has sometimes been mistaken for scarlatina. This effect is much greater in some patient than in others; it may occur with therapeutic doses. It due to dilatation of the cutaneous vessels (vasodilator stimulation) with increased general blood pressure. This hyperemia may be so intense as to lead to desquamation.

**TEMPERATURE.**

Atropin suppresses perspiration, and thus causes a rise of temperature with moderate doses, notwithstanding the cutaneous vasodilatation. Animals which do not possess sweat glands (dog) do not show this rise. Larger doses produce a fall of temperature from lessened heat production, the result of the general depression. The final convulsions may again cause a rise.

**GASEOUS METABOLISM.**

This is increased by therapeutic doses (1 mg.) in man (Edsall and Means, 1916; Higgins and Means, 1915).

In dogs, the intravenous administration of atropin diminished the respiratory movements and reduced the CO₂ of the blood. This effect is mutually antagonized by pilocarpin (Klemen, 1918).
ATROPIN GROUP

341

ACTIONS ON THE EYE

Atropin dilates the pupil (mydriasis) and renders it insensitive to light. It also paralyzes accommodation (cycloplegia), the lens being adjusted only for far vision. These actions are entirely peripheral and consist in paralysis of the oculomotor endings. The intraocular tension in glaucoma is increased through the mydriasis.

The atropin effects may be removed by drugs which stimulate the oculomotor endings (pilocarpin, phystostigmin, muscarin); and vice versa.

The atropin mydriasis and cycloplegia are very persistent; the mydriasis especially may last for several days. The ocular actions are produced to a varying degree by all the atropinoid alkaloids.

Localization of Actions on the Pupil.—To understand the pharmacology of the interesting papillary reactions, it is necessary to recall the anatomical relations of the iris mechanism (see Fig. 10).

The iris contains two sets of smooth muscle fibers, the sphincters and dilators. The sphincters are innervated by fibers contained in the oculomotor. These terminate around the cells of the ciliary ganglia. From here the fibers pass as the short ciliary nerve.

The nerve fibers for the dilators run in the cervical sympathetic and terminate in the superior cervical ganglia. The fibers which arise from here go directly to the dilator muscle without passing through any other cells. They run to the Gasserian ganglion, where they join the first branch of the trigeminal, and go from here as the long ciliary to the muscle.

Stimulation of the Sympathetic Mechanism, in any of its parts, results in (submaximal) dilation of the pupil, with little disturbance of accommodation; in exophthalmos and separation of the eyelids; and in constriction of the ocular vessels. These are the effects produced by the drugs which stimulate the sympathetic division; typically by cocaine; less typically by epinephrin, for this can produce mydriasis only if the oculomotor tone is low, or if the sympathetic endings are hyperexcitable.

Stimulation of the Oculomotor Mechanism, in any of its parts, results in constriction of the pupil (miosis), spasm of accommodation, and lowering of intraocular pressure.

These are the typical effects of the drugs which stimulate the cranio-sacral division—Pilocarpin and phystostigmin, etc.

Paralysis of the Oculomotor Mechanism has the opposite effect; namely these just described for "Atropin." (The asphyxial dilation of the pupils is perhaps due to paralysis of the oculomotor center.)

Oculomotor Tone.—The iris appears to be normally controlled chiefly by variations in the oculomotor tone, the sympathetic playing mainly the part of a reciprocal antagonist—that is, it is stimulated when the oculomotor is inhibited, and vice versa. The strong oculomotor (constrictor) tone is normally held in check by a great variety of sensory and psychic impulses. When these inhibitory impulses are abolished (i.e., by sleep, narcosis, and in a specific manner by morphin), the pupils are constricted by the

[Diagram of eye showing nerve pathways]
unchecked oculomotor tone. On the other hand, when the inhibitory impulses are reinforced, the pupils dilate. This occurs in excitement.

Causes of Mydriasis.—Mydriasis can be due to any of the following causes:

Stimulation of the sympathetic mechanism (cocain).
Paralysis of the oculomotor mechanism, peripheral (atropin) or central (asphyxia).

Increased inhibition of the oculomotor center (excitement).

Causes of Miosis.—These may consist in:
Stimulation of the oculomotor mechanism, peripheral (pilocarpin, physostigmin), or central (picrotoxin).
Lessened inhibition of the oculomotor center (sleep, narcosis, morphia).

Paralysis of the sympathetic mechanism (practically unimportant). Experimental Localization of the Atropin Mydriasis.—Atropin dilates the pupil on local, as well as on systemic application. The mydriasis remains confined to the eye, and even to that side of the eye, to which it is applied. The dilation is produced in the excised eye of the frog, and even in the isolated iris. Its action must therefore be peripheral.

The constrictor response to stimulation of the oculomotor nerve is abolished by atropin. Stimulation of the postganglionic fiber (short ciliary) is also ineffective. The oculomotor mechanism is therefore paralyzed peripherally to its ganglia. The iris, however, still contracts to direct electric stimulation, so that the muscle fibers are shown to be unaffected. The paralysis must therefore be located in the oculomotor endings or in the receptive substance. This is as far as the analysis can be safely carried.

The Behavior of the Sympathetic Mechanism.—There has been considerable discussion as to whether atropin in addition to paralyzing the oculomotor, also stimulates the sympathetic mechanism. The question may now be safely answered in the sense that there is no direct sympathetic stimulation by atropin; for stimulation of the sympathetic, electrically or by cocain, causes a further dilation of the pupil, even after maximal doses of atropin. The atropinized pupil contracts somewhat when the sympathetic is divided; but this is the natural result of cutting off the tonic sympathetic impulses. It has been argued that the atropin dilation can not be a passive process, since it is of sufficient force to tear firm adhesions of the iris. This merely shows that the dilator muscles contract actively; but their contraction is simply the result of the withdrawal of the constrictor tone, and need not involve a direct stimulation of the sympathetic mechanism. It is quite probable, however, that the natural sympathetic tone is heightened when the constrictor tone is withdrawn, for this would harmonize with the general law of reciprocal innervation.

Direct Actions on the Iris Muscle and Ciliary Ganglia.—The statement that the muscular fibers are not affected by atropin must be limited to moderate doses. In greater concentration (according to most observers) it at first stimulates them, producing a temporary narrowing of the pupil; later it paralyzes them.

Direct application of very strong solutions to the ciliary ganglion also depresses this structure.

The iris of birds is not dilated by atropin, but by curare, since it consists of striped muscle.

Changes in Intraocular Tension.—All mydriatics tend to increase intraocular tension in glaucoma, although not in the same degree. Conversely, the tension is lowered by miotics. Neither has much effect on the normal intraocular tension (Wessely, 1905; Bollet and Curtii, 1911; Luebs, 1913; Myashita, 1913). 1

1 Slight effects may be obtained from atropin and physostigmin for three or four hours after death in the human eye (Groenow, 1910).
Mechanism of the Change in Tension.—It is commonly assumed that the rise of pressure in mydriasis is produced mainly by lewened filtration of the aqueous humor into the venous sinuses of the channels of Fontana and canal of Schlemm. These lie in the angle of attachment of the iris, and would be compressed by the contraction of the ciliary muscle, and by the crowding back of the iris. Miosis would have the opposite effect (especially in glaucoma; in the normal eye miotics are said to lower the pressure very little). The intraocular tension is also controlled by the blood pressure, in the vessels of the iris (Leber), and would be lowered whenever these are ischemic either through fall of the general blood pressure (relatively little influence; Kochmann and Koerner, 1914); or through local vasococonstriction. The vasoconstricting cocaine therefore, generally lowers intraocular tension, although it produces mydriasis; and it is claimed that atropin also tends to lower the pressure in the normal eye. Exceptionally, however, glaucoma has been reported after cocaine, atropine, and even after epinephrin (Gifford, 1916).

Glaucoma.—The phenomena of this very serious eye disease depend mainly upon excessive intraocular tension: due, presumably, to blocked drainage (Schoenberg, 1913). It is therefore treated by miotics (see physostigmin); and it contraindicates the employment of mydriatics. If their use is indispensable, the choice should fall upon cocaine; and if cyclopia is necessary, the briefly acting homatropin would be preferred to atropin.

Practical Application of Atropin to the Eye.—The effects of atropin are utilized mainly for paralyzing the ciliary muscle to facilitate ophthalmoscopic examination; and in the treatment of iritis.

For diagnostic work, the persistent cyclopia is often objectionable, but in other cases the enforced rest of the eye may be desirable. The atropin can be temporarily antagonized by physostigmin; but if a short action is preferred the less persistent homatropin may be substituted. This is also much less liable to provoke glaucoma. However, homatropin should be used as dilute as possible (1 or 2 per cent.), and followed by physostigmin, 0.2 per cent., a drop three times daily until the pupil and accommodation have returned to normal (Gifford, 1916).

In iritis, the atropin mydriasis is used to secure rest, to prevent adhesions of the iris to the lens, or break them if already formed; and to effect assumed favorable changes in the circulation of the iris. It is also a weak anesthetic. The more prolonged action of atropin causes it to be preferred for this purpose.

Administration to Eye.—The atropin is always applied locally, by dropping an aqueous solution of the sulphate, or an oily solution of the free alkaloid, on the cornea; or by placing impregnated gelatin discs (Lomelce Atropine, B.P., 3/6,000 gr.) in the conjunctival sac. Watery solutions tend to flow into lachrymal duct, thereby lessening the local action, and tending to systemic poisoning. To avoid this, but a single drop of 1 per cent. solution should be applied at a time, and the lachrymal sac should be compressed with the finger. For continued use, in iritis, greater dilutions may be employed, down to 1/4 per cent. (even 1/100,000 is somewhat effective). The effect is increased by the addition of cocaine.

Duration of Action of Atropin.—With a single drop of 1 per cent. solution, the mydriasis reaches its maximum in about twenty-five minutes, the cyclopia in about two hours. The cyclopia disappears in two or three days (seven to nine days if the application has been continuous); the mydriasis endures even longer, ten to twelve days.

Side Actions.—Besides the increase of tension, atropin causes photophobia (because of the irresponsible pupil); and micropsia, from the loss of accommodation.

In sensitive individuals, atropin produces some conjunctivitis, and
rarely edema of the eyelids. If it is used carelessly, it may give rise to systemic poisoning, headache, dryness of the mouth, palpitation, etc. Species of chronic poisoning may occur in this way (Tyrrell, 1906).

If atropin causes local irritation, scopolamin should be substituted since this may be used in one-fifth the concentration.

**Substitutes for Atropin.**—These fall into two classes: (1) Those which produce mydriasis without cycloplegia (Euphthalmic, Ephedrin); and (2) those which produce both mydriasis and cycloplegia (Atropin, Hyoscyamin, Scopolamin, Eumhydrin, and Homatropin—in the order of their persistence of the cycloplegia). Of these, atropin is the standard, the others being used only when it is contraindicated.

The action of hyoscyamin is similar to atropin, but it is effective in about one-half the concentration. Scopolamin is effective in one-fifth the concentration.

Quantitative measurements of the relative efficiency of mydriatics and miotic agents alone and combined, are given by Jackson, 1885; by Grube, 1905; by Horovitz, 1911; and by Joachimoglu, 1915.

The following table shows the strength of solutions usually employed for ophthalmoscopic examinations; and the ordinary duration of their actions.

**PREPARATIONS—SYNTHETIC MYDRIACTICS**

*Homatropin Hydrobromidum* (Homatrop. Hydrobr.), U.S.P., B.P.; C₁₉H₁₄BrF₂N.H₂Br,—Mandelic ester of tropin. Freely sol. in water (1:6); sol. in alc. (1:4). Instilled as 1 to 2 per cent. solution. Dose, 0.5 mg., 1/2 gr., U.S.P.; 1 to 2 mg., 1/4, 1/2 gr., B.P. Maximum dose, 2 mg., 1/4 gr.

Systemic actions similar to atropin, less toxic. Its action on the vagus is purely paralytic, but weaker than atropin (Zulik, 1915).

*Lam. Homatrop.* B.P.—0.65 mg., 1/40 gr.

Eumhydrin, N.N.R. (Methylatropin Nitrate).—Readily sol. in water. It acts very closely with atropin in systemic actions, and may be substituted for it, in the same dosage; in eye, 1/4 per cent. Its toxicity is about one-fifth that of atropin. Cusby, 1910, found it 1 1/2 times more active than atropin in the salivary pilocarpin antagonism. Continued use often leads to tolerance (Self Nebenwirk., 1915, p. 66).

*Euphthalmia Hydrochlorid, N.N.R.—Closely related to betacaucaix in composition. It is readily soluble in water; 2 to 3 drops of 5 to 10 per cent. solution are instilled. Side actions, Self, Nebenwirk., 1915, p. 66.*

**PARALYSIS OF SECRETION**

Atropin and the related alkaloids arrest all secretions which depend upon central innervation: This includes the sweat, saliva, tears, mucous, gastric juice and ordinary pancreatic secretion; but not the urine, bile or secretin pancreatic secretion. The action is localized in the nerve endings or receptive substance, and is mutually antagonistic with the pilocarpin action.
Suppression of Saliva (Antisialogogue Action).—The submaxillary glands furnish a classical object for localizing the action of Atropin. This suppresses the secretory response to chorda-tympanic stimulation, even when this is applied at the hilus of the gland, i.e., to the postganglionic fibers. The paralysis must therefore be peripheral to these. The cells, however, still respond to sympathetic stimulation, so that the paralysis must be in an intermediary substance, in the nerve-endings.

This argument involves the assumption that the chorda tympani and the sympathetic act upon the same cells in the salivary gland. This is doubted by A. P. Mathews, and by Gaskell, 1916. The evidence is, therefore, not as conclusive as in the case of smooth and cardiac muscle, where the excitability of the contractile substance can be confirmed by direct stimulation; but the analogy is otherwise so complete, that the conclusion is fairly safe.

Large doses of atropin inhibit the response so sympathetic stimulation (Cannon and Cattell, 1906); perhaps by paralyzing the secretory cells directly.

In man, Ewing, 1911, found that 0.5 to 1 mg., by mouth, caused a marked decrease in the volume of saliva secreted. The percentage of organic solids was somewhat diminished; the percentage of inorganic solids showed only a trifling decrease. The percentage of ptyalin fell markedly, but recovered, or was even somewhat increased, before the volume or solids had returned to normal.

Residating Fibers of the Chorda Tympani Nerve.—These are not affected, so that stimulation of the atropinized nerve still dilates the vessels and produces an increased venous outflow from the gland. (The effects of atropin and pilocarpin on the submaxillary circulation are discussed by Henderson and Loewi, 1905.)

Antagonism.—Atropin completely suppresses the nicotine stimulation (since this stimulates the ganglion cells); it is mutually antagonistic with pilocarpin, etc., but the atropin action, as usual, tends to be the stronger.

The quantitative relations have been studied by Cusimy.

Atropin is also said to suppress the mercurial salivation, but not the "paralytic secretion." which is produced when the divided sympathetic terminates.

Paradoxic Reflex Secretion in Chronic Poisoning.—Abundant reflex secretion of saliva occurs in cats and dogs after repeated injections of atropin, and continues for months if the injections are continued. The chorda nerve may be excitable or not. The sympathetic is excitable. The action is referred to the salivary center (Arima, 1918).

Practical Significance of the Antisialogogue Action.—This is mainly a rather unpleasant side effect in the therapeutic use of the drug. Small doses (0.5 mg.) may be employed to suppress practically any form of ptyalism. It is not much used, since the benefits scarcely offset the inconveniences attending the use of the drug.

Suppression of Mucous Secretion.—This may be employed in the hypersecretion of corzyla, bronchorrhea, ether anesthesia, etc. Minimal doses of atropin are used to abort incipient colds (0.5 mg., 1/80 gr. or less, in a glass of water, slipped slowly in the course of an hour.—Kohnstamm, 1906). The cutaneous vasodilation may play a part in this abortive action.

Suppression of Sweat (Anhydrotic Action).—This is one of the earliest actions, and can be secured with small doses (0.3 to 1 mg., 1/20 to 1/50 gr., hypodermically). It is the most effective means of suppressing the night sweats of phthisis, but the relief is only symptomatic, and scarcely justifies the inconveniences.

Other Anhydrotics.—The night sweats may also be suppressed by sodium or eumydrin. Acetic acid also arrests sweating by a peripheral action of the sweat glands, but is uncertain. Camphoric acid has been employed, but it does not act upon the sweat glands. If it has any effect (which is doubtful), it must be indirect, through improvement of the respiration.
Sodium Taururate appears to act similarly, to atropin but is objectionable on account of the persistent gastric odor which it gives to the breath.

Local measures are often preferred, especially for local hyperhydrosis. Spousing with cold lotions containing alcohol, dilute acids, tannin, salicylic acid, formaldehyde, etc. Dusting-pouders are likewise useful (talcum with 5 per cent. of salicylic acid or 10 per cent. of boric acid).

**Gastric Actions.**—The secretion of gastric juice, and especially of hydrochloric acid, is diminished or suppressed, through paralysis of the secretory vagus endings (Chiari, 1913). The motor activity (pylorospasm, etc.) is also depressed by the vagus paralysis (Auer and Meltzer, 1906). Both actions make atropin useful in hyperchlorhydria, gastric ulcer, tumors, etc. It is especially indicated (0.5 to 1 mg., 0.75 to 1.5 gr., before meals) in acute conditions with severe pain and vomiting (Mathieu and Girard, 1913; A. Schmidt, 1914). It has been used in *stenickeiner* (atropin, 0.5 mg.; strychnin, 1 mg., hypodermically—Girard, 1906). The sojourn of meat in the stomach is delayed by large doses of atropin (Tyebaert, 1912, 1913).

**Excited Stomach.**—Atropin counteracts the pilocarpine contraction and produces relaxation. (M. Smith, 1918).

**Influence on Normal Gastric Secretion.**—In dogs, intramuscular injection of atropin (0.0125 mg. per Kg.) completely inhibits secretion in response to food. Smaller doses (0.005 mg. per Kg.) diminishes the volume and the peptic activity. The acid-concentration is not affected until a dosage is reached that diminishes the volume by 50 to 80 per cent. There is a mutual antagonism toward histamin and gastrin, extending to nearly fatal doses of atropin. With large doses, the atropin and gastrin appear to act directly on the gland-cells; smaller doses probably act on some other site (Koren et al., 1920).

**Influence in Hyperacidity.**—Crolm, 1918, distinguished two clinical groups, in the response to 1 mg. of atropin, hypodermically:

(a) Patients with Normal Secretion Period.—Atropin, 3/4 hour after eating, had its effect at first; later it increased the acidity. The motility was not affected.

(b) Patients with Continuous Secretion.—Atropin, 2½ hours after eating, arrested the acid-secretion within an hour, while in the controls, the secretion would last over hours more. The degree of acidity was, however, increased.

**Atropin in Diarrhoea.**—According to the fluoroscopic studies, the response to 1.2 mg. of atropin, hypodermically, is uncertain. Sometimes it produces sudden relaxation; in other cases it is ineffective (Barclay, 1915).

**Atropin in Pylorospasm.**—Only large doses relax this, in infants (Ochsenius, 1909. **Clinical Benefits.**)—Bastedo, 1930, concludes that atropin is useless in hyperacidity.

In cases with continuous secretion, this may be checked, but only by impractical doses. Large doses may be useful in pylorospasm.

**Antagonism to Emetics.**—Eugleton, 1916, finds that very small doses of atropin (0.01 mg. per kilogram) prevent the emetic action of pilocarpin and nicotine, but not a-somatropin, morphin, nicotine, or emetin. The ant-emetic dose being smaller than required against peripheral actions of pilocarpin, suggests that atropin depresses the emetic center.

**Pancreatic Juice.**—Atropin suppresses the increase of pancreatic secretion which ordinarily follows stimulation of the vagus or the administration of pilocarpin, cholin, etc. Large doses, however, provoke a pancreatic flow in the dog (Popielski, 1899; Modrakowski, 1909). The mechanism of this peculiar action is not understood; it may possibly be connected with the actions on the liver.

On the secretion flow, atropin has no direct effect (Chiari, 1912), but since it diminishes the secretion of acid in the stomach, it probably lessens the production of secretin indirectly, and hence interferes with the physiologic pancreatic secretion.

The pancreatic stimulants which are antagonized by atropin yield active juice, whereas those which are not affected by atropin require the addition of ergotin (Canis and Gley, 1909).

Atropin prevents the pancreatic secretory response to vagus-stimulation and to lister in acute experiments; but in permanent fistula experiments Savich, 1919, found it ineffective.
Uric Acid.—Atropin is said to prevent the increase of uric acid that normally follows the ingestion of food; presumably by preventing the secretion of the digestive juices (Mendel and Stehle, 1913). It also prevents the cinchophen increase (Abl, 1912).

Lacteal Secretion.—Ott and Scott, 1912, confirm Roehrig, that this is somewhat diminished by atropin.

Glycogenolysis.—The old statement that atropin prevents the transformation of the hepatic glycogen into sugar, appears to be erroneous. It originated with Morat, 1881, who concluded that pilocarpin stimulates, and atropin inhibits, the conversion of glycogen into sugar. Cavazzani and Soldaini, 1896, also stated that atropin paralyses glycosecretory nerves in the liver. The evidence, however, was unsatisfactory and has been disproven by the results of Mosenthal, 1913, and of Macleod, 1908. The latter showed that splanchnic stimulation produces the same hyperglycemia after atropin as normally. McGuigan, 1916, also finds no direct effect of atropin or pilocarpin. Large doses of atropin may increase the blood sugar (also observed by Flini, 1908). This is due simply to the excitement.

On the other hand, E. L. Ross, 1920, claims that atropin diminishes ether glycuresia materially. The mechanism was not investigated. Chloriform hyperglycemia, which is probably asphyxial, is not checked by atropin (Ross, 1920).

Atropin in Diabetes.—It has been asserted that atropin increases the tolerance for carbohydrates (Rudisch, Forchheimer); but the statement needs confirmation (Mosenthal, 1913).

Hepatic Actions and Consolubility of Blood.—The secretion of bile is sometimes slightly diminished by atropin (Okada, 1914; Yanagawa, 1916). The lymph-flow may be either increased or unchanged (Yanagawa).

The injection of large doses of atropin into the portal vein lowers the consolubility of blood, first of that of the hepatic vein. This effect can not be produced by injection into the jugular vein, nor by addition of atropin to shed blood (Doyen and Kareff, 1904 and 1906), and is due to an action on the liver. The anticoagulant substance is also produced by the perfusion of atropinized blood through an excised liver (Doyen, 1910).

The leucocytes are not changed by ordinary doses. Toxie doses, especially when often repeated, diminish the eosinophiles. The action is probably indirect (Herrick, 1914; Port and Brunow, 1914). The emigration of leucocytes in exposed mesentery is not inhibited by atropin or scopalamin (Ikeda, 1916).

Vesic Formation.—This is stimulated by small quantities, inhibited by large doses (Iomoggi, 1916).

Actions of Atropin on Peristalsis.—These vary according to the dose and conditions: Minimal doses quiet excessive peristalsis provoked by toxic peripheral vagus stimulation, as by pilocarpin, cholín, physostigmin, etc. These doses do not affect normal peristalsis.

Ordinary therapeutic doses relax the intestines in man and rabbits (Katzin, 1913; Hitz, 1914). In cats, they may increase peristalsis (Magnus). It is conceivable that this also occurs in man in some conditions.

Excessive doses, such as can be brought into play only by local application, paralyze the intestine. All these actions are peripheral, but affect different structures in the intestine. The details are described in the general section on autonomic drugs.

Therapeutic Use of the Peristaltic Actions.—The inhibitory action of atropin is utilized against toxic spasms of the intestine, which presumably depend upon peripheral vagus stimulation: the colic pains of indigestion, and colic, ptomain diarrhoea, etc. The dose for this purpose is usually 1 mg. (1/60 gr.).

It also lessens, in this way, the "gripping" effect of purgatives. The atonic preparations would be preferred, to prolong the local action: for pills, Extractum Belladonne, 15 mg. or 1/4 gr.; for liquids, Tr. Belladonae, to minimas.

Biliary and Renal Colic.—Atropin paralyses the innervation of the smooth muscle of the bile ducts and ureters, and therefore relaxes the painful and obstructive spasm which results from the passage of calculi.
through these tubes. The vagus paralysis is also useful in this connection by preventing the dangerous cardiac reflex which sometimes occurs. Thiacetamin, 1 mg., 3/40 gr., is given hypodermically, usually combined with morphia, 15 mg., 1/4 gr.

**Gall Bladder.**—This may be relaxed (Lieb and McWhorter, 1913); but not by ordinary therapeutic doses (Macht, 1917).

**Excited Uriner.**—Small doses of atropin may stimulate the tone and periarticular movements. Stronger solutions (1:10,000) inhibit them, as also the stimulant effect of pilocarpin, physoestigmin and cholnin (Macht, 1916).

G. B. Roth, 1917, however, found nicotine, pilocarpin and atropin practically ineffective.

**Hyoscyamin Isomers on Uriner.**—The latter stimulates the contractions and slight raises the tonus; very large doses depress. The dextro inhibits from the start, without stimulation (Macht, 1918).

**Urinary Bladder and Incontinence of Urine.**—Atropin is employed to relieve incontinence of the urine, due to overaction of the bladder muscle; and retention of urts from overactivity of the vesical sphincter. The details of dosage are described by Huhreah, Am. J. Med. Sc., February, 1912. A. Jacobi advised for children 1/4 gr. Belladonna Extract at night, increasing if necessary, to flush the cheeks.

The action of the atropin patch on the bladder has not been definitely determined (Edmunds and Roth, 1920).

**Urine Flow.**—Discordant results have been described by different investigators. They are summarized by Cow, 1912 and 1913. He finds that atropin has no effect if the urine is collected directly from the pelvis of the kidney; but that it merely modifies the flow through the ureter, by lessening its tone.

The suppression of sweat and other secretions might temporarily increase the output of urine.

**Uterus.**—The effects of atropin correspond to its actions on the intestine: Smaller doses increase, large doses abolish, the uterine movements (Kehrer, 1908). Minimum doses abolish the pilocarpin and physoestigmin spasms. Even large doses of physostigmin are ineffective after atropin.

**Atropin in Dysmenorrhoea.**—This was introduced by Drenkham, 1910, and is advocated by Novak, 1912; especially in the spasmodic, colic type. The administration is started two days before the expected menses, and continued for two or three days during menstruation; usually in doses of 0.6 mg. (3/100 gr.) by mouth, three or more times daily. If dry throat, itching skin or disturbed accommodation develop, the dosage is reduced. These side-actions interfere greatly with its therapeutic availability (Litzenberg, 1910).

**Curare Action.**—In frogs, large doses of atropin paralyze the motor endings of striped muscle and abolish the physostigmin twitchings, after the manner of curare. This effect would not occur with doses which can be used in mammals.

**Anodync Action.**—The local application of atropin dulls, rather than paralyzes, sensory nerves. It is therefore applied in the form of belladonna liniment or plaster, for the relief of pain, especially neuralgic and rheumatic. Belladonna suppositories (extract, 0.1 Gm., 1/4 gr.) are also used in painful hemorrhoids.

**Dosometric Table.**—The following (Schmiedeberg) may be useful in the therapeutic use of atropin:

<table>
<thead>
<tr>
<th>Mg.</th>

ATROPIN GROUP

ATROPIN POISONING

Atropin is very readily absorbed, somewhat even from the intact skin, so that toxic symptoms have been observed (though rarely) after the use of belladonna plasters (Doland, 1906). They occur rather commonly in ophthalmic use, through the lacrimal ducts. Where the plant grows wild, the berries are often eaten by children.

Symptoms.—These set in promptly, but usually run a long course; lasting five to fifteen hours, or even several days in fatal cases. The first to be noticed are those arising from dryness of the mouth and throat; difficulty of deglutition and articulation, great thirst, a sense of burning and constriction in the throat. On the eyes, the dilatation of the pupils, impaired vision, absence of reaction to light will be noticed. There is often nausea and sometimes vomiting. Excitement, passing into delirium, is a prominent feature. The delirium may be pleasing, with spectral illusions; or anxious or furious (a graphic description of the psychic experiences is given by L. L. Jepson.) The onset of the paralytic symptoms is ushered in by giddiness, numbness of the limbs, and staggering gait, and passes into drowsiness and stupor. The pulse is quick (to 170) and small. The respiration is stertorous, fast or slowed. The face is flushed scarlet. In fatal cases death is preceded by coldness of the extremities, rapid and intermittent pulse, and deep coma. Convulsions are rare. Glycosuria is sometimes seen and may be attributed to the asphyxia. The postmortem findings are those of asphyxia.

A fatal ending is, however, quite rare (12 per cent.). The fatal dose of atropin is probably 0.1 Gm. or more for adults; 0.01 Gm. for children. Therapeutically, children bear proportionately larger doses than adults, and this holds also for young animals.

Recovery starts within two days, the respiration, pulse and pupils returning gradually to normal. Sometimes violent delirious symptoms may last for days, and it has happened that patients have been consigned to the insane asylum on a mistaken diagnosis.

A psychic "slowness," disturbance of vision, and some other symptoms, may persist for weeks.

Chronic Atropin Poisoning has been reported, especially from ophthalmic use (Tyrrell, 1906). However, the continued use of small doses establishes partial Tolerance to the toxic action, but not to the effects on the vagus or oculomotor (Anrep and Roussbach, 1880; Cloetta, 1912).

Treatment of Atropin Poisoning.—This is usually effective since the prolonged course gives ample time for interference. It resolves itself into chemic neutralization, prompt removal, and meeting the symptoms. The delirium is best treated by the ice-cap, the general symptoms by pilocarpin (10 mg., 1/6 gr. hypodermically, repeated until mouth is moist). Morphin (10 mg.) is also indicated in the early stages, but not after depression has set in. The latter is combated by the usual medullary stimulants (coffee, etc.) Artificial respiration should be kept up persistently, if necessary.

The effects on the eye may be abolished by the local application of physostigmin.

Excretion.—The greater part of the atropin disappears rapidly from the body (Cloetta, 1908). It is excreted mostly unchanged, entirely by the urine, mainly within thirty-six hours.

The application of a drop of this fluid to the eye of a cat is the most
convenient test for poisoning. Mydriasis occurs with a single drop of 1:150,000 solution, equivalent to 0.000245 mg. of atropin. Of scopolamin, the minimal mydriatic dose is 0.0000855 mg. (Joachimoglu, 1915). The human pupil is about equally sensitive (Metzner, 1912). The excretion is not complete, more or less of the atropin being destroyed in the body.

A part is excreted as tropin and as another base (Fickewirth and Heffer, 1912). The variations in this destruction and in the rapidity of excretion explain the racial and individual idiosyncrasies and acquired tolerance.

Atropin resists hydrolysis for a long time, and may be found in the cadaver even months after burial. Confusion with ptomaine (a putrefactive alkaloid) must be guarded against.

RACIAL AND ACQUIRED TOLERANCE

Rodents and marsupiads are very tolerant, as also, to a less extent, the goat, dog, birds, and some other animals. (The dosage for different animals has been determined by Wilberg, 1914.) The immunity is in no case complete. It is perhaps greatest in the case of rabbits, and can be increased by habituation. In rabbits, it is due mainly to destruction of the atropin by the serum and organs.

Heckel, 1875, found that rabbits and guinea pigs did not only thrive for weeks on an exclusive diet of atropin-containing plants (Schroff, 1852), but that this exclusive diet could be continued for several generations. A further degree of immunity was thus acquired, so that the mydriatic effect was smaller and the fatal dose (hypodermically) higher. The flesh of these animals contained relatively little atropin, although the meat of ordinary rabbits poisoned with atropin is toxic to other animals and man (Kopp, 1866; Lewin, 1804).

Cause of the Tolerance.—This has been investigated chiefly in rabbits. It is not due to defective absorption or superior excretion, for the tolerance exists also for hypodermic injection, and after ligation of the renal vessels (Hermann, 1894). The leucocytic theory of Calmette, 1893, need not be further considered since it was disproved by Ellinger, 1901. The correct explanation was furnished by Fleischmann, 1910 and 1911. He found that digestion of atropin with rabbit's serum gradually weakened its activity; r c.c. of the serum may thus destroy 0.1 mg. in twenty to thirty minutes. The serum of man, dogs, cats and rats does not have this action (except some cases of human tissue: Doeblin and Fleischmann, 1914). These observations have been fully confirmed by independent workers. Cloeota, 1911, and Clark, 1912, find that the destruction is also effected by emulsions of rabbit's liver. In frogs, the heart and kidneys also have this effect. The blood corpuscles are not concerned in the reaction. Since the property is destroyed by heating to 55° to 60° C., it is probably due to a ferment, formed in the liver (Metzner, 1912; Clark). Doeblin and Fleischmann, 1913, find that it has the characters of the albumin fraction. Metzner believes that there is a change of tropic acid and tropin, which may recombine on very prolonged standing. Homatropin and scopolamin are also destroyed (Doeblin and Fleischmann). Fleischmann found that the destructive power varies greatly in different rabbits, being practically absent in some; he attributed this to goiter. Metzner and Hedinger, 1913, confirmed the variation, but showed that it bears no relation to the thyroid; nor does the injection of thyroid confer a destructive power for atropin when this is deficient. Heffer and Fickewirth, 1912 find that the tolerance of rabbits to rapid intravenous injection is relatively small, since this does not permit time for the destruction. The rapid passage of atropin out of the blood indicates that its destruction must take place mainly in the tissues (liver).

Cause of Habituation; Excretion in Animals.—Cloeota, 1912, found that non-habituated rabbits excrete 15 to 20 per cent. of the atropin, the excretion being completed in two to three days. (Fickewirth and Heffer find that the total excretion of all basic is about 50 per cent. of the administered quantity.) After immunization, the excretion is complete in one day; and as little or none can be found in the tissues, it appears that the rapidity of destruction and excretion has been increased. The destructive
HYOSCYAMIN

Actions and Uses.—This is the levo-isomer of the racemic atropin. Cesnhy, 1903, compared these two alkaloids and the dextro-isomer. He finds that the peripheral actions on the iris, cardiac vagus and glanis are 12 to 18 times as strong with the l-isomer (ordinary hyoscyamin) than with the d-; and about twice as strong as with atropin. Hyoscyamin, herefore, has some advantage when the peripheral effects are desired, specially in ophthalmic work. Internally, it has no advantage. All the isomers act practically alike on the central nervous system of mammals. The d- has a greater stimulant effect on the spinal cord of frogs.

On the intestine, the isomers act quantitatively alike (Liugstrand, 1919).

PROTocatechyl TropEin

This has been investigated by Marshall, 1910. It paralyses the vagus endings, but loses power than atropin or even homatropin. It produces a curare effect on the nictitating membrane and a temporary central paralysis of respiration. There is also an independent partial fall of blood pressure.

PREPARATIONS—ATROPIN GROUP

**Atropina, U.S.P., B.P.; C₁₅H₂₃NO₃S—**The alkaloid obtained from Belladonna and her plants of the Solanaceae family. Slightly sol. in water (1:452); freely sol. in alc. (1:2); sol. in fat solvents and oils. **Dose.** 0.3 mg., ½₃₄ gr., U.S.P.; 0.3 to 0.6 mg., ¾₃₄ gr. to ¾ gr., B.P.

*Atropina Sulphus (Atrop. Sulph.). U.S.P., B.P. (C₁₅H₂₃NO₃S₃H₂SO₄ + H₂O) white crystalline powder; odorless. Very sol. in water (1:04); freely sol. in alc. (1:2); sol. in glyce. (1:2). Incompatible with alcalies, tannin and mercuric salts. Atropin fusions deteriorate rather rapidly; a 1,000 solution losing considerably in trinity within three days (I. Simon, 1912). Sterilized solutions in ampoules, however, serve their full activity at least four weeks (Iachimoghiu, 1915). **Dose.** 0.5 mg., 1 gr., U.S.P.; 0.3 to 0.6 mg., ¾₃₄ gr. to ¾ gr. gr., B.P. **Maximum dose.** 1 mg., ¾ gr. gr. Commercial atropin is usually contaminated with varying quantities of hyoscyamin (Lisnstrand, 1910).

*Lam. Atrop., B.P.---0.013 mg., ½₃₄, 0.005 mg., B.P.

*Liq. Atrop. Sulph., B.P.---1 per cent. **Dose.** 0.005 to 0.06 c.c., 1/₄ to 1 min. B.P.

**Hyoscyamin. Hydrogr., U.S.P.; C₁₅H₂₃NO₃S·HBr.---Strongly lectoratory. Very sol. water; freely sol. in alc. (1:2:5). **Dose.** 0.3 mg., ¼ gr.

Commercial hyoscyamin is usually contaminated with varying quantities of atropin (Lisnstrand, 1910).

**Hyoscyamin. Sulph., B.P.** (C₁₅H₂₃NO₃S₃H₂SO₄ + 2H₂O.---Very sol. in water (1:2). **Dose.** 0.3 to 0.6 mg., ¾₃₄ gr. to ¾ gr. gr., B.P.

**Belladonna Folia, U.S.P., B.P.; Belladonna Leaves (Deadly Nightshade).---The** sol leaves and tops of Atropa Belladonna, yielding not less than 0.3 per cent. of stratic alkaloids. **Dose.** 0.06 Gm., 1 gr., U.S.P. **Maximum dose.** 0.2 Gm., 3 gr. **Belladonna Radix, U.S.P., B.P.; Belladonna Root.—The** dried root of Atropa Bellu- mana, yielding not less than 0.45 per cent. of mydriatic alkaloids. **Dose.** 0.045 Gm., ½₃₄ gr., U.S.P.

Est. Bellad., Fol., U.S.P.—1 gm. represents 1 gm. of leaves, 1.25 per cent. of alkaloids. Occurs in both pulvilar and powdered form. Dose, 15 mg., 0.5 gr., U.S.P. Maximum dose, 50 mg., 3 gr.

*Est. Bellad., Fol., B.P.—1 per cent. of alkaloids of leaf. Dose, 10 to 60 mg., 3/4 to 1 gr., B.P.

*Fledest. Bellad. Rad., U.S.P.—0.45 per cent. of alkaloids. Dose, 0.05 c.c., 1 minin, U.S.P.

Est. Bellad., Liq., B.P.—0.75 per cent. of alkaloids of the root.

Lin. Bellad., B.P.—50 per cent. of Liq. Ext. Bellad. (root); 5 per cent. of Camphor.

*Tr. Bellad., Fol., B.P.—10 per cent. of the leaves, 0.05 per cent. of alkaloids. Dose, 0.75 c.c., 12 minims, U.S.P. Maximum dose, 1 c.c., 15 minims.

*Tr. Bellad., B.P.—10 per cent. of leaves, 0.05 per cent. of alkaloids. Dose, 0.5 to 1 c.c., 5 to 15 minims, B.P.

Supp. Bellad., B.P.—1 mg. of the alkaloids of the root.

Ung. Bellad., B.P.—0.5 per cent. of the alkaloids of the root.

Datura Folia, B.P.—The dried leaves of Datura Fastuosa and Metel.

Datur. Sem., B.P.—The seeds of Datura fastuosa.

Tr. Datur. Sem., B.P.—25 per cent. Dose, 0.5 to 1 c.c., 5 to 15 minims, B.P.

Hyoscyamus, U.S.P.; Hyoscy. Fol., B.P.—The dried leaves and tops of Hyoscyamus niger, yielding not less than 0.05 per cent. of alkaloids, chiefly hyoscyamine, with some atropine and scopoletin.

Dose, 0.25 Grm., 4 gr., U.S.P. Maximum dose, 0.5 Grm. 6 gr.

Est. Hyoscy., U.S.P.—A pulvilar extract, 1 gm. representing 4 Grm. of drug, 0.25 per cent. of alkaloids. Dose, 0.06 Grm., 0.1 gr., U.S.P. Maximum dose, 0.3 Grm., 3 gr.

*Est. Hyoscy., B.P.—A dry extract, with 0.5 per cent. of alkaloids. Dose, 0.3 to 0.5 Grm., 2 to 8 gr.

Fledest. Hyoscym., U.S.P.—About 0.05 per cent. of alkaloids. Dose, 0.2 c.c., 3 minims, U.S.P.

Tinctura Hyoscyami (Tr. Hyoscym.). U.S.P., B.P.—10 per cent. Miscible with water or ale.

Dose, 2 c.c., 30 minims, U.S.P.; 2 to 4 c.c., 3/4 to 1 dram, B.P.

Maximum dose, 4 c.c., 1 dram.

*Stramonium, U.S.P.; Stramon. Fol., B.P.; Stramonium (Jameson Weed, Linson Weed).—The dried leaves of Datura Stramonium (also Datura Tatula, U.S.P.).

Contains not less than 0.25 per cent. of alkaloids, chiefly hyoscyamine, with some atropine and scopoletin.

Dose, 0.06 Grm., 0.1 gr., U.S.P. Maximum dose, 0.3 Grm., 5 gr.

Tr. Stramon., B.P.—10 per cent. Dose, 0.5 c.c., 8 minims, U.S.P.

*Tr. Stramon., U.S.P.—A pulvilar or powdered extract, 1 gm. representing 4 Grm. of drug, 1 per cent. of alkaloids. Dose, 10 mg., 1/6 gr., U.S.P.

Ung. Stramon., U.S.P.—10 per cent. of the extract.

AGARIC ACID

Acidum Agericum, N.N.R., and the impure mixture Agericium, is derived from a fungus of the larch tree. It is a white, odorless and tasteless crystalline powder, but slightly soluble in cold water and alcohol.

The anhydrotic action of the fungus was probably known for some centuries. Agaric was introduced against the night-sweats of phthisis by Young, 1882. The effect appears only after some hours (if at all) and then lasts for about 24 hours. It is a local irritant, and therefore can not be given hypodermically. Large doses produce vomiting, diarrhea, and death through central paralysis (Hofmeister, 1886). The maximum single dose should not exceed 0.03 Grm. (3/4 gr.) and the daily dose should be below 0.1 Grm. (1/4 gr.). As habituation occurs, it is better to start with 0.2 mg. (1/3 gr.) Clinical opinions differ as to its value.

The mechanism of its action has not been satisfactorily explained. Hofmeister claimed that it prevents the sweating-response of the cat's paw to icatic stimulation of heat, indicating that its action is peripheral and similar to atropin. However, it does not arrest the saliva or tears. McCartney, 1917, finds that it has a digitalis action, and that it stimulates smooth muscle. He therefore suggests (but without direct evidence) that it arrests perspiration by a special action on the muscular tissue of the sweat glands.
SCOPOLAMIN OR HYOSCIN

General Statement.—The commercial samples of scopolamin (also called hyoscin) are usually indefinite, and often rather impure mixtures of two isomeric alkaloids (tropic esters of oschin): scopolamin proper (levorotary, 55.76%), and atrocin (optically inactive). They occur in the various atropin-containing plants, but are now prepared mainly from Scopolas. The U.S.P. now specifies the optically active alkaloid i.e., scopolamin proper.

The peripheral actions of scopolamin agree qualitatively with those of atropin; but there are quantitative differences; for instance, the actions on the oculomotor and secretions are stronger, while the vagus action is relatively weak.

The central actions differ qualitatively; scopolamin being mainly sedative, in all doses; while moderate doses of atropin are excitant. However, there are great individual variations in the response to scopolamin, and, therefore, in its toxicity. The variable toxicity is due mainly to idiosyncrasy, for it occurs with the purest samples; although the uncertain composition of the commercial samples probably plays a part.

Chemical Differences in Scopolamin.—It is often stated that there are specific differences in the effects according to the origin of the alkaloids; and that "hyoscin" derived from hyoscyamus is therapeutically superior to the "scopolamin" of scopol. No such difference can exist if the pure alkaloids are employed; for these are identical, wherever their source (E. Schmidt, 1892 and 1894). Impure mixtures doubtless produce different effects, but impurities are quite as likely to be present if the alkaloid is prepared from hyoscyamus. A purified "scopolamin" is much more reliable than an impure "hyoscin." Moreover, there is no way of determining from which plant the alkaloid has been prepared (J.A.M.A., 1907, 107:1209). It is, therefore, useless to make this distinction between "scopolamin" and "hyoscin."

Apotropin (C18H23NO5, also called belladolamin or atropamin) was demonstrated in a commercial sample by Kohert, 1905, and has been held responsible for the occasional toxic effects. This is improbable. It is a rare impurity (Klonka, 1908) and its presence is easily shown, by reduction (brown color); on adding a few drops of permanganate solution (Kessel, 1906). It exists preformed in the plants and may be derived chemically from atropin by the abstraction of one molecule of water. It causes, in rabbits, a rise of blood pressure, paralysis of cardiac vagus endings, central excitation, and death with relatively small doses, by paralysis of respiration. The oculomotor and secretory endings are not paralized (Marcacci, 1885; Kohert, 1905).

Deterioration of Solutions.—This has been suggested as a cause for idiosyncrasy (f.e., by Gauss, 1907; Langer, 1913, and Sachs, 1913); but according to the seemingly more reliable experiments of Klonka, 1908; Willstatter and Hug, 1921; and Beck, 1914; the solutions keep unchanged indefinitely, at least in sealed ampoules.

Pharmacologic Differences between Scopolamin and Atrocin.—These play an important part in the peripheral actions, but not in the more important central effects. Cushny and Peebles, 1905, found that the l- and l-alkaloids act alike on the central nervous system in mammals, and on the motor endings; but that the left-alkaloid (scopolamin) is twice as active on the salivary and vagus endings as the racemic atrocin.

This has been confirmed, also for the pupil, by Hug, 1912. Königsdörfer, 1906, claims that there is no difference in the pupil action. Coletta, 1913, contends that the isomeric is less toxic than the l- in man, but without good evidence (Cushny, 1912). Smith, 1913, found the fatal dose the same for mice.

Psychic Actions.—In man, doses of 1 to 3 mg. (1/60 to 1/20 gr.) generally produce, within ten or fifteen minutes, fatigue, drowsiness, and a natural, dreamless sleep, lasting several hours. The response, however,
is variable. In some the sleep is preceded by hallucinations, which may be rather pleasant with small doses, but which become violent if the dosage is increased. Animals are also affected differently by scopolamin (Kochmann, 1913).

_Dogs_ react similarly to man: very small doses produce sleep and hallucinations; larger doses cause more marked hallucinations and restlessness, ataxia, and often emesis. The excitability of the motor arcs is said to be lowered (Sohrt, 1886; Ramon, 1893)._ Rabbits_ react by a mixture of depression and stimulation (Lønestrænd et al., 1919)._ Frogs_ show a central abolition of reflexes (Wood, 1883), preceded by more extensive spreading of the reflexes (Kochmann).

**Therapeutic Use of Sedative and Hypnotic Action.**—Scopolamin is employed especially in acute maniacal excitement, delirium tremens and tetanus. It has _advantages_ over morphin, by quieting the reflexes and by avoiding habit formation; and over chloral, in that it does not usually depress the medulla. On the other hand, it produces the unpleasant _side effects_ of mydriasis, cycloplegia, and excessive dryness; sometimes muscular tremors; and occasionally serious delirium (the latter is said to be promptly controlled by small doses of morphin). The therapeutic dose lies much below the ordinary fatal dose; but small doses (0.2 to 0.75 mg.; 1/200 to 1/85 gr.) have produced serious poisoning, with cardiac and respiratory collapse. On the other hand, 1/16 and even 1/8 gr. (6.5 and 50 mg.) have been taken without ill effects. Insane patients generally seem to be tolerant, so that the effective doses (1 to 3 mg.; 1/60 to 1/20 gr.) may be given; with ordinary individuals it is not safe to exceed 0.5 mg. (1/120 gr.), repeating this smaller dose every six to eight hours, if necessary, and it would be safer to use this dosage also for the insane. Smaller doses (0.2 mg.; 1/400 gr.) may be used to enhance the hypnotic effect of morphin. The use in _drug additions_ has been described under “Morphin.”

**Respiration and Circulation.**—Therapeutic doses ordinarily do not produce any important effects (Kochmann, 1903). The respiration is practically unchanged. The pulse may be unchanged or considerably slowed (central vagus stimulation). The blood pressure shows no change, or with somewhat larger doses a moderate rise (stimulation of vasomotor center). Toxic doses depress the respiration, the heart, and the blood pressure. With fatal doses, the respiration stops before the heart.

**The Eye.**—The effects of scopolamin correspond qualitatively with those of atropin. They are produced more quickly and by doses only one-fifth or one-tenth as large (Joachimoglu, 1915), but are not quite as lasting. The intraocular pressure is less affected (Bollet and Curtil, 1911). It is less irritant than atropin, and patients who have an idiosyncrasy against atropin can often tolerate scopolamin. It is used like atropin (iritis, etc., 0.1 per cent.; cycloplegia, 0.2 per cent.).

**The secretion of saliva, sweat, mucus, etc.,** is paralysed by therapeutic doses of scopolamin, more actively than by atropin.

**The effects on the intestine** correspond to those of atropin. The excited uterus is stimulated (Kehrer, 1907; Barbour and Copenhagen, 1915).

**Iatremes on Excited Ureters**.—The levo stimulates the contractions and slightly raises the tone. Very large doses depress. The dextro inhibits without stimulation. The racemic is also inhibitory (Macht, 1918).

**Scopolamin Poisoning.**—The symptoms resemble those of atropin poisoning, except for the early tendency to sleep, coma, collapse, and the lesser effect on the pulse rate (Details, Seifert, Nebenwirk., 1915, p.
87). The treatment would be as for atropin. The excretion occurs by the urine.

**Scopolamin-morphin Narcosis.**—The combination of the two alkaloids results in a deep narcosis that may permit of major surgical operations (Scheiderlin, 1900; Korf, 1901 to 1902; Bilos, 1902). Smaller doses produce a partial anesthesia ("Seminarcosis," "twilight sleep" or "Dämnerschlaf," Gauss, 1906 and 1907) which has been used in obstetrics. Still smaller doses quiet the patient, and may be employed to facilitate the administration of the ordinary inhalation anesthetics.

Scopolamin alone is not narcotic (for rabbits or mice), even in large doses; nor does it diminish the concentration of ether or chloroform required for light anesthesia; but it does permit a deep anesthesia with relatively lower concentrations. It also deepens the morphin narcosis. The two alkaloids used together produce a deeper anesthesia with a given concentration of inhalation anesthetic (Ludewig, 1913).

The earlier investigators believed that the mixed alkaloids produce a deeper narcosis than would correspond to the simple addition of their individual actions; i.e., a "potentiated synergism" (Madelung, 1900; Buerger, 1910; Kochmann, 1913). The later work of M. I. Smith, 1915, and van Leeuwen et al., 1919, fails to confirm this, and indicates a simple summation of the effects.

The advantages of exclusive scopolamin-morphin anesthesia, as compared with ether or gas, are rather minor, while the disadvantages are very serious (see Hatcher, J.A.M.A., 1910, liv. p. 446; H. C. Wood, Jr., J.A.M.A., 1906, xii. p. 546; Bevan, ib., 1915, 65:1418; M. Kochmann, 1903; A. Mayor, 1908). The combination increases not only the narcotic action, but also the depression of respiration and circulation; and this in a very irregular degree. The susceptibility varies so much that the surgical anesthesia is often incomplete and must be supplemented by ether; and on the other hand, serious accidents and fatalities are alarmingly frequent. The anesthesia can not be modified to suit the needs of the moment. Delirium, sometimes serious, is not uncommon. The obstetric anesthesia is especially dangerous to the child, owing to the great susceptibility to morphin. In non-fatal cases, the child may show somnolence and deficient respiration for days after delivery (Jung, 1914). The use of scopolamin-morphin anesthesia is justified (if at all) only in specially equipped institutions, and not in private practice, or even in ordinary hospitals.

The smaller doses used preliminary to anesthesia would alone appear justifiable; and even these may cause marked fall of blood pressure (A. Mayor, 1908). Chloroform is especially dangerous (W. Straub, 1913). Bevan, 1915, believes that the use of the alkaloids in ordinary doses (morphin, 1/4 gr.; scopolamin, 1/80 gr.) adds distinctly to the risks of chloroform, ether or gas or local or spinal anesthesia, more than morphin alone; and that it has been responsible for many deaths, especially by masking the danger signals. It also increases the percentage of vomiting and of bladder paresis, and reduces immunity.

**Dosage for Surgical Anesthesia.**—As a preliminary to inhalation anesthesia, Korf injects hypodermically a mixture of 0.4 mg. 1/100, of scopolamin hydrobromid, and 0.2 mg. 1/50, of morphin hydrochlorid, one and one-half hours before the operation, and repeats the same quantity an hour later. If the scopolamin-morphin is to be the chief anesthetic, to be merely supplemented by ether if necessary, he precedes these injections by another, of the same size, two and one-half hours before the operation. The total dosage would therefore be 1.8 mg., 1/50 gr.; scopolamin; and 0.2 mg., 1/50 gr., morphin.

**Results of Scopolamin-morphin Seminarcosis in Obstetrics.**—The introduction of the "twilight sleep," intended to deprive labor of its terrors, has led to much discussion
and diversity of opinion. Its advocates do not claim that it abolishes pain, but they assert that it successfully removes the memory of the experience, in the majority of cases, and with practically no danger to mother or child; provided it is used by experienced operators, under exactly prescribed conditions, and with proper dosage. The experience of independent observers has been contradictory, but by no means as favorable. The early failures may be attributable to excessive doses of morphin or other faults of technic; but this criticism can not apply to the later compilations. The serious objections are: prolonged labor (averaging three to four hours); frequently delayed expiration of child, sometimes requiring vigorous measures; larger number of fetal asphyxias; excessive thirst and intense headaches; difficult control of patient with chance of infection; more frequent postpartum hemorrhage; blurred vision; ghastly deliriums persisting for long time; difficult recognition of onset of second stage; masking of early symptoms of accidents; failure of narcosis in one-seventh to one-third of the cases and uncertainty of the whole treatment (Baer, 1915; Libby, 1915).

Effects on Uterus.—Morphin and scopolamin slightly increase the tone of the excised uterus, without synergism or antagonism (Barbour and Copenhagen, 1915). In anesthetized animals, there is little effect of any kind (Barbour, 1915). The clinical delay of labor is therefore probably cerebral (narcotic).

Dosage for Twilight Sleep.—The minutely defined technic can not be described here with sufficient detail to be useful. The reader is referred to the original articles, to text-books of obstetrics. It involves painstaking exclusion of noise, light and all excitant factors—apparently the cooperation of suggestion is essential. The drugs are not started until the regular pains occur, perhaps every four to five minutes at lasting half a minute. The first injection is of 0.008 to 0.015 mg. of morphin and 0.5 mg. of scopolamin hydrobrom. The Freiburg school prefers naropin, 30 mg., to morphin, but this is immaterial. The morphin or naropin must not be repeated. The scopolamin, however, is repeated; first in three-quarters of an hour with 0.45 mg., then every one and one-half hours with 0.5 mg., until amnesia (loss of memory) is sufficiently advanced. This is tested every half hour. When successful, the pains are fully felt, but promptly forgotten. The patient is rather drowsy; the heart slightly quickened (the simplified technic is described by Siegel, 1914).

PREPARATIONS—SCopolamin

*Scopolamina Hydrobromidum (Scopolamin. Hydrobrom.), U.S.P.; Hyoscynam. Hydrobrom., B.P.; C₈H₁₃NO, HBr + 3H₂O.—An alkaloid obtained from various plants of the Solanaceae. The U.S.P. specifies the levorotatory isomer (27° to 27.5°). Colorless crystals. Freely sol. in water (1:25); sol. in alc. (1:20). Dose, 0.3 mg. to 0.5 gr. B.P. Maximum dose, 0.6 mg., 0.8 gr.

PILOCARPIN

General Statement.—Pilocarpin, the principal alkaloid of jaborandi leaves (Pilocarpus), stimulates these peripheral structures which are paralyzed by atropin. It therefore increases the secretions, augments the gastro-intestinal movements, constricts the pupils, etc. The stimulation of these functions persists even with large doses. The vagus, however, is first stimulated, then depressed. All these autonomic actions are purely peripheral (on the myoneural junction). The central effects of pilocarpin are unimportant.

Pilocarpin is used as a miotic, but especially as a diaphoretic; in this respect it surpasses all other drugs. Pulmonary disease enjoins caution in its use, to guard against fatal pulmonary edema.

The stimulant effects of pilocarpin are easily inhibited by atropin. Conversely, pilocarpin removes the depressant effects of small doses of atropin, but is ineffective against large doses.

Other Jaborandi Alkaloids.—Pilocarpus contains two other alkaloids: vis., isopilocarpin and pilocarpinid. These differ merely in the strength of their action, pilocarpin
being by far the strongest, and pilocarpinid the weakest. It was formerly believed that pilocarpus contained another alkaloid, jaborin, with atropin actions. This view has been shown to be erroneous (Jowett, 1900 and 1905; Marshall, 1904). 

**Arecotin**, the alkaloid of Areca of Betel nut, is closely related to pilocarpin in its actions and is formulated (1885, Kernig, 1897). It stimulates perspirable (Paez, 1910) and produces marked bronchial constriction by peripheral action, but is overcome by atropin or epiphenin (D. E. Jackson, 1914).

**Glands.**—Pilocarpin increases the secretion of saliva, sweat, tears, mucus, and of the gastric, pancreatic, and possibly of the intestinal juice and of the milk, not of the urine or bile. A gallon of water may be removed by these secretions, after a single injection.

Pilocarpin continues effective after degeneration of the nerve, but is easily inhibited by atropin. Its action is therefore located in the myoneural junction. Acceleration of the blood current through the glands occurs as a secondary effect of their increased action. A common effect of pilocarpin, a hyperemia of the skin (resulting in an increase of its temperature), may possibly be due to the increased activity of the sweat glands.

The increased circulation of the skin is said to increase the growth of hair, and to darken its color. The statement may be doubted.

**Gastric Secretion.**—The quantity and the ferment content of the gastric juice are increased (Chiari, 1914).

**Production of Gastric Ulcers.**—G. A. Friedman, 1918, claims that repeated hypodermic injections of pilocarpin into rabbits results in acute gastric ulcers; and that alternate injections of pilocarpin and epiphenin produce also erosions in the duodenum. Confirmation is desirable.

**Pancreatic Secretion.**—Lannoy, 1905, claims that this not increased if the pylorus is ligated. He therefore believed that the ordinary increase is indirect, due to the increased secretion of acid in the stomach, and therefore increased production of secretin. Gans and Older, 1913, found, however, that it is effective even when the small intestine has been removed, so that it must act directly on the pancreas.

**Milk Secretion.**—The earlier investigators claimed some increase (Rockliff; Ott and Sott, 1912; O. H. Henderson, 1915; McCandlish, 1918); but Hays and Thomas, 1920, found the response inconstant and within the range of accidental variation. Other spayed lactating stimulants were also ineffective.

**Urine.**—Ordinarily, pilocarpin has no direct action on the urine (Maccallum, 1905); but the great loss of fluid by other channels usually diminishes the water and chlorid output by the kidneys (Asher, 1907; Cow, 1912). Repeated injections of large doses induces glycosuria and diuresis, which Waterman, 1911, attributes to increased renal permeability.

**Glycogenolysis.**—This is not directly affected (McGuigan, 1916). 

**Bile and Lymph Flow.**—Janagawa, 1916, claims that these are increased.

**Cerebro-spinal Fluid.**—This is increased by the respiratory embarrassment (Dixon and Halliburton, 1913).

**Sialagogue Action in Man.**—Five to 10 mg. of pilocarpin, by mouth, increases the volume of saliva considerably. The percentage of inorganic solids is unchanged; that of organic solids shows an insignificant increase. The proportion of ptyalin is markedly diminished, but its total quantity is considerably increased (Ewing, 1911). The combination of pilocarpin saliva is not changed by the injection of sodium phosphates, sulphate or carbonate, or of glucose, unless toxic doses are given (Asher, 1908). The submaxillary gland, when perfused with Locke’s solution, can be provoked to secretion by pilocarpin, but not by chorda stimulation (Demoor, 1921).

**Therapeutic Use.**—The sialagogue action is employed (10 mg., 1/4 gr. by mouth, three or four times a day) against poisons which suppress this secretion (atropin, meat-poisons, etc.). The increased secretion of mucus may be used in a dry cough. This also results in loosening croupous membranes. The increase in biliary mucus is said to facilitate the passage of gall-stones. Its utility is doubtful.

**Diaphoretic Action.**—To produce this effect, pilocarpin should be injected hypodermically (5 mg., 1/2 gr.), the patient being kept warm.
This dose may be repeated in half an hour if necessary. Several liters of alkaline sweat may be excreted.

This dosage usually produces salivation, sweating, and nausea, often vomiting and singultus; exceptionally slowing of the pulse; sometimes considerable general depression, and with larger doses even serious collapse, especially in children. As has been said, pilocarpin should be avoided in pulmonary disease, since the increase of mucus and the action on the circulation may result in dangerous pulmonary edema.1

The diaphoretic action is used especially in nephritis, to relieve the kidneys and to remove the toxic metabolites.

In paralyses of the cortical psychomotor region, the corresponding parts of the skin are said to perspire especially strongly in response to pilocarpin (Biklees and Gerstmann, 1915).

Other Diaphoretics (Sudorifics or Hydrotics).—The secretion of sweat may be increased (a) by stimulating the secretory structures, (a) peripherally (pilocarpin) or (b) the sweating center (camphor, ammonium acetate); or (b) by increasing the cutaneous circulation, (a) locally (mustard; external heat) or (b) through the vasomotor center (internal heat; alcohol salicylates, acetaminid, nauseants, etc.).

Children sweat more, old people less easily, than adults. Among animals, horse sweat most profusely; pigs and beef, not very readily; dogs, rabbits, and sheep not at all; cats only on the paws.

Indications for Diaphoretics.—The various sudorific measures specially adapted to the different indications are as follows:

For the Absorption of Edemas and Exudates.—A powerful action is needed: pilocarpin combined with external heat (hot baths or packs).

To Relieve Inflamed and Overlooked Kidneys.—The large amount of fluid and excrementitious material removed by a thorough sweating secures functional rest to the kidneys and lowers blood pressure. Hence also, pilocarpin and hot baths are preferred.

Ordinary sweat (Hoelscher, 1904) contains 0.22 to 0.81 per cent. of ash, and 0.04 to 0.084 per cent. of nitrogen, mainly in the form of urea. (0.25 per cent. of NH3 and 0.21 per cent. of urea; Kovacs). The daily cutaneous excretion of nitrogen is first 0.3 to 1.5 Gm. (Benedict, 1902; Schwenkenbacher and Spitta, 1907). Even during rest, the sweat averages 0.07 Gm. of nitrogen per day. This is considerably increased in proportion to muscular labor, to 0.22 Gm. of nitrogen per hour (F. C. Benedict, 1907).

The sweat excreted under the influence of pilocarpin contains in normal individuals 0.091 to 0.095 per cent. of nitrogen, and 0.20 to 0.21 per cent. of ash. Three liters of sweat—a not unusual quantity after pilocarpin—would therefore remove about 2.5 Gm. of nitrogen. In nephritis, the nitrogen content may be much higher, to 0.08 per cent.; so that the 3 liters could remove to 8 Gm. of nitrogen. This indicates how efficiently the kidneys may be relieved by diaphoresis. This is also shown by the excretion of the blood; the abnormally great depression of the freezing point of the blood of uremic patients may be reduced to normal by diaphoresis (Bendix, 1904). The freezing point of the blood of normal animals is not affected. Alimentary glycemia could also be prevented by free diaphoresis, the excess of sugar being excreted by the skin. However, Austin and Miller, 1914, could find no evidence that sweat baths materially diminish the nitrogen retention in nephritis.

To reestablish disturbed circulation in the skin, and thereby to influence the circulation of internal organs: this determines their use in colds, rheumatism, etc.; in cold skin from whatever cause; in inflammations of the lungs, pleura, etc. Relatively mild diaphoretics suffice for this purpose: External heat; hot drinks (tea, lemonade of alcohol); Sweet Spirits of Nitre; Dover's powder; salicylate, etc.

1 The edema produced by the drugs of this series consists rather in the aspiration of the bronchial effusion, than in a true acute effusion. Injury to the walls of the capillaries is a necessary factor for the latter.
PILOCARPIN GROUP

The increased vascularity of the skin is also used to hasten the outbreak of febrile conditions, to promote the absorption of salves, etc. Further, in certain diseases of the skin where its nutrition is defective.

In the removal of poison, especially in chronic intoxication by the metals. The efficiency is rather doubtful. Hot baths and drinks would be used.

In ophthalmology, diaphoresis has been found useful in congestive and exudative lesions of the uveal tract, in retinal detachment and in toxic blindness; it is useless in atrophic and cicatricial lesions.

Pilocarpin on Unstriped Muscle.—The simulation of the myoneural junction of the cranio-sacral autonomic nerves results in contraction of most unstriped muscles (not of the blood vessels). The intestines are especially stimulated, with diarrhea and colic. The stimulation extends also to the muscles of the bronchi, uterus, ureter, bladder, spleen, stomach, etc. However, the nausea and emetic action are essentially central (Eggleston and Hatcher, 1915). They are antagonised by atropin (Eggleston, 1916).

Excised Mammary Stomach.—All regions are stimulated (M. Smith, 1918).

Intestinal Stimulation.—The location was described in the general section on autonomic nerves. Neukirch, 1912, finds that the action on the excised intestine is purely stimulant, even with 5,000 times the effective dose. The action can be removed by washing; but during the passage of the pilocarpin out of the cells, there seems to be a supplementary stimulation, the reverse of Strain's muscarin phenomenon. The bronchial muscle constricts (Dixon and Brodie), even outside of the body (Trendelenburg, 1912).

Urine Stimulation.—This is rather weak and inconstant (Gunn and Gunn, 1912).

Urinary Bladder.—The localization is rather confused (Edmunds and Roth, 1910).

Ureter.—Stimulation was described by Cow, and by Macht, 1916. High concentrations paralysed. G. B. Roth, 1911, obtained no effect.

Cysto-bladder.—This is stimulated (Lieb and McWhorter, 1915).

Drugs on Bile Duct.—Vater's papilla is closed by intravenous injection of morphine, epinephrin, histamin, caffeine, large doses of atropin, and especially by pilocarpin. It is relaxed by papaverin, yohimbine and nitrates (Keach, 1914).

Leucocytosis results from the contraction of the spleen and lymph glands (Harvey, 1916). The gall-bladder is stimulated (Lieb and McWhorter, 1917).

Development of Ova.—Sollmann, 1904, has described the phenomena of antagonism with atropin.

Yeast Formation.—Somogel, 1916, claims that this is inhibited by small concentrations, but stimulated by larger doses.

Eye-effects.—The application of pilocarpin produces miosis and spasm of accommodation, by peripheral stimulation of the oculomotor (p. 172). The intraocular tension is affected as with physostigmin, first raised, followed by more persistent fall. Pilocarpin nitrate in 1/5 to 4 per cent. solution is applied as a milder substitute for physostigmin in glaucoma, corneal ulcer, etc.

The miosis begins in fifteen minutes (independently of the concentration); reaches its maximum in thirty to fifty minutes, and disappears in twenty to twenty-four hours. The spasm of accommodation also begins in fifteen minutes, and lasts about two and one-half hours.

Suprarenal Stimulation.—Dale and Maudslay, 1913, describes evidences of oculomotor stimulation even if the cervical ganglia have been excised but not if the suprarenal has been removed. They ascribe this to stimulation of the suprarenals i.e. increased production of epinephrin. There is a similar condition as regards the uterus. Jackson, 1913, accepts the same explanation for a dilator effect on bronchial muscle.

Circulation.—Pilocarpin first stimulates, and then paralyses the vagi peripherally, and therefore produces slowing (in frogs, diastolic stand-
still, Harnack and H. Meyer, 1880), followed by quickening of the heart rate. In mammals, the stage of stimulation and slowing is very short; it may be entirely absent in dogs, and often in man. In these the blood pressure rises, partly from the faster heart, and perhaps partly through stimulation of the vasomotor center.

Perfused blood vessels are dilated (frogs, Froelich and Pick, 1913; lung, Bacher and Pick, 1913). Berezn, 1914, claims constriction of the lung vessels.

**Pren’s Heart.**—The slowing occurs after nicotine (Guilbeke, 1911) and is therefore probably postganglionic. The vagus excitability is increased. Combinations with muscarin give additive effects; physostigmin does not (Loewi, 1912). In the secondary vagus depression, stimulation of the sinus produces but little slowing, showing that this action is also largely postganglionic. High concentrations paralyze the cardiac muscle. Small doses of chloral, by depressing the cardiac muscle, delay the escape from vagus inhibition, whether by pilocarpin, muscarin, or electric stimulation (Loewi, 1912).

**Chlorotic and Inotropic Antagonists.**—Perfusion of the excised frog heart with 0.001 to 0.02 per cent. pilocarpin produces both slowing and weakening. These are due to distinct functions of vagus stimulation. Both are antagonized by atropin which paralyzes both the choroitropic and inotropic functions; and by epinephrin and caffeine, which stimulate the heart muscle. The digitaloids antagonize the weakening, but not the slowing (F. Ramon, 1917).

**Terrapin’s Heart.**—Pilocarpin arrests the contractions, but does not affect the auricular tonus waves (Gruher and Markel, 1918; Gruher, 1920).

**Excised Mammalian Heart** (Hedbom-Langendorf).—The effects are similar to the frog heart, but the stage of vagus stimulation is short; the rate is suddenly slowed; the lasts but a short time, then there is marked quickening with increased tonus (peripheral paralysis of vagus). If the auriculo-ventricular bundle is divided, pilocarpin or muscarin does not produce inhibition (Callis and Tribus, 1913); nor do they inhibit isolated ventricular strips (Leetham, 1913). Their action must therefore be on the auricular vagus terminations. Large doses paralyze the muscle.

**Central Nervous System.**—The action is weak and appears late, so that it is entirely overshadowed by the peripheral actions. The effects are mainly degressing. *Motor paralysis* is a rather early and prominent symptom; it leads to *dyspnea*. Later, the respiratory center is also depressed. The motor centers, especially those of the cord, show some stimulation (increased reflexes, tremors, convulsions) and later paralysis. The emetic center is stimulated.

**Metabolism.**—Pilocarpin somewhat increases CO₂ production and tends to raise the temperature, even in curarized animals, i.e., by direct stimulation of the glands and unstripped muscle. The increase is antagonized by atropin (Kleeman, 1918). Mendel and Stehle, 1915, claim that pilocarpin and other stimulants of digestive glands increase the excretion of uric acid.

**Fate and Excretion.**—A large part is excreted unchanged, but in combination, by the urine (Curci).

**Distoxication of Pilocarpin by Tissues.**—The activity of pilocarpin is destroyed by digestion in the presence of curarizing agents; but active pilocarpin can be extracted from such mixtures by acidified alcohol. The inactivation is therefore probably an adsorption phenomenon. The inactivating substance is not chloroform or leptin. Its quantity varies for the serum of different animals, the distoxication occurring most readily in the serum of rabbits and least readily in dogs; with cat or ox serum intermediate (van Leeuwen, 1918).

**Symptoms of Poisoning.**—The toxicology of pilocarpin is not very important. The symptoms, which apply also to muscarin, begin with greatly increased secretion of saliva, sweat, and tears; then nausea, profuse vomiting, and painful diarrhea; papillary contraction and spasm of accommodation; pulse variable in rate, tense, and rhythmic; palpitation; dyspnea with râles; sometimes confusion of ideas, vertigo, tremors, and feeble convulsions. Death occurs either by paralysis of the heart or edema of the lungs.

**Urethral effects from the alimentary canal are seen most frequently if the drug is given by mouth, but occur also on hypodermic administration. They consist in very prolonged and depressing nausea and vomiting, sometimes leading to collapse. The disturbance of accommodation causes misty vision. A burning sensation in the urethra, with sudden and irresistible desire to urinate, is often noted.**

**Treatment.**—Atropin is a physiologic antidote. Otherwise, the general treatment of alkaloid poisoning would be employed.
PHYSOSTIGMIN GROUP

PREPARATIONS—PILOCARPIN

* Pilocarp, hydræchi, U.S.P.—Very sol. in water (1:0.3). *Dose, same as the Nitrate. *The hydrochlorid is highly deliquescent and therefore undesirable (A.M.A. Laboratory Report, 1920, 12:96).

* Pilocarpine Nitrate (Pilocarp, Nit.), U.S.P., B.P.; C₁₀H₁₄N₂O₄HNO₃—Colorless, thinly bitter crystals. Freely sol. in water (1:14). *Dose, 10 mg., 1/4 gr., by mouth; hypodermic, 5 mg., 1/5 gr., U.S.P.; 3 to 12 mg., 1/12 to 1/3 gr., B.P. *Maximum dose, 30 mg., 1/2 gr.

Pilocarpus, U.S.P. (Jaborandi)—The dried leaves of Pilocarpus species, yielding not less than 0.6 per cent. of alkaloids.

Follet. *Pilocarp., U.S.P.—About 0.6 per cent. of alkaloids. *Dose, 2 c.c., 30 minims, U.S.P.

PHYSOSTIGMIN

General Statement.—Physostigmin (also caud Exerin), the alkaloid of Physostigma or “Calabar bean,” stimulates the peripheral structures which are paralyzed by atropin. Its most important actions consist in powerful contraction of the smooth muscle of the eye (miosis) and intestines. It is employed in eye diseases (glaucoma, etc.) and in intestinal atresia. The glandular stimulation is less marked than with pilocarpin. It also causes fascicular twitching of striped muscle and is mutually antagonistic with curare and substances having a curare action. On the central nervous system, the effects are mainly paralyzing. They have a toxicologic importance and limit its internal use.

Actions on the Eye.—Physostigmin causes constriction of the pupils (discovered by Fraser of Edinburgh, 1863); spasm of accommodation (near vision); twitching of the eyelid and lowering of the intraocular pressure. These actions are due mainly to increased excitability of the oculomotor endings or myoneural junction. The effects of physostigmin can be removed by the application of atropin, and vice versa; but this requires much larger doses than does a normal eye.

The action on the pupil appears somewhat earlier, and lasts somewhat longer, than that on accommodation; on local application of a 1 per cent. solution, the miosis begins often within ten minutes, reaches its maximum in thirty to fifty minutes, stays maximal for three or four hours, and then disappears gradually in three or four days. The physostigmin contraction is greater than can be produced by the strongest light, although the physostigmin pupil contracts further even to weak light. With the maximal contraction, the pupil is generally irregular in shape. Physostigmin is much more effective in counteracting the mydriasis of cocain than that of atropin.

The spasm of accommodation begins in about twenty minutes, and passes off in about two and one-half hours, leaving the excitability somewhat increased. Through the contraction of the ciliary muscle, the lense becomes more spherical, and objects appear enlarged and more distant.

Excised Iris Specimen of Mammals.—This is constricted by dilutions down to 1:50,000, the intensity varying with the concentration. With 1:50,000, it dilates (R. K. Joseph, 1917).

Localization of Action.—Paralysis of the sympathetic may be excluded, for stimulation of this nerve dilates the pupil somewhat, even when the physostigmin effect is complete. The muscle may also be excluded, for no miosis occurs if the oculomotor endings have degenerated (after section of the short ciliary). The action is therefore a stimulation or increased excitability of the oculomotor; and since it occurs on the excised eye, the effect must be on the endings. The antagonism with atropin, etc., was discussed on p. 322.
If the experiment is arranged so that the sympathetic is left intact, while the short ciliary is divided, physostigmin will not constrict the pupils (even if the oculomotor endings are intact), because the physostigmin stimulation is evidently unable to overcome the sympathetic tone. Since the physostigmin easily overcomes the sympathetic tone if the oculomotor tone is intact, it has been argued that the physostigmin action does not consist in direct stimulation, but in increase of excitability to the normal oculomotor impulses (Meyer and Gottlieb). It is possible that this phenomenon is related to synergism (Dixon and Ransom, 1912).

Intracocular Tension.—In the normal eye, physostigmin produces a slight fall (1 to 3 mm.) lasting some twelve hours (Luebs, 1913; Mushita, 1913). The fall is not marked in glaucoma (Bollet and Curtill, 1911).

Trypan Red.—After intravenous injection, this dye appears in the aqueous humor much more abundantly when the eye is inflamed, or when physostigmin is applied. It is not influenced by atropin (P. A. Lewis, 1916).

Therapeutic Use of Oculomotor Actions.—Physostigmin may be used to counteract the effects of atropin; to break up adhesions of the iris and lens (in alternation with atropin); in the treatment of peripheral corneal ulcer and to lower the intracocular pressure in glaucoma (see p. 343). The continued use of physostigmin or pilocarpin produces distinct amelioration of the glaucoma symptoms, often more than iridectomy; but they are, of course, not curative (Posey, 1914). The mechanism of its action in ulcer is not understood; it is perhaps explained by contraction of the iris vessels.

Application.—Physostigmin is always used locally, in 1/500 to 1 per cent. solution of the sulphate or salicylate (in glaucoma 0.1 to 0.4 per cent., two to six times a day). Solutions of 0.5 per cent. and higher sometimes cause considerable irritation and pain. This is lessened by employing an oily solution of the free alkaloïd. Casey Wood advises the addition of 5/ per cent. of cocain to 3 per cent. of physostigmin; or pilocarpin or arecolin may be substituted.

Intestine.—Physostigmin greatly increases the gastric and intestinal movements, acting directly on the nerve endings (see p. 330). With therapeutic doses the peristaltic movements are more active. Toxic doses produce tetanic contraction of the gut. The action is utilized in intestinal paresis (postoperative ileus, etc.). 2 mg. (1/50 gr.) hypodermically (larger doses would be dangerous). Cannon and Murphy, 1907, have shown that it has a marked effect, lasting, however, only a few hours.

Other unstripped muscles contracted by physostigmin are those of the bladder, spleen, uterus, arterioles, and bronchial muscles.

Earthenware.—Physostigmin produces peculiar contortions (Sollmann, 1918).

Glandular Secretions.—Physostigmin stimulates the same glands as pilocarpin (except milk; Ott and Scott, 1912); but the increase of secretion is much less marked, being counteracted by the vasocostriction. Like other intestinal stimulants, physostigmin increases the elimination of urea (Obl., 1913).

Sweat.—Physostigmin provokes sweating of cat’s paw. This is decreased or arrested by section of the nerves, so that the action is perhaps partly central (Langley and Kato, 1913).

Striped Muscle.—The fascicular twitchings, and the antagonism with curare, were discussed on p. 124. A similar antagonism exists between physostigmin and magnesium salts (Meltzer and Auer, 1906; Joseph, 1908; Joseph and Meltzer, 1909).

Small doses of physostigmin lower the threshold of nerve-stimulation, without producing twitching. With larger doses, nerve stimulation with tetanising currents may provoke fibrillation that persists for some time after the current is withdrawn (Langley and Kato, 1905).

Fibrillary twitching of the muscle by tetanisation of the nerve can be produced in mammals and frogs without physostigmin, as a constant phenomenon of a certain stage of fatigue (Langley, 1916).

Aside from the fascicular contractions, physostigmin also provokes coarser con-
otions of the muscles; nystagmus, and rhythmic movements of the nictitating membrane of cats. These are of central origin and are abolished by atropin, which has little effect on the peripheral fascicular twitches.

Circulation.—In mammals, ordinary doses slow the heart by vagus stimulation, and raise the blood pressure by vasoconstriction. Large doses produce further slowing and fall of pressure. In man, however, serious dizziness and faintness occur before the heart rate is affected (Robinson, 1905). In frogs, the heart muscle is stimulated directly so that it contracts more strongly, and can not be stopped by vagus stimulation. The action of cardiac depressants is antagonized. (This stimulant action is not noted in mammals.)

The slowing in mammals is due to peripheral vagus stimulation, sufficiently powerful to counteract even atropin (Winterberg, 1907).

The rise of pressure must be vascular, since the cardiac output is not increased. It occurs after destruction of the spinal cord and must therefore be peripheral. It is due partly to the contraction of the intestines, and partly to direct stimulation of the arterial nerve-ends. It does not occur after atropin (Dixon, 1902). The fall of pressure is due to central vasomotor paralysis and to cardiac depression.

Central Effects.—The action on the central nervous system is first tetanizing (Linnaeus, 1905); then rapidly paralyzing, beginning, at least in man, in the lower portion, so that consciousness is preserved to the end. The respiration is at first increased; this is due largely to stimulation of the afferent endings of the vagi; for the quickening is much less after the vagi have been cut.

There are also other evidences of stimulation—excitement, etc.—but these have been considered secondary to respiratory paralysis, the central actions of the alkaloid being mainly depressing. Dyspnea is a marked symptom, due to paralysis of the respiratory center and spasm of the bronchial muscles. Asphyxia forms the cause of death (Harnack and Witkowski, 1870).

The depressant action of physostigmin has led to its therapeutic trial in epilepsy, chorea, tetanus, etc., without much success.

Physostigmin Poisoning.—The symptoms consist in restlessness, weakness, nausea, vomiting, sometimes purging; epigastric pain; rarely miosis; salivation, lachrymation and sweating, palpitation with slowed pulse; dyspnea; muscular twichings; convulsions. Death occurs by paralysis of respiration, under general collapse, with the reflexes present at the moment. The fatal dose is not known.

The location of the emetic action has not been definitely determined, because of the difficulty of fixing the emetic dose (Eggleston and Hatcher, 1913).

TREATMENT OF PHYSOSTIGMIN POISONING.—This consists in evacuation, stimulants and atropin (1/2 to 1 mg.).

Frazier found that small doses of atropin saved animals from three times the fatal dose of physostigmin; but that larger doses are synergistic; Curare and Magnesium are effective in the laboratory, but are dangerous for man.

FETE.—Physostigmin is not destroyed by frog's liver (Clark, 1912).

PREPARATIONS.—PHYSOSTIGMIN

Physostigmina Salicylas (Physostigminum, Sal.), U.S.P. (Essen Salicylate); C,H, N,O, CH,H,O — Colorless or faintly yellow crystals; of slightly bitter taste. Soluble in water (1:75) and in alc. Dose, 1 mg., 1/64 gr., U.S.P. Maximum dose, 1 mg., 1/40 gr. Watery solutions of Physostigmin salts (not the dry salts) oxidize under the influence of light, air, and the alkali of glass vessels, acquiring a pink color (due to "rubresinier," Woehler, 1853.). Such colored solutions should not be employed; Hallauer, 1891, states that they are more irritant, although the medicinal action is not impaired. The decomposition is retarded by the addition of a little boracic acid.

Physostigm. Sulph., B.P.—More freely soluble, but less stable. Dose, 1 to 2 mg., 1/4 to 1/2 gr., B.P.

Lam. Physostigm. B.P.—0.003 mg., 1/10,000 gr.

Physostigma, U.S.P. (Calabar Bean).—The dried ripe seeds of Physostigma venenum, yielding not less than 0.15 per cent. of alkaloids; mainly physostigmin; also small quantities of the related eseridin, and of eserinum. (Calabarina, a strychnin-like alkaloid, was formerly stated as a constituent, but has not been confirmed.) The drug was introduced into England about 1840. Dose, 0.1 Grm., 1/14 gr., U.S.P.

Ext. Physostigmatis, U.S.P.—A powdered extract of 1 Grm. representing 15 Grm. of drug, 1 per cent. of alkaloids. Dose, 8 mg., 1/48 gr., U.S.P.

Tr. Physostigm., U.S.P.—10 per cent.

Dose, 1 c.c., 15 minims, U.S.P.
MUSCARIN

Muscarrn, an organic ammonium base, found in a mushroom, and a similar base, prepared synthetically from cholin, produce typical peripheral stimulation of the parasympathetic system, i.e., all the effects of pilocarpine; and also a nicotin and curare action.

The most characteristic action of muscarin is a vague standstill of the frog’s heart. Its interest is mainly scientific, and to some extent toxicologic, since it occurs in the most poisonous fly-mushroom.

Constitution.—Muscarrn, as isolated by Schmiedeberg and Koppe, 1860, from the fly agaric (0.016 per cent. in the fresh fungus; Harmsen, 1903), is a substituted ammonium base:

\[
CH_3 = N^+ CH_3 CH(OH)_3 OH
\]

It is closely related to cholin (trimethyl-oxyethyl-ammonium hydroxide):

\[
CH_3 = N^+ CH_3 CH_2 OH
\]

Synthetic Muscarin.—“Synthetic Muscarin” is prepared artificially by the addition of cholin (“cholin-muscarin”) and was supposed to have the same composition; later investigations, however, showed that it is the nitrous ester of cholin (Dahn and Ewins, 1914). Its actions agree qualitatively with those of the natural, but exhibit quantitative differences; the natural being ten times stronger on the heart, while the synthetic produces more pronounced nicotin and curare actions (Schmiedeberg and Harnack, 1876; Boehm, 1885; H. Meyer, 1893; Honda, 1911). The antagonism to atropin is also less complete with the synthetic base.

Muscarrn Action on Frog’s Heart.—Muscarrn causes slowing, with lessened systolic and increased diastolic excursions, and finally stoppage in diastole. These effects resemble those of electric vagus stimulation (also the electrocardiogram; Samouiloﬀ, 1913) and the results of submaximal vagus stimulation and muscarin are strictly additive, i.e., in frogs (Honda; O. Loewi), in turtles (Fleischhauer, 1912), and in mammals (Schott, 1912). Muscarin also produces additive results with pilocarpin. Large doses of both paralyze the vagus (Loewi) and the ganglia (Schott). The muscarin effect is more persistent than electric vagus stimulation, and occurs even in calcium-poor hearts, in which ordinary vagus stimulation is ineffectual (Loewi, 1912).

The refractory period of the heart to artificial stimulation is shortened by weak muscarin, as by vagus stimulation (Raafäulb, 1914). The effects of muscarin on the electric response of the heart was investigated by Mines, 1914.

Perfusion of the excised frog heart with very dilute muscarin in Ringer’s solution produces simultaneous weakening and slowing. If it is perfused in blood, it may also slow without weakening; while perfusion of muscarin blood through the isolated ventricle may give weakening without slowing (Raafäulb, 1914).

Turtle Heart.—Muscarrn increases the auricular tones waves (Fano and Schill; Gruber and Markel, 1918).

Location of Action.—In mammalian hearts, muscarin causes no inhibition if the auriculo-ventricular bundle is cut (Cullis and Tribe, 1913), or in ventricular atrio (Leatham, 1915); but in frogs, the muscarin standstill occurs also in the isolated atrio, showing that the stimulation is peripheral to the ganglia; and since it can be abolished by atropin (Schmiedeberg and Koppe), the action can not be on the muscle. It is therefore assumed that it stimulates those endings which atropin paralyses. If muscarin and atropin are exhibited at the same time or successively, their respective quantities will determine which predominates, but atropin is much the stronger. Drugs which act upon the ganglia—e.g., nicotine—will be ineffectual; but the standstill may be raised by substances affecting a direct stimulation of the muscle fibers—e.g., physostigmine, veratrin, digitalis, anilin, camphor, guanadin. It should be added, however, that the type of contractions under muscarin differs in some respects from those of vagus stimulation (Rhodius and Straub, 1908). This may possibly be due to the action
MUSHROOM POISONING

Active Constituents.—Many fungi contain poisonous constituents, varying in the different species. Ford, 1912, 1913, has studied a large number of species, and finds that the principles toxic to man belong mainly to three classes: (1) muscarin, which is confined practically to the "flying-mushroom," Amanita muscaria; (2) substances producing degenerative changes in internal organs (especially Amanita phaloides); (3) substances producing gastroenteritis.

Glucosidal hemolysins are also present in Amanita phaloides and several related species, especially in Helvella esculenta (Ford, 1913). They are easily decomposed by heat and digestion, and are therefore not concerned in poisonous effects. Actinomycins, perhaps glucosidal, are also widely distributed; some of these are not destroyed by boiling, but they are probably not pathogenic (Ford and Rockwood, 1912). Practically all species of Amanita slow or stop the frog heart on direct application. In the case of A. phaloides, this is not due to muscarin, but to inorganic salts (Ford and Hurb, 1914).

From Amanita phalloides, two interesting principles were isolated in pure form, one a hemolysin, the other a toxin. Both are allergens, a high-voltage serum being obtainable against the hemolysin, a much weaker one against the toxin. Nevertheless, the hemolysin is a typical glucosid (Abel and Ford, 1907), identical with the "phallin" of Robert, which was formerly considered a toxaumin. It is readily destroyed by cooking. The toxin (which was considered an alkaloid by Robert) is alone responsible for the symptoms of poisoning (widespread fatty degenerations of important organs; Ford, 1906 and 1909; Abel and Ford, 1905). Kabe, 1911, claims to have also isolated an alkaloid of muscarin action.

Symptoms of Mushroom Poisoning.—These must vary with the species. More or less common features are: Abdominal pain, nausea, vomiting, and violent diarrhea. Nausea, vomiting; labored respiration; consciousness unaffected, or delirium; coma or convulsions. Some cause fatty degeneration of the liver and kidneys. Many mushrooms produce abdominal symptoms simply by being indigestible.

The treatment, would be by evacuation, and symptomatic. The chance of poisoning may be somewhat diminished by prolonged boiling, as some of these substances are decomposed in this manner, but reliance on this would be dangerous. Drying does not diminish the toxicity. Verrill, 1914, reports symptoms of inebriation (not dangerous) from eating Psilocyclus papilionaceus (Maine).

Symptoms of Amanita Phalloides Poisoning.—These set in after a latent period of six to fifteen hours; sudden abdominal pain, with vomiting and diarrhea, containing food and mucus; rapid loss of strength; cyanosis; death in two to three days. Histological examination shows extensive necrosis and fatty degeneration of visceral organs (Ford, 1913). Uremia, from greatly impaired kidney function, may be responsible for part of the symptoms (Clark, Marshall and Rowntree, 1925).

Edible Mushrooms.—The food value of mushrooms is popularly supposed to lie in a large percentage of ascorbic acid. This is not borne out by analyses; they contain 0.1 per cent. in the fresh condition, or 0.15 to 1.2 when dried; i.e., no more than potatoes, and only one-tenth as much as wheat bread, or one-thirtieth of that in lean meat. As the fiber of mushrooms is also quite indigestible, their dietary value is as a flesh rather than as food.

* Agaricus renatus also owes its effect to muscarin (Mato, 1914).
CHOLIN

General Statements.—Cholin (trimethyl-oxyethyl-ammonium) occurs as a constituent of lecithin probably in all animal and vegetable tissues, although often merely in traces. It is probably not free in the living tissues, in detectable quantity, but may be liberated by putrefaction or autolysis, not by pepain or trypsin (Coriat, 1904). It therefore occurs in greatest concentration in many vegetables (Schulze and Trier, 1912) and in certain drugs (especially ergot). It may be liberated in intestinal putrefaction and thus contribute to the systemic phenomena of constipation; but it is readily destroyed by the intestinal bacteria and is less toxic than the analogous neurin and various amines which are also found in putrefaction. Cholin is also but slightly toxic on hypodermic injection.

The peripheral actions comprise two independent elements: a muscarinic effect (stimulation of parasympathetic endings, similar to physostigmine); and a nicotinic effect (stimulation and paralysis of autonomic ganglia; curariform action on muscle). These two sets of actions are produced, in varying degree, by all quaternary ammonium bases (Dale, 1924).

The most marked effects of cholin are on the blood pressure, which it usually lowers, often with a secondary rise. After atropin, it produces a rise instead of fall. The fall is due mainly to a powerful vasodilator action, exerted directly on the vessels, but not fully understood.

Action on Blood Pressure.—Cholin generally produces a marked fall of blood pressure (Mott and Halliburton, 1897); but sometimes there is instead a rise of pressure. In cats, the rise generally follows the fall (Pal, 1912). The variable response does not depend upon impurities (Renshaw, Underhill and Mendel, 1912). The result is influenced by the dose, anesthetic, and other conditions (Abderhalden and Müller, 1912). The fall predominates if the blood pressure has been high (Benelli, 1914); in proximated ether narcosis, and after some sorts of curare. It counteracts the epinephrine rise (Gastrelet, 1909). The pressor effect is more prominent in light anesthesia, or after section of the medulla (Pal, 1912).

When large doses of atropin, cholin gives only a rise; and it also constricts the vessels of excised and perfused organs, after atropin (Mueller, 1910). Nicotin does not act like atropin (Hunt and Tavenre, 1912).

Mechanism of the Circulatory Actions.—This involves to a varying degree the vasomotor center, the vessels themselves, and the heart.

The work of Hunt, 1913, indicates that the peripheral vasodilation is the most important. With acetyl-cholin, there is an intense dilation of the vessels of most organs, including the skin; relatively feeble in the splanchnic area in comparison with the splanchnic fall; doubtful in the kidneys; absent in the lungs. Larger doses are constrictor.

This dilator effect is more powerful than that produced by any other method. It is diminished or prevented by atropin, but synergized by physostigmine. It does not involve any of the known vasodilator paths, sympathetic or parasympathetic, or the posterior roots. Apparently it is not connected with the nerves, and is different both from epinephrineria and nitrate dilation, which are not antagonized by atropin.

Peripheral vascular dilation by cholin was previously described by Handosky and Pick, 1913, and Hunt, 1914. Mueller attributed the fall of pressure partly to cardiac stasis, but also to vasodilation in the extremities, intestines, kidneys and brain; he attributed the atropin reversal to paralysis of the dilator elements.

Vasomotor Center.—Fickher and Sollmenn, 1915, showed that cholin produces a marked direct depression of the vasomotor center, which seems to play an important part in the fall of blood pressure, and which is abolished by atropin. However, other causes contribute to the fall; and when these predominate they may overcome the vasomotor depression, and may even stimulate the center by anemia.

Heart.—Pal found the effects on the heart and vagus inconstant. Patts and Vernon, 1915, refer the main effect to vagus stimulation, both central and peripheral. Goed-
CHOLIN GROUP

wisis, 1914, claims stimulation of intracardiac vagus and accelerator, in mammals. Hugo, 1912, finds that the heart generally slows down; the slowing being sometimes relieved by vagotomy, but not always. Lausana, 1913, finds that it slows and strengthens the heart of the turtle, while that of the frog is slowed and weakened, and its irritability to electric stimulation is diminished.

**Organ Extracts.**—The fall of blood pressure produced by the extracts of many organs and of nerve tissue may be due partly to their cholin content; but some characteristic differences have been described (Osborne and Vincent, 1906; Bouquet and Pouchon, 1910).

**Cholin Derivatives.**—Hunt and Taveau, 1906, 1909, 1911, Hunt, 1911, Evans, 1914, and Dale, 1912, have investigated the relative toxicity and circulatory effects of a large series of cholin derivatives, with very interesting results. For instance, the substitution of OH in cholin, in almost any manner, generally increases its activity, often very greatly (Dale). The introduction of the acetyl radical increases the depressor effect 100,000 times, the toxicity only three times (Hunt). Evans, 1914, has found acetylcholin in ergot, and considers it responsible for the cardiac inhibition.

**Other Peripheral Actions.**—The effects on intestine and other smooth muscle agree with phystostigmin. The secretion of saliva and tears is increased. Gastric secretion is diminished. Pancreatic secretion is diminished by small doses through inhibitory vagus stimulation; increased by large doses through peripheral stimulation (Chap, 1911). The output of uric acid is increased (Ahl, 1913).

Cholin as "Intestinal Hormone."—Cholin may be extracted from the intestinal walls (Wetland) and may perhaps be essential to the automatic function of Auerbach's plexus. It also renders the intestine sensitive to the inhibitory action of atropin (Le Heux, 1920).

**Sterility.**—Werner and Lichtenberg, 1906, claim that cholin injections, in rabbits, reduce sterility or lessened fertility, analogous to the effects of X-rays or thiorham No. Werner and Asher, 1912, find similar blood and skin changes.

**Distribution.**—Normal serum contains about 1 part of cholin in 400,000; about the same concentration exists in amniotic fluid; somewhat more in the urine, and in cardiac and skeletal muscle; much less in cerebro-spinal fluid and saliva. The proportion in the blood or cerebro-spinal fluid has not been found increased in any pathologic conditions examined in man. It has been reported increased by removal of the supraarenals, but the evidence is not decisive and does not prove any causative connection (Hunt, 1915).

** Fate.**—Cholin is largely destroyed in the body (v. Hoeßlin, 1900); a part of the acetyl being probably oxidized to formic acid, the remainder to CO₂ and water. After oral administration, only 3 per cent. of the cholin can be recovered from the tissues; intravenous, about 50 per cent., the greater proportion from the skin (Ellinger, 1914). It disappears rapidly from the blood stream (Hunt, 1915).

Practically none is excreted by the urine after hypodermic injection of large doses; only very little after intravenous injection (Gugenhein and Loeffler, 1916).

**Bibliography.**—An extensive list is given in Merric's Report for 1914, 28:53.

---

**NEURIN**

(CH₃)₃N⁺CH₂-COOH

CH₂-COOH

(CH₃)₃N⁺CH₂-COOH

May be formed from cholin by bacteria. Its actions are similar to cholin, but much stronger (Pal, 1912); and it is not toxic (Lohmann, 1911).

---

**BETAIN**

(CH₃)₃N⁺CH₂-COOH

OH

(CH₃)₃N⁺CH₂-COOH

OH

Is nearly inactive by mouth; hypodermically, it acts similarly to cholin. It is quite non-toxic (Velig, 1914); even 2.4 Gm. per kilogram by this route, are harmless. It is excreted unchanged, and is therefore not a food (Andrieg; Velig and Stanek, 1920). The preparation and properties of its salts are described by Steenenberg, 1914.

Lobner (1917) considers the betaine ring as probably essential to antineuritic action. Betain itself is somewhat protective, although not very efficient.

Betain hydrochlorid dissociates in solution, and has been utilized as a means of administering pure hydrochloidal cholin. The dose, 0.5 Gm.; 8 gr., corresponds to about 1.1 cc. of Acid Hydrochlorid Dilute.
QUATERNARY AMMONIUM BASES

General Statement.—The organic derivatives of ammonium are strikingly similar in their action. They produce a curare effect, i.e., paralysis of the nerve endings of striated muscle (Brown and Fraser, 1889); some also muscular tremors in frogs; and those possessing three or four methyl groups cause a muscarin effect, i.e., peripheral stimulation of the cardiac vagus; and a nicotin action, i.e., paralysis of sympathetic ganglia. The curare effect evidently depends on 5-valent nitrogen; or rather, on the stereochemical configuration; for the same characteristic is shown by the corresponding phosphorus, arsenic and antimony compounds. The various actions differs in degree with the various derivatives—i.e., the methyl and ethyl ammoniums—in ways which are not easily explainable by their constitution (Burn and Dale, 1915).

TETRA-METHYL AMMONIUM CHLORID

This produces a typical curare effect in mammals and frogs. Ammonium convulsions occur in mammals, but not in frogs, being prevented in the latter by the non-powerful curare paralysis. The circulation shows a fall of blood pressure, generally with slowing of the heart, by peripheral vagus stimulation and peripheral vasomotor depression. The respiration is temporarily paralyzed by intravenous injection; in debricated animals, this is preceded by respiratory stimulation. The paralysis is due to a curare effect on the phrenic nerves (Marshall, 1913). Looenhart, 1914, however, believes that the respiratory action is entirely central; i.e., primary stimulation and later depression of the medullary centers.

TETRA-ETHYL AMMONIUM CHLORID

In frogs, this produces irregular muscular contractions and tremors; first fictillary, then tonic. With larger doses, these are succeeded by paralysis. Both actions are seated in the muscle-nerve endings. Mammals also show increased excitability and depression of the endings. Rabbits exhibit dyspnea, tremors, convulsions, and arrest of respiration. In distinctness to tetra-methyl ammonium, there is no direct action on the circulation; the respiratory effects are also smaller (Marshall, 1914). Burn and Dale, 1915, found no curare or muscarin action, but a good nicotin effect.

METHYL-ETHYL AMMONIUM COMPOUNDS

The actions of these are, on the whole, intermediate; but without definite ratio to the alkyl radicals (Marshall, 1915; Burn and Dale, 1915).

NICOTIN

General Statement.—Nicotin, the chief alkaloid of tobacco, has no therapeutic importance, but considerable scientific and toxicologic interest. Both the central and peripheral actions are important; both consist in short stimulation, followed by depression or paralysis. Centrally, small doses cause chiefly a respiratory stimulation; larger doses produce convulsions of the medullary type. The action is enormously rapid, approaching hydrocyanic acid. Peripherally, nicotin paralyzes all autonomic ganglia, parasympathetic as well as sympathetic. The paralysis may be preceded by stimulation. The most important effects are on the circulatory and gastro-intestinal systems. It has also a curare action on muscle-nerve endings.

The effects of tobacco are due practically solely to its nicotin. Limited tolerance to the acute toxic effects is soon acquired, after which it acts
chiefly as a central sedative. Overindulgence produces chronic nicotine poisoning, with digestive disturbances, functional akrhytias, optic changes, etc. The differences in the various forms of tobacco habit are probably explainable by differences in absorption.

Related Drugs.—Very similar in their actions to nicotine are *piparic*, the alkaloid of *Piparia Digitata*, which is chewed by the natives of Australia as a substitute for tobacco; and *cinnamomum* (Dale and Laidlaw, 1912), the alkaloid of the ornamental Laburnum tree (*Cytisus Laburnum*). *Caulophyllum* also contains methylcynarin, with similar actions; besides volatile oil, a saponin (*Lloyd's Lemon*), and caulophyliosaponin (Power and Salway, 1913). *Lototes* is less perfectly related.

Central Actions of Nicotine.—These consist in stimulation, followed by depression, of the whole cerebro-spinal axis, from above downward. The symptoms from large doses resemble those of asphyxia or hydrocyanic acid.

The stimulation may be entirely absent, especially in large doses, so that the animal may drop dead almost instantaneously, without any other symptom. But this is not common. The effects of small doses, such as are noticed in the first attempt at smoking, will be discussed later. In mammals, moderate doses act mainly on the hemispheres, producing transitory excitement, followed by lasting depression, with violent headache. (In frogs, the action on the cerebral centers seems to be very small, for the effects are the same, whether the hemispheres are intact or removed.)

Medullary Centers.—The action on these is marked and violent. Inspiration is at first increased, and then markedly depressed; paralysis of the respiratory center being the *cause of death*. The vagus and vasomotor centers are also first stimulated, and then paralyzed. The salivation and vomiting, which are so prominent with moderate nicotine intoxication are probably also due to medullary stimulation (Eggleston and Hatcher, 1915). The emotive action is antagonized by strychnine (Eggleston, 1916).

*Nicotiana Aquatica.*—In anesthetized dogs, nicotine intravenously may produce prolonged arrest of respiration (de Almeida, 1906).

*Bronchial Muscles.*—This is constricted in the surviving hogs (Baehr and Pick, 1913).

*Spinal Cord.*—The motor cells are strongly stimulated, resulting in *convulsions*, passage of feces and urine, etc. If the nicotine is applied to one part of the cord, the convulsions remain confined to the muscles innervated from this area (difference from strychnine, which acts on the sensory cells). The stimulation is followed by paralysis. The nicotine convulsions are not seated exclusively in the spinal cord, but involve the hippocampus and medulla as well. They are much weakened by anesthesia.

The *cerebral reflexes* of frogs are depressed. Partial tolerance to this action is acquired by repeated administration (Howat, 1917). The *spinal ganglia* (posterior roots) are not affected, even when a 1 per cent. solution of nicotine is applied directly to them.

Location of Peripheral Actions.—The important work of Langley, 1896, on the localization of nicotine in the autonomic ganglia was mentioned on p. 318.

If the preganglionic fibers have degenerated (seven to twenty-six days after section of the nerve), nicotine is still active, so that it must act upon the ganglion cells themselves. The effects are more complex in the intestines (p. 318). Dogs are relatively insusceptible to the peripheral actions.

*Antagonists.*—From the situation of the nicotine actions, it follows that they can be removed by atropin or muscarin, but that the latter are quite unaffected by nicotine. The antagonists for striped muscle are described on p. 324.

Sequence of Paralysis of Ganglia.—The results of Langley, 1918, were discussed in the general section on autonomic drugs.
Circulation.—The effects are shown in Fig. 11, and explained in Fig. 21. They consist, involving stimulation and paralysis of the heart-muscle, vagus and vasa centrally and peripherally. The total effects are fairly constant and characteristic

Initial Effects.—The heart is first greatly slowed, from central and ganglionic stimulation. At the same time the output of the heart begins to rise, due to the vasodilation of the vasomotor center (Pflüger and Sollmann, 1915), and ganglia (Hoskins Ranson, 1915); the central and peripheral stimulation playing about an equal rôle.

The blood pressure may be raised by nicotine (and anagyrin) even in the absence of the vasomotor center, but not if the suprarenals are also excised (Gley, 1914). A rise of the blood-pressure rises seems therefore attributable to increased output of epinephrine.

Smoking of tobacco increases the coronary pressure (Bond, 1911). In novices, it is generally a rise, then fall of systemic blood pressure (Lee, 1908). John, 1913, found in typical cases, after smoking eight to ten cigarettes or two medium cigars, that diastolic pressure rises, and often remains high for two hours. The effect is proportional to the nicotine content, and is perhaps due to the nausea. The effects on the p.v. rate were variable.

W. G. Thompson and Sheldon, 1917, investigated the acute effects of smoking patients with high blood pressure. The response differed greatly: The maximal effects ranged from a rise in systolic pressure of 25 mm. and in pulse pressure of 21 mm to a fall in systolic pressure of 30 mm. and in pulse pressure of 34 mm. Rise, fall, and effect were about equally numerous, and varied even in the same patient. There was no difference between cigars and cigarettes.

J. Parkinson, 1917, studied the immediate circulatory response to the smoke of or 5 cigarettes in normal subject and "soldier's heart.

All the subjects who "inhale" the smoke showed effects, which were generally greater in the patients with circulatory instability. The response consisted in increased pulse rate, averaging 9 beats in 15 patients, and slight rise of blood pressure, 3-10 mm. systolic, 5 mm. diastolic. Respiration was unaffected; but exertion easily rendered the subjects "breathless."

Nicotine is the Essential Agent in Cardiac Effect of Tobacco Smoke.—This has been shown by Clerc and Pozzi, 1914. Ringer's solution through which tobacco smoke has been passed produced the typical nicotine effects on perfusion through excised rabbit heart, i.e., temporary vagus standstill. Prolonged perfusion, however, leads to permanent arrest which is not due to the nicotine, but to collidin and other bases that occur in the smoke of tobacco or other leaves, for instance, oak.

Carotid Reflex.—The reflex fall of pressure which ordinarily results from traction of the cephalic end of the carotid artery is abolished by nicotine (Sollmann and Brod 1912).

Arrhythmia.—With larger experimental doses, the slow heart beat is replaced quite suddenly by great quickening through paralysis of the vagus ganglia. The nicotine heart may therefore be slowed by muscarin, or stimulation of the sinus, but not stimulation of the vagus trunk. According to Kose, 1905, the secondary accelerat

Electrocardiograms (dog) often show a nodal rhythm (synchronous action of atria and ventricles), interrupted by extrasystoles; and other irregularities identical w
those of stimulation of the vago and accelerators, separately or together (Pozzi and Chc., 1915; Bull, Clerc and Pozzi, 1914).

Blood Pressure in Toxic Stage.—This may be very high and the central vasomotor stimulation may persist into death (Pilcher and Sollmann, 1913); but as the peripheral vasomotor mechanism becomes more and more depressed, the vessels become dilated and the pressure falls. The dilation can be plainly seen in the intestinal vessels of the rabbit's ear. The vasomotor paralysis is rarely complete, so that direct or reflex stimulation, or a second injection of nicotine, again causes a short constriction.

When the paralysis of the vasomotor ganglia is complete, it is impossible to restore the blood pressure permanently (Langley, 1918). The heart-muscle eventually wears out, mainly because of the lowered coronary pressure.

Coronary Circulation.—This is slowed by 30% constriction of the coronary vessels, notwithstanding the raised blood pressure (Morawitz and Zahn, 1914).

Pulmonary and Hepatic Vessels.—These are constricted (Berczi, 1914).

Renal Vessels.—When one kidney is denervated in a normal animal, the urine on that side is more abundant and richer in chlorid and urea. This is attributed to the vasodilatation. When nicotine is injected (0.7 to 1.5 mg. per Kg.), the difference disappears, since the vessels on the sound side are also paralyzed by the alkaloid. Ergotoxin, atropin and ether have a similar effect (A. C. Kolls and Marshall, 1917).

**Reaction in Shock.**—The blood pressure of animals in peptone or anaphylactic shock reacts but little to epinephrin, but rises sharply under nicotine (34 mg. per Kg.). This rise, however, is attributed essentially to the increased respiration (J. P. Simonds, 1916).

**Peripheral Actions on Frogs' Vessels.**—By perfusion through decerebrated frogs, nicotine produces immediate vasoconstriction and muscular fibrillation. These effects disappear in a few minutes, during the perfusion, and can not be restored by further nicotine. Epinephrin is still effective. Tyramin suppresses the nicotine constriction almost completely (Handovsky and Pick, 1913).

**Erised Mammalian Heart.**—When perfused with nicotine, this shows typical vagus effects; first, diastolic standstill; then gradually resumption and finally acceleration close normal, with increased amplitude. The primary standstill is abolished by strychnin. The secondary acceleration is probably due to accelerator stimulation (Clerc and Pozzi, 1912).

**Frog Heart.**—The application of nicotine produces a brief diastolic standstill (stimulation of vagus ganglia). The heart then resumes its beat, and stimulation of the vagus trunk becomes ineffective, whereas sinus-stimulation or muscarin slows or arrests the heart. The nicotine has therefore paralyzed the vagus ganglia.

**Ivax and Nicotine on Frog Heart.**—The typical effects of heat are opposite to those of nicotine; nevertheless, a heated heart responds more readily to the drug (Zanda, 1915).

**Intestinal Actions.**—Nicotin provokes violent contractions, due mainly to stimulation of the Auerbach cells, but also involving other structures...
(see p. 330). These peripheral actions explain the diarrhea, and are perhaps also concerned in the nausea and vomiting; but these are essentially central.

Excised Stomach.—This is contracted in most mammals, but relaxed in a few forms (M. Smith, 1918).

Excised Ureter.—G. B. Roth, 1917, found practically no effect. Macht, 1916, describes primary stimulation and secondary depression.

Pupils.—These show both contraction and dilatation at different times, nicotine acting upon the ganglia of both the oculosympatic and sympathetic fibers. There may even be a direct action upon the iris muscle. The effect is different in different animals: The dog and cat usually show dilatation; the rabbit first constriction and then dilatation. The effects on the bronchial muscles have been described on p. 337; those on the uterus on p. 325.

Effects on Glands.—Secretion is generally stimulated through the ganglia. This is particularly prominent with the saliva. Small doses, however, change the response to stimulation of the chorda nerve, so that this diminishes secretion (Dale and Lafleur, 1911). Lacteal secretion is not increased (Ott and Scott, 1913).

Glycosuria.—Nicotine prevents the glycosuria which ordinarily follows the injection of caffeine and epinephrin; or on pique (Macleod and Dolley, 1905). This could be due to paralysis of the ganglia, or to the lowered blood pressure.

Epinephrin Output.—This shows a brief increase, followed by marked and enduring decrease, presumably by stimulation and paralysis of the ganglia. The epinephrin state of the gland is apparently unchanged (Stewart and Rongel, 1919).

Cerebro-spinal Fluid.—The pressure simply follows the circulatory changes (Dixon and Halliburton, 1914).

Skeletal Muscles.—In frogs, injections of nicotine produce fibrillary twitches. These disappear after section of the nerves, but are started again by short stimulation of the nerve or muscle. They are abolished by curare; and conversely, nicotine counteracts the curare paralysis. The stimulant effect must therefore be on the nerve structures, namely, the nerve-endings.

Immersion in 0.01 to 0.05 per cent. nicotine also causes twitching in normal leg muscle, but not in weakened muscle.

Mammals also show fibrillary contractions, but these are of central origin. Excessive doses of nicotine do not produce these central convulsions; although they do not prevent strychnin convulsions (Langley, 1918). This indicates that the nicotine convulsions start from a different center than those of strychnin. The peculiar muscular phenomena in fowls (Langley) were discussed in the general section on autonomic post.

Tobacco Smoking on Ergographic Response.—This produces a periodicity in the contractions, apparently due to central fatigue and depression (RaphaeI, 1900).

Curare Action.—Nicotine also has a curare-like effect, which becomes prominent later. In the milder stages this is shown by an equally strong, or stronger, current being required to obtain contraction when the stimulus is applied to the nerve than when it is placed on the muscle. In the normal preparation the opposite is the case. Tissue excitability and irritability of the muscle cells is also diminished by nicotine on direct application.

Local Actions.—Free nicotine is caustic by its alkalinity. Strong solutions paralyze the nerve fibers.

Invertebrates.—In the squid (Loligo) nicotine acts on the cerebral, and not on the stellar ganglion (A. R. Moore, 1910). In star-fish (Asterias) it produces ventral flexure, whereas strychnin produces dorsal flexure. When both drugs are used, the strychnin effect predominates (Moore, 1920).

Insecticide.—Nicotine is one of the most efficient insecticides (McClinton, Hamilton and Lowe, 1911). However it is applied, it kills the insects by paralysis, ascending along the ventral nerve cord, from the abdomen to the brain. It produces structural changes in the nerve cells, analogous to those of oxygen deprivation (McIndoe, 1916).

Asphyctic Action.—Tobacco juice and smoke are distinctly antiseptic, and Fullerston, 1912, claims that they tend to preserve the teeth.

Fate.—Nicotine is absorbed extremely rapidly from mucous membranes, and especially from the lungs; more slowly from hypodermic injections
and from the intact skin. It is excreted only in small part, mainly by the kidneys, but also by the lungs and sweat.

Eismon and Lee, 1912, confirm the older statement that it is partly destroyed in the liver, and claim that this destruction is increased by habituation; but Clark, 1913, found no destruction by frog's liver.

**ACUTE NICOTIN OR TOBACCO POISONING**

**Etiology.**—Serious poisoning is usually the result of attempts, especially by the laity, to use tobacco as a medicine; and of the swallowing of the concentrated nicotine solutions used as plant-sprays (Feil, 1916; McNally, 1920).

The application of tobacco to wounds or bruises is not without danger. E. G. Garvin, 1913, has reported the death of a girl of six and one-half years, forty-five minutes after the administration of less than 1.5 Gm. of tobacco by enema, against pinworms. In other cases, the time of death has varied from three minutes to seven hours. Prompt death has also occurred from swallowing nicotine plant spray (Feil, 1916).

**Toxicity.**—Nicotine is one of the most fatal and rapid of poisons; the vapor arising from a glass rod moistened with it and brought near the back of a small bird causes it to drop dead at once, and 2 drops placed on the gums of a dog may give a similar result. The fatal dose for a man is about 60 mg.; of tobacco, about 2 Gm. It acts with a swiftness equaled only by hydrocyanic acid. In view of the high nicotine content of tobacco (one cigar contains a quantity of nicotine which would prove fatal to two persons, if directly injected into the circulation), also because of its popular distribution, it appears astonishing that fatal nicotine poisoning is not more common; but just this wide distribution and knowledge of the drug form the safeguard, as also the marked taste.

**Symptoms.**—In lighter cases, such as commonly occur in smoking, the peripheral and nauseant actions predominate. There is first an increased flow of saliva, partly reflexly through the mechanical irritation of smoke, but mainly by direct stimulation of the glanglia through the nicotine. Nausea, vomiting, and diarrhea soon appear. There is a sensation of choking sweat, which does not actually break out. A feeling of exhaustion appears very early—partly as the result of nausea, partly as the first indication of central collapse action. Palpitation is also noted.

**Severe cases** show immediate faintness, prostration and muscular weakness; severe nausea, vomiting and diarrhea; followed quickly by convulsions and collapse (Garvin).

The effects of poisoning with pure nicotine, which have been very carefully studied experimentally on man, bear the greatest resemblance to the above. After 1 to 4 mg. there were burning in the mouth, a scratching sensation in the pharynx, increased salivation, a sensation of heat spreading from the region of the stomach over the whole body; excitement with headache now appeared, then vertigo, confusion, disturbed vision and hearing, photophobia, dryness in mouth, cold extremities, nausea, vomiting, and diarrhea. Respiration quickened, but difficult. Pulse at first increased, then irregular. After forty-five minutes there was syncope, with clonic spasms. Recovery occurred, but general depression persisted for three days.

The treatment, aside from the chemic from coffee and other stimulants and in meeting the symptoms. Emetics will usually not be necessary.

The postmortem appearances are not characteristic, although large doses cause, in animals, anemia of the meninges and peculiar anatomic changes in the cortical nerves. When taken by the mouth, there may be gastric and intestinal hyperemia, since nicotine is sufficiently alkaline to be somewhat caustic. The odor may furnish a valuable indication.
The proof of the poison after its separation may be had by its odor and by obtaining its physiologic actions on frogs. The muscular tremors and the position which a frog assumes after nicotin (Van Praag, 1885) are highly characteristic (Fig. 13). A control animal should, of course, be used.

The chemical tests are of no practical importance, since very similar reactions are given by colchicin and by a piotamin.

Nicotin is very resistant to putrefaction, and has been isolated from the decomposed bodies of animals three months after death.

![Fig. 13.—Nicotin. Successive positions of frog poisoned with 25 mg. nicotin.](image)

HABITUAL USE OF TOBACCO

The question of the effects of smoking has been largely discussed with rather unscientific emphasis, some contending that it is entirely harmless when moderately used; whereas, on the other hand, an enthusiastic French writer has gone so far as to attribute the defeat of his nation in the war of 1870 to the prevalence of cigarette smoking. Of the two views, the former would seem to come nearest the truth if the stress is laid upon the word “moderate.”

Since, next to caffeine, nicotin is the alkaloid most widely used, an impartial discussion of this question is important.

Composition of Tobacco Smoke.—The effects of the smoke are due practically entirely to the nicotin contained in it. There are other toxic constituents, but their quantity is too small to be practically important. This has been proved both by chemical considerations and by animal experiments (Lee, 1908; K. B. Lehmann; van Leeuwen, 1918).

Nicotin exists in tobacco mainly in the form of salts of organic acids (Garner, 1908). By the heat of smoking, these are largely dissociated, a part of the nicotin being burned and a part passing into the smoke as free nicotin (Lehmann, 1900). The drier the tobacco, the greater the heat, the less nicotin will escape destruction. Most tobacco, especially cigars, therefore, produce severer effects. This is more important than the nicotin content of the original tobacco (Lee, 1908). In experiments, between 15 and 30 per cent. of the nicotin present in the tobacco are recovered from the smoke; but a greater part of this is inhaled or expectorated. In natural (intermittent) smoking, the aspirated smoke contains only a sixth of the nicotin. About 1 to 1.4 mg. of nicotin would actually be absorbed from a cigar (Lehmann, 1907). In cigarette smoking, when inhalation is commonly practised, the percentage absorbed would be relatively high, thus accounting for its reputed deleterious effects. The average nicotin content of
cigarettes (5.69 per cent.) is rather lower than that of other forms of tobacco (leaf, 3.04; cigars, 1.52; chewing, 1.14); nor is there anything in the popular notion that cigarettes contain opium or other added narcotics (Thurston, 1913).

The smoke of a cigarette, with intermittent smoking, contains 6 to 8 mg. of nicotine (Ashkenon, 1919); but only a fraction of this would be absorbed.

All the preceding data are based on chemical methods, which do not actually identify the nicotine. This may be done quantitatively by the blood-pressure rise produced by solution of the smoke. By this means, and with intermittent smoking, cigarette smoke contains 100 to 275 mg. of nicotine per 100 grams of cigarette consumed. "Light" and heavy cigars do not show constant differences. So-called "nicotin-free" cigars yield just as much nicotine in the smoke as ordinary tobacco (van Leeuwen, 1918).

Other Toxic Constituents.—These are formed by combustion, and vary greatly according to conditions. As an illustration, Lee found in the smoke of 100 Gm. of tobacco, besides 1.165 Gm. of nicotine, the following: Pyridin bases, 0.146 Gm., chiefly pyridin and collidin; hydrocyanic acid, 0.06 Gm.; ammonia, 0.36 Gm.; CO, 410 c.c. The pyridin bases act somewhat similarly to nicotine, but with important differences (Lee) pyridin is a strong local irritant with low toxicity; a 10 per cent. solution has been used by atomizer in asthma and febrile bronchitis. It produces first dyspnée then shallow respiration. Brunton and Tunncliffe (J. Physiol., 17: 302) refer the effects mainly to sensory paralysis. Large doses arrest the heart. Smaller amounts stimulate the bone-marrow to increased production of blood-platelets (R. L. Lee and Minot, 1917).

The hydrocyanic acid in the smoke of a cigar amounts only to 0.002 to 0.5 mg., and would have no significance (Lehmann and Gundermann, 1912). If a large number of persons smoke in a confined atmosphere, the carbon monoxide in the air of the room may rise to a dangerous degree. The aromatic essential oils, which give the flavor to tobacco, are practically inactive. Areic is sometimes present in harmful quantities when Paris green has been used on the plant as an insecticide.

Tolerance and Habituation.—The quantitative effects of nicotine vary considerably in different persons. Similar variations are observable in animals. Young individuals are more susceptible than adults. Considerable tolerance is acquired by continued use, so that moderate doses lose all the usual unpleasant acute effects. The rapidity and completeness of the habituation also varies with individuals; dependent partly on individual susceptibility; partly on the manner in which the drug is used, whether the smoke is inhaled, the saliva expectorated, etc. The tolerance is never absolute; it seems to be higher against sublethal than against lethal doses.

Habituation in Animals.—These acquire only a limited tolerance (Hatcher, 1904; Edmunds, 1905; Adler and Henschel, 1905, could not produce any tolerance). Hatcher showed that the serum of habituditated animals does not protect others against intoxica
tion. Dixon and Lee, 1912, claim that the liver of habituated animals destroys nicotine somewhat more rapidly. Edmunds, 1916, failed to confirm this. At best, since the destruction is slow, it would protect only when small doses are introduced gradually.

Effects of Moderate Use of Tobacco.—When the tolerance has been acquired, the continued use of tobacco within a certain individual limit produces no unpleasant symptoms; but if the limit be at any time sufficiently exceeded, the symptoms of chronic poisoning, presently to be discussed, arise. After a long time, some twenty years, these symptoms may also, but rarely, occur in those who have always kept within bounds.

With habituated individuals, the use of tobacco by smoking, chewing, or snuffing brings with it a certain pleasant sensation, which is somewhat difficult to define. There appears to be a certain repose, which, while if neither directly aids nor hinders the psychic processes, leaves the mind free, and in general raises the user's enjoyment of other pleasures, or lessens his annoyance at the opposite.
The experience of military campaigns appears to show that the use of tobacco enables soldiers to endure greater hardship and hunger. With the ergograph, Pälmén, 1911, found that cigarette smoke at first increased the muscular work, but that fatigue set in sooner, and the total efficiency was decreased. Nice, 1912, found that the muscular activity of mice in a revolving cage was not diminished by fairly high and long-continued doses of nicotine.

C.S. Berry, 1917, reports that smoking enabled his subjects to do more rapid and correct arithmetic addition.

The blood pressure during smoking rises slightly and slowly in moderate smokers; in inexperienced smokers, it shows a sharp rise at first, and considerable fall when collapse sets in (Lee).

Nicolai and Staehelein, 1910, found that in tobacco users the heart rate averaged somewhat higher, especially in work; no definite changes could be made out in the systolic and diastolic blood pressure or electrocardiograms. Aliprandi and Fornaroli (1921) claim that tobacco chewing causes distinct constriction of the cerebral vessels.

Factors of Psychic Effects.—How much of the psychic effects is due to nicotine, how much to other factors, we can not say. It is certain that the nicotine strength of the tobacco is not the determining feature of this action—rather the aroma. Smoking in the dark does not give as much enjoyment; and simply holding an unlighted cigar in the mouth, the chewing of other objects, etc., give similar, though much weaker, sensations. The truth would seem to be that it depends upon a reflex stimulation, from the mucous membrane of the mouth, nose, etc., in which the nicotine plays a part; and with this may be associated a direct action of the nicotine upon the central nervous system, at once stimulating and depressing.

Chronic Intoxication.—The phenomena resulting from the excessive use of tobacco take many forms; especially local irritation of the respiratory tract; digestive and nutritional disturbances; functional cardiac arrhythmias; depression of various parts of the central nervous system; neuralgias; more rarely impairment of vision.

Local Effects.—The nicotine and other basic constituents of the smoke act as fairly strong irritants, as shown by the biting sensation on the tongue, noted especially when the smoke is concentrated on one point, as in pipe smoking. This constant local irritation seems to favor the development of epithelioma of the lip and tongue, if the quantity consumed is very large or the smoker specially disposed. There is also a more general irritation of the mucous membrane of the mouth, throat, and pharynx, leading to catarrh and hoarseness.

Circulatory Disturbances.—The first warning symptoms are occasional palpitation, quickened heart rate and arrhythmia. These become persistent if the nicotine is continued, but disappear on withdrawal. In advanced cases, the abstinence must be continued for months. The arrhythmia is purely functional, due to extrasystoles (premature beats with long pause), pointing to increased irritability of the cardiac structures. It is similar to that of caffeine, hysteria and neurasthenia. In graver cases, the cardiac irregularity may become extreme and lead to sudden fainting (syncope). Respiratory distress naturally accompanies the marked cardiac phenomena. Angina pectoris is so rare in these subjects that it must be attributed to causes other than the nicotine. On the other hand, arteriosclerosis appears to be favored by it, although there is no conclusive evidence of a causal connection.

The extrasystoles are usually auricular. Auricular fibrillation and "flutter," and sino-aortic block have also been encountered (Neuhof, 1918). The block disappeared within three days after stopping the tobacco.

In rabbits, chronic nicotine poisoning produces anatomic arterial and cardiac changes, similar to those of epinephrin (Adler and Hense, 1905; Basha, 1906; Otto, 1911;
Adler, 1914). These results can be only cautiously transferred to man. Pawinski, 1914, claims that 42 per cent. of 1,000 cases of coronary sclerosis had histories of immoderate smoking; and that nicotine produces marked changes in the coronary vessels and heart-muscle in animals. Lissauer, 1914, also describes histologic changes in the cardiac and other ganglion cells.

**Digestive and Nutritional Disturbances.**—The symptoms next in order are probably those arising from the alimentary canal, and depending upon the continued irritant action of the nicotine. These are: Loss of appetite, then dyspepsia and chronic intestinal catarrh, shown by alternating constipation and diarrhea. (With moderate smoking the nicotine seems rather to have a tendency to keep the bowels regular.) These conditions lead to emaciation and anemia.

Smoking inhibits the hunger contractions of the stomach, the effect being proportional to the local stimulation of the mouth, etc. (Coxton and Lewis, 1914). The digestive movements of the stomach are presumably not arrested. A direct action upon the blood may also have a part in the anemia; the continued administration of nicotine to animals leading to diminution of red corpuscles, and increase of leucocytes. It is also claimed that it diminishes the oxygenating power of hemoglobin. The nitrogen excretion is rather more diminished than the assimilation, so that there may be a gain in bodynitrogen. Transitory albuminuria may occur.

**Nervous Disturbances.**—These are rarely serious. The psychic functions show slowness and want of energy. Anxiousness and insomnia are quite frequent. There is general muscular debility, tremors, and want of control over movements.

The reflexes are lightened. Vertigo and a tachicardia condition may set in. There is then an increase of excitability in the sensory and pain areas, and consequently headache and neuralgias; but the latter are in part due to referred pain from the cardiac disturbances. They are often early and quite characteristic, and take the form of pain and hypesthesia in the precordial region, left nipple and ulnar surface of left arm.

**Nicotine Blindness.**—This is relatively rare. It seems to be favored by alcoholism. The sight gradually becomes dim, with central scotoma, impaired accommodation, and often nystalgia. It is always bilateral. The anatomic changes consist in retrolubar optic neuritis, with subsequent atrophy. Until degeneration has set in, a complete cure can usually be effected by abstaining from nicotine; later, this will only arrest the latter progress (de Schweinitz, 1860).

**Other Toxic Amblyopias.**—Many poisons may produce blindness, temporary or permanent, in susceptible individuals, especially on continued administration. This has been recorded for strychnium, cannabis, chloroform, opiates, carbon disulphid, tannin, isocyanide, ascidium, quinin, salicylic, methyl alcohol, etc. For most of these the changes are analogous to those of nicotine. With methyl alcohol, quinin and salicylic, the retinal ganglion cells are also involved. The metals and aspidium may produce primary optic atrophy without preceding neuritis (de Schweinitz, 1866 and 1891).

Of other effects which have been attributed to nicotine, but with insufficient cause, may be mentioned: Impotence, epilepsy, and insanity (G. W. Jacoby, 1866; Naecke, 1890).

**Treatment.**—It will be seen that the catalogue of injurious actions to be charged against the abuse of this drug is sufficiently large; but on the other hand, it must be noted that these are absent with moderate use, and can be abolished if the use of the drug is promptly limited on their first appearance. Actual withdrawal is not always necessary. Limitation in quantity, sufficient expectoration, and the avoidance of deep inhalation of the smoke are often sufficient. Quick total withdrawal does not lead to abstinence symptoms, as with morphin (except possibly in some especially neurotic subjects), although it may disturb the function of the bowels for a few days. The principal point in the treatment is to keep the thought
of the patient off the topic of tobacco, and to supply the accustomed stimulus to the mouth in some other manner, as by chewing ginger or gentian.

The use of tobacco must, of course, be avoided in pathologic conditions in which there are special contraindications to it—in heart disease, dyspepsia, inflammation of the respiratory tract, etc.

PREPARATIONS—NICOTIN

Tabacum (Tobacco).—"The commercial dried leaves of Nicotiana Tabacum, Linne (N.O. Solanaceae)," an annual plant, probably indigenous in tropical America, and now cultivated in most parts of the world. The annual production of the world is estimated at 1,000,000 tons (1,000,000,000 kg). Other species also contain the nicotine. The plant was introduced into Europe shortly after the discovery of America. Its use by smoking was practised by the natives at the time of Columbus.

The important constituents are nicotine, which is also present to a less extent in all other parts of the plant, and a volatile oil developed in drying and "sweating." The percentage of nicotine varies between 1 and 8 per cent: In Havana and Maryland, 1.5 to 2; Virginia and Kentucky, 6 to 8; South American, 2 to 6; German, 1.5 to 3. A number of other alkaloids have also been announced to exist in small amount in tobacco (Picet and Rotschy, 1901).

The dried leaves were formerly official, but are now obsolete in medicine; if used, an infusion may be made. The dose was given as 0.5 Gm.

Nicotin, C16H2N4N, is a fluid, volatile, oxygen-free alkaloid, of strongly basic characters. It forms salts, most of which are soluble. It is colorless and almost odorless when freshly prepared; but it partly decomposes on keeping, acquiring a characteristic odor and a brown color. The dose would be to 0.001 Gm.

LOBELIA

The herb Lobelia inflata was used by the American Indians as a substitute for tobacco. It was introduced into medicine by Samuel Thompson about the beginning of the nineteenth century as the main basis of his peculiar system of treatment. The chief constituent is the alkaloid Lobeline with actions resembling nicotine (Edmunds, 1904).

Actions.—Small doses lower the CO2 threshold of respiration (Wieland, 1913). Larger doses paralyze the respiratory center and cardiac muscle (Muto and Iwashawa, 1917). Relatively small doses paralyze the bronchial muscles (Dresser, 1886), which may explain its use in asthma.

Circulation.—Lobelin raises the blood-pressure like nicotine (van Leeuwen, 1917).

Excited Intestines.—The effects have been studied by Ikeda, 1916.

Nausea and Emesis.—These are central (Eggleston and Hatcher, 1915).

Poisoning.—The symptoms are of ten alarming but rarely dangerous, because emesis occurs nearly always. Many of the specimens of the dried drug are almost inactive.

Poisoning is treated by gastric lavage and stimulants.

Uses.—Lobelia is used in respiratory affections, especially in spasmodic asthma, spasmodic croup, spasmodic bronchitis. It is a nauseant expectorant, but demens digestion. As emetic it is effective, but not sufficiently safe.

Altogether, lobelia is an unreliable, depressant and dangerous drug.

PREPARATIONS—LOBELIA

Lobelia, U.S.P., B.P. (Indian Tobacco).—The dried leaves and flowering tops of Lobelia inflata. Dose, 0.15 Gm., 2.5 gr., U.S.P.

Frital. Label., U.S.P.—Dose, 0.15 c.c., 15 mins, U.S.P.

Tr. Label., U.S.P.—To per cent. Dose, 1 c.c., 15 mins, U.S.P. Maximum dose, 2 c.c., 30 mins.

Tr. Label. Aeth., B.P.—30 per cent. in Spir. Aeth. Dose, 0.3 to 1 c.c., 5 to 15 mins, B.P.
CONIUM—GEELSEMIUM

CONIUM

Conium or "Water-Hemlock," an Umbelliferous herb, contains a number of alkaloids, of which conium is the most important. This is a simple derivative of Piperidine, and was the first alkaloid synthesized. Children are sometimes poisoned by eating the root. The juice is believed to have been the poison administered to Socrates. It was introduced into medicine by Steerck, 1770, but is now practically obsolete. It was formerly used as a sedative and antispasmodic in cholera, mania, convulsions, whooping cough and asthma; and locally in hemorrhoids and other anal lesions. Its peripheral actions are similar to those of nicotine, but it produces more pronounced paralysis of the central nervous system and of the skeletal muscle-nerve endings. Poisoning is treated by tannin, evacuation and stimulants. A bibliography is given in Cushny’s "Pharmacology."

In actions on the excised intestines are also similar to nicotine (Ikeda, 1916).

LUPINES

These have some importance as poisons of grazing stock. They contain bitter alkaloids, one of which appears to be related to conin (C. D. Marsh, Clawson and Marsh, 1916; Sollmann).

LATHYRISM

The eating of the peas of Lathyrus produces in man paralysis of the legs, which may be permanent if the consumption is continued (Stockman, 1917). The pea contains small quantities of two active alkaloids with identical central effects: motor paralysis, apparently cerebral; increase, then decrease of spinal reflexes. Both weaken the heart. One also produces a curaroid effect on skeletal muscle endings (Dilling, 1918).

GEELSEMIUM

This, the root of Yellow Jasmine, acts similarly to nicotine and conin. Its central depressant action is relatively more marked (Cushny, 1892). It contains a crystalline alkaloid, Geelsemin, with weak strychnin action; and several amorphous alkaloids, Geelsemin and Geelsemidin (C. W. Moore, 1910; Sayre, 1910 and 1912; Sayre and Chil- digworth, 1914), which are chiefly responsible for the effects of the drug. "Gelsemin" Merck has been shown to consist of Gelsemin. Stevenson and Sayre, 1915, describe a further alkaloid, "sempervirin."

Excised Intestines—Gelsemin depresses the tone and contractions (Ikeda, 1916). Therapeutic Uses—Gelsemin (1 to 10 drops of the fluid extract) is employed in neuralgic conditions, especially trigeminal neuralgia, nervous headaches, cerebral hyperemia, and hysteria. There is no pharmacologic explanation of these uses. Its local application to the eye dilates the pupil, but produces considerable irritation (Potzeys and Romey, 1887). It is no longer used as a mydriatic.

Toxic Effects.—Even small doses sometimes cause toxic symptoms, which may be delayed for hours. The warning signs are ptoisis, double vision, dilated pupils, weakness and depression. Fatal doses produce slowing and arrest of the respiration. A dram of the fluidextract is said sometimes to cause death, and 10 minims is dangerous. Treatment of Poisoning.—Evacuation; atropin and stimulants.

PREPARATIONS—GEELSEMIUM

Gelseminum, U.S.P.; Gelsem. Rad., B.P. (Yellow Jasmine Root).—The dried rhizome and root of Gelsemium sempervirens (nittidum, B.P.). Dose, 0.03 Gm., ½ gr.

Est. Gelsem., U.S.P.—A powdered extract, 1 Gm. representing 4 Gm. of the drug. Dose, 20 mg., ½ gr. U.S.P.

Fluid. Gelsem., U.S.P.—Dose, 0.03 c.c., ½ minin, U.S.P.

Tr. Gelsem., U.S.P., B.P.—10 per cent. Dose, 0.25 c.c., 4 minims, U.S.P.; 0.3 to 1 c.c., 5 to 15 minims, B.P.
Spartein

General Statement.—This alkaloid has been used to slow the heart in cardiac disturbances; but its effects are uncertain, it weakens the heart and can not take the place of digitalis.

Spartein is a pyridin derivative, like nicotine and conlin, and has similar effects (Fick, 1873). Its central effects are slight and its toxicity relatively low (Griffith, 1904). It took 0.4 Gm., 0.5 gr., without bad effects, except slight confusion. It has no action on the vasomotor center; but the depression of respiration tends to produce asphyxial stimulation (Pichler and Sollmann, 1913). Peripherally, it has a strong action, arresting respiration by paralyzing the phrenic nerves. (Chapman and Matthews, 1895). Larger doses also paralyze the respiratory center (Muts, Ishizaka, 1903). It has a weak local anesthetic effect (Guinaud and Gley, 1894). Habituation cannot be induced in guinea pigs (Doucrott, 1913).

Excised Intestines.—Spartein depresses the tone and contractions (Ikedo, 1912).

Circulation.—The experimental data give a confused picture of its actions. Doses produce peripheral vagus paralysis (Fick and all subsequent workers). This sometimes result in preliminary quickening of the pulse (Gluziński, 1885) and rest of vagus rhythmias (Mastius, 1887). The most constant feature is slowing of the rate, which is not prevented by atropin, and is therefore due to direct depression of the cardiac muscle. Because of the slowing, the pulse waves appear large; but in truth to digitalis, the tendency of the heart is diastolic instead of systolic (Cassidy, Matthews). Frogs' hearts also show decrease of rate, strength and tone. With its enox injections, the slowing becomes so extreme that it may be fatal; but this effect is of short duration, does not occur on oral administration, and is probably due to direct irritation of the endocardium.

Electrocardiograms of excised mammalian hearts show that spartein in vivo checks the functions in all directions (Sakai, 1912).

The blood pressure shows a progressive fall, explainable by the cardiac depreexcised arteries are dilated (Cow, 1911). Rise of blood pressure has been reported of is of constant occurrence (Cerna, 1904), and is perhaps due to the mechanical effect of the injection and to asphyxia.

Diuretic Effect.—This has been affirmed and denied, clinically and experimenter (MacNider, 1910; Griffith, 1886). Its existence is very doubtful. Frommuller, contends that the reputed diuretic effect of the parent plant (Scopus auriculatus) is due to scoparin, a neutral principle.

Uses.—Spartein was recommended by Seé, 1885; Laborde and Léonard, 1886; and many others, in cardiac disease, valvular and functional, ner palpitation, Graves' disease, asthma, etc. Clarke, 1887, claimed that it produces marked slowing and strengthening of the pulse, the effect appearing in thirty minutes and lasting for five to six hours. Probably clinicians consider it useless (Leo, 1887; H. C. Wood). It is certainly devoid of the cardiac tonic action of digitalis; and without this the solution would be of little value. The influence of drugs on functional cases is difficult to judge. Atropin would be more efficient for preventing the vagi.

Dosage.—10 mg., 5 gr., gradually increased to 0.13 Gm., 2 gr., e six to eight hours. A. Jacobi, 1907, advises not less than 1 gr. per eve for babies. Overdoses produce nausea and vomiting.

Preparations—Spartein

Spartein Sulphate (Spart. Sulph.), U.S.P.; C,H,N,SO, + 3H,0.—Hep scopio colorless crystals or powder; odorless; slightly bitter. Freely soluble in water (1 of 10). Dose, 10 mg., 4 gr., U.S.P. Maximum dose, 0.2 Gm., 3 gr.

Scoparii Cacumina, B.P.; Broom Tops.—The fresh or dried tops of Cytisus scoparius, B.P.—10 per cent. Dose, 50 to 100 c.c., 1 to 2 ounces, B.P.

Faucarii Scoparoi (Succ. Scopar.), B.P.; Juice of broom.—The juice expressed fresh plant and preserved with one-third its volume of alcohol. Dose, 4 to 1 dram, B.P.
CURARE GROUP

CURARE

General Statement.—This is practically important in laboratory technic, for paralyzing the skeletal muscles through a selective depression of their nerve-endings, as shown in the classical researches of Cl. Bernard, 187. It has no effect on sensory nerves and is not an anesthetic. It produces a number of side effects, resembling nicotin in depressing autonomic ganglia (vagus); and strychnin in stimulating the spinal cord. It may produce glycosuria. Intravenously, it causes a temporary fall of blood pressure, returning rapidly to normal with moderate doses. Death occurs by paralysis of the respiratory muscles; animals may be saved by artificial respiration, the drug being rather rapidly excreted by the urine. Curare is mutually antagonistic with physostigmin. It is much less toxic by the stomach, on account of slow absorption and rapid destruction and excretion. It has been used therapeutically against tetanus and other convulsions, but only obviates the fatigue and exhaustion, and is quite dangerous because of the uncertain dosage.

Other Drugs Producing the "Curare Effect."—These are quite numerous.

Among the most important poisons possessing this action are the following:
Certain ammonium bases, amidin, cholim, muscarin, etc.
Methyl-strychnin, guanadin (Brown and Fraser, 1860).
Dolphocuranin, Hey! (Kahn, 1900).
Aromatic series: Pyridin, quininol, thallin.
Nicotin series, piperdin.
Morphin and related alkaloids.
Cocain.
Camphor in frogs, but not in warm-blooded animals.
Certain putrefactive products.
Products of muscle metabolism.

The curare effect of many of these drugs is an unimportant side-action, which can only be demonstrated in frogs, being obscured by other actions in mammals. S. Frankel, 1904, attributes the curare action of the ammonium bases and related drugs to the stereoschonic orientation of the valences.

Origin.—Curare, Wooren, Urari or Piennes, comprises several varieties of extracts, prepared by South American Indians as arrow poisons, from the root-bark of several Strychnos plants. It was first brought to Europe from Guyana by Sir W. Raleigh, 1591. Little is known of their preparation. They vary greatly in composition (certain varieties were supposed, probably erroneously, to contain snake venom); and they deteriorate on keeping, especially if moist, so that commercial curare is a very unreliable drug. The naming of the active alkaloids is so confused that they are not much better.

Varieties.—These are designated by the kind of containers in which they reach commerce: Calabash (Gour) curare is obtained principally from Strychnos toxifer and certain curaria. Tube curare, in bamboo tubes, is of undetermined source, and contains tubocuran and curin. It is the least desirable but the most common variety. Pet or jar (Tupi) curare comes from Strychnos Castelnani and Cocculus toxiferus, and contains protacuranin and protacurin. All the varieties consist of brown masses, intensely bitter, not wholly soluble in water, more soluble in dilute acid.

Active Principles.—All the above-named constituents are alkaloids. Curarin and protacurin have the most typical effects, and the latter is probably stronger. Tubocuranin has a much weaker muscle-nerve action, a stronger strychnin effect, and increases the heart rate. Curin is devoid of the muscle-nerve action, but first stimulates and depresses the heart. It can be converted into curarin (Bochum).

Curarin is related chemically and in actions to strychnin. Its preparation from calabash curare by the method of Bochum, 1867, is described in the Reports, Counc. Pharm. Ches., 1910. Tubocuranin is not a proper synonym although it has been so used.

Paralysis of Muscle-nerve Endings.—Ordinarily the only symptoms of "curare" poisoning consist in this paralysis. When the curare is
introduced under the skin, it causes a total loss of motion, first of the voluntary and then of the respiratory muscles.

Sequence.—The order in which this disturbance appears is the following: Shor muscles of the toes, ears, and eyes; then the limbs, head and neck; finally the respiratory muscles, first the thoracic, then the diaphragmatic, and lastly the abdominal (Chu 1912).

The heart is not affected except with very much larger doses. The muscles which are least affected by curare are those which contain the largest amount of utilisable oxygen, and survive longest after the death of the animal. The supply of oxygen accounts, perhaps, for the lesser susceptibility to the depressin action of amodi of curare.

Development of Paralysis.—The first sign of curare action consists in incapacity for sustained effort on repeated stimulation of the nerve; i.e., whereas a single contraction is normal, fatigue sets in more readily than usual (Boeun, 1824). Then the height of contraction is somewhat lowered. Then the current must be strengthened to obtain any response; and finally even the strongest stimulation of the nerve—Inefficient.

Location.—This was investigated by Fontana and established by the work of C. Bernard, 1857. It is evident that some structure is paralyzed. The paralysis might have its seat in any part of the central nervous system or it might be peripheral. Stimulation of the sciatic does not produce a contraction if the dose has been sufficient. The point of attack must, therefore, be peripheral to the sciatic nerve. This leaves the nerve trunk itself, the nerve-endings, and the muscle fibers. Stimulation of the muscle directly is effective, so that this is excluded. To decide between the nerve trunk and the nerve-endings, he placed a ligature around the body of a frog, with the exception of the sciatic nerves, and tightened the ligature so as to entirely exclude the lower extremities from the circulation. He then injected the curare. In this manner the peripheral portions of the sciatic nerves and the endings did not come into contact with the curare and the nerve trunk was alone exposed to the poison. He found that stimulation of the trunk caused normal contraction, consequently that curare had no action on it, the leaving only the endings.

He also proved the point in a simpler manner by ligating one leg exclusive of the nerve, or by placing the muscle of one and the nerve of another muscle-nerve preparation into the solution. Garten, 1912, has shown by careful methods that even prolonge exposure to strong curare solutions does not affect the nerve trunk. The “muscle-nerve” endings affected by curare need not necessarily be identical with the anatomic end plates, although this is possible (Edmonds and Roth, 1906; Kuebne, 1826, described some observations which indicate that the action is not always strictly localized. The peculiar antagonism with nicotine was discussed on p. 926. The nerve-endings of invertebrates are not paralyzed (Strasb).

Paton and Findlay, 1916, believe that larger doses of curare paralyze the receptive substance beyond the nerve-endings; but there seems no need of this assumption. Direct stimulation of the muscle (in cats) requires a somewhat stronger current under curare, but not if the nerve has degenerated. Epinephrin also restores the threshold of muscular stimulation. Fatigue increases the threshold (Gruber, 1914).

Sensory Nerves.—These are not affected by curare. The reports of early travelers who describe poisoning by curare arrows mention that sensation is not impaired when motion is entirely impossible. Bernard also studied this action directly on the frog. He ligatured one leg with the exception of the sciatic nerve, injected the poison, and applied the stimulus to one of the upper extremities. This caused a reflex movement of the ligated leg, which would not have been the case had the sensory endings of the foreleg been paralyzed.

Paralysis of Respiration as Cause of Death.—In cold-blooded animals in which the respiratory exchange takes place largely through the skin, and respiratory movement are unnecessary, the poison is gradually eliminated if the animal be kept in a moist atmosphere. Complete recovery occurs after eight to ten days, except when the dose is extremely large, in which case other factors come into play. Warm-blooded animals die of paralysis of the respiratory muscles. If artificial respiration be kept up and the dose has been only just large enough to produce paralysis they may also recover.

The recovery of the respiratory muscle begins immediately, while the sciatic endings require several hours. The effect of the curare increases progressively with the dose; it is as if an increasing resistance were gradually introduced between the nerve and the muscle.
The seat of the respiratory paralysis is also peripheral, for stimulation of the phrenic nerve does not result in contraction of the diaphragm.

The respiratory paralysis, if it is not too profound, is promptly removed by physostigmin; stimulation of the sciatic also becomes effective again.

Knee-jerk is not affected by curare (Trendelenburg).

Metabolism.—Curare paralyses the temperature nerves of the muscles, as well as the motor nerves, so that cocain, e.g., cannot raise the temperature.

The muscular paralysis lowers the metabolism. It is claimed that this diminution is far more conspicuous in the nitrogen than in the carbon-metabolism.

Oesophagus.—This has been considered as an index of the tonic functions of muscle, and is supposed to be controlled by the sympathetic system. It is not affected by curare, nor does curare prevent the increase by epinephrin, caffeine, etc. (O. Kiesscr, 1916).

Gusvastus is a frequent but not constant phenomenon (Morishima, 1890). It is not liable due to asphyxia, for it cannot be completely prevented by artificial respiration (Muced, 1909). The earlier literature is reviewed by S. Weber, 1904.

Epinephrin Output.—This is markedly depressed by curare in the dosage required to paralyze skeletal muscle (Stewart and Ruggo, 1919).

Peristalsis.—This is often increased, partly by asphyxia, but also with artificial respiration. Bidder, 1863, found no direct effect on intestinal or other smooth muscle, even with the largest doses.

Reba, 1910, with excised intestine found stimulation of the muscle and slight increase of tone.

Autonomic Ganglia.—The vagus, vasomotor, salivary, pupillary, etc., ganglia are depressed, but usually not as strongly as with nicotine.

The antagonism to nicotine stimulation indicates that the paralysis involves the ganglion cells. The order in which the ganglia are affected is also the same as with nicotine (Langley, 1918), and has been discussed in the general section on autonomic poisons.

Effects on the Circulation.—If artificial respiration is maintained, the first effect of curare is a slowing of the heart. The action consists in a fall of blood pressure, due to peripheral vasomotor depression (Tille, 1890; Sollmann and Pitcher, 1910). The action is apparently on the ganglion cells (Langley, 1918). This is soon accompanied by quickened heart beat, from depression of the vagus ganglia.

The depression does not readily pass into paralysis, so that stimulation of the vagus or sciatic is still effective; indeed, the vasomotor relaxes may be increased, through the central action of the curare. Martin and Stiles, 1914, also found that the threshold of the vasomotor center is not raised, even by large doses. The reflex depressor fibers are rendered more sensitive (Langley, 1912), or rather, the depressor response is more nearly proportional to the strength of the stimulus, than in normal animals (Martin and Stiles, 1914). Porter, 1915, finds that the response to sciatic and depressor stimulation may be enhanced while the level of blood pressure remains practically unchanged; and interprets this as evidence that the vasomotor and vasoreflex centers are distinct and independent.

These effects on the circulation pass off within fifteen minutes, and the circulation returns to normal, while the muscular paralysis persists. They therefore do not seriously interfere with the employment of the drug in experiments. The main objection which may be urged against the latter is that it does not produce sensory paralysis, with the absence of struggling, etc., might cause the inexperienced operator to neglect a proper enforcement of other means of anesthesia.

Perfusion of frog's efferent vasomotor nerves is not affected by curare (Pearce, 1913).

Vagus.—The peripheral effects correspond to those of nicotine. Electric stimulation of the vagus does not arrest the heart, but it may be slowed, or beat faster (Dale and Law, 1911).

The vagus conductive is slowed, in the frog heart, analogous to the skeletal muscles (M. Lapinque and Vell, 1916).

Perfusion of the medulla oblongata, in the turtle, may stimulate the cardio-inhibitory center somewhat, but more commonly tends to diminish the sensitivity of the center to other stimulants (Rush, 1920).

The lymph hearts of frogs are arrested (Bernard).

Central Nervous System.—When curare is applied directly to the spinal cord of frogs, it causes typical circulatory convulsions. With ordinary methods of administration these are masked by paralysis of the nerve-endings. Certain samples, however, cause certain convulsions before the typical curare action appears.

In deep, the convulsions produced by injecting curare into the spinal canal or cere-
384 MANUAL OF PHARMACOLOGY

Inactivity by Gastro-intestinal Canal.—The effects of curare are obtained only if it is introduced under the skin or into the circulation, but usually not if introduced into the stomach. The experiments on the administration of curare by the stomach (mainly by Bernard) have shown that:

1. It is not destroyed by the gastric juice, pancreatic juice, or saliva.
2. It passes very slowly through the walls of the stomach when the epithelium has been killed, and not at all if the epithelium is still living. (It will be remembered also that strychnin is not absorbed by the stomach in rabbits.)
3. It is to some extent fixed or destroyed by the liver, for it is much less active when injected into the portal than into the jugular vein. However, the discrepancy between the gastric and hypodermic dose persists, even when the liver is largely excluded by Kocher's operation. As the liver destruction can not be very important in mammals (Folin- manti, 1914). It is also destroyed in vitro by ox-bile, and by bacteria.

In frogs the liver is the main agent in the disinactivation: in normal animals 30 times as much curare is required by mouth as hypodermically; the difference disappears completely if the liver is excised; digestion of curare with liver substance destroys its activity.

4. It is very rapidly excreted unchanged in the urine.

In mammals: the inactivity of curare by the mouth is due partly to its destruction by the bile and bacteria; but mainly to the capacity for absorption being less than the capacity for its destruction or excretion. If the renal vessels are tied, poisoning occurs quite readily even when it is taken by the stomach. If very large doses are taken on an empty stomach, sufficient may be absorbed to cause symptoms.

Use of Curare in Convolusions.—This is still largely experimental and not very promising. It has been suggested to combat the convulsions of strychnin, tetanus, and hydrophobia (E. Collis, 1903). It is certainly quite possible to suppress the spasmodic condition by sufficiently large doses. Unfortunately, however, it is impossible to secure this without at the same time paralyzing respiration. This latter may, theoretically, be counteracted by artificial respiration, but this prolonged manipulation is in itself injurious. On the other hand, minimal doses may be considered useless, and indeed, as has been pointed out, even if the spasms could be suppressed without affecting the respiration, this would not be an ideal treatment for strychnin. In well-chosen cases, however, curare may be the means of saving life. Convolusions certainly tend to heighten fatigue and paralysis of the medullary centers, and if in a case in which the degree of poisoning just exceeded the lethal limit by a very little a minimal amount of curare were injected, this might, perhaps, reduce the spasms sufficiently to turn the scale, or somewhat larger doses might be given which would require some, but not very much, artificial respiration. This has actually been done, and in desperate cases curare is worthy of a trial; but in addition to the other objections come the very uncertain quantitative effects. It would be justified only to work with tested samples, and these are rarely accessible when needed.

Administration.—The drug should be given hypodermically, using per kilogram of patient one-tenth the fatal dose determined per kilogram of dog; and being prepared for artificial respiration and physostigmin. Curarin, if pure, would give an exact substance, in the dose of 1 to 2 mg. hypodermically. The reliability of the alkaloid is, however, open to doubt.

GUANIDIN

This and methyl-guanidin produce peripheral stimulation of striated muscle (fibrillary contractions), then central paralysis and finally a curare action. The muscular effects, therefore, resemble nicotin.

Guanidin is imido-urea, NH = C = (NH)2. It is a constituent of creatin and arginin. Methyl-guanidin occurs in urine and in protein putrefaction.

Toxicity.—The comparative toxicity of guanidin and its amino derivatives has been investigated by Garret, 1916.

Muscular Twitchings.—These are especially interesting. Their peripheral origin was shown by Gerges and Baumann, 1875. They occur if the isolated muscle is laid in 1:1000 to 1:4000 solution of the chlorid. The twitchings are less marked in solutions above 1 per cent, since the effect is there complicated by the curare action (McEwath, 1917).

In living animals the twitchings persist if the motor nerve is divided but fail when it
EPINEPHRIN GROUP

has degenerated; so that the action is apparently located in the anatomic endings. It is suppressed by calcium or magnesium (Fuehrer, 1907 and 1912), and by weakening of the muscle (Lazegley, 1912). In cats, the symptoms resemble chorea (Fuchs, 1912).

Calcium and Phosphate Equilibrium.—Watanabe, 1918, claims that the injection of corrosive doses of guanidin into rabbits greatly increases the phosphate of the serum, and that generally the calcium of the serum is somewhat decreased. Confirmation would be desirable.

Protection Against Anaphylaxis.—D. Burns states that guanidin confers protection if injected immediately before or after the provocat ve dose. Confirmation is desirable.

Other Substances Producing Fibrillary Twitchings are: Physostigmin, aconitin, nicotine, NaCl and sulphocyanid, and the salts of Ba, Zn, Cu, Ni, and Pb.

EPINEPHRIN

General Statement.—Epinephrin (also called Adrenalin, Supra-renin and numerous similar names) is the active principle of the medulla of the suprarenal gland. It is a relatively simple amin derivative of catechol, and can be prepared synthetically. It behaves as a feeble base and might be classed with the alkaloids. Its solutions are very unstable, unless a preservative is added.

Its typical actions consist in a highly specific stimulation of the physiologic endings (receptive substance) of the entire sympathetic system. The effects upon any given organ—whether augmentory, inhibitory, or indifferent—therefore correspond with the effects of stimulation of its sympathetic innervation. Very dilute concentrations may have opposite effects.

The most important practical manifestation of this action consists in a high rise of blood pressure, from peripheral stimulation of the vasconstrictor mechanism of the systemic vessels, and of the accelerator mechanism of the heart.

Epinephrin is used locally for arresting hemorrhage and enhancing the anesthetic effects of cocaine; hypodermically in bronchial asthma; intravenously, for tiding the patient over acute circulatory collapse.

Its systemic action is very brief. It is entirely ineffective by oral administration; but little effective subcutaneously, and of moderate efficiency intramuscularly.

Overdoses, intravenously, kill by acute dilution of the heart.

Historical.—Epinephrin is identical with the "chromaffin substance" (giving a brown color with ferric chloride, and pink with alkalies, lodin or chlorin, and taking up chromium salts; Hesse, 1865), which was discovered by Vulpian, 1826, in the medulla of the adrenal bodies, and also in association with sympathetic cells elsewhere. The suprarenal medulla, as shown by Balfour, is a direct outgrowth of the sympathetic system, and consists at first of neuroblasts. The cortex is of mesoblastic origin, and does not contain epinephrin, but cholin (Lehmann, 1907).

The pressor action of the medullary substance was discovered by Oliver and Scharer, 1893, and by Czybulski and Symonovics, 1894. This was followed by many attempts to separate the active principle. The researches of v. Füth, 1896, and particularly those of Abel, paved the way to its isolation in crystalline form, which was first accomplished by Takamine, 1901, Aldrich, 1901, and Abel, 1903. Its structural constitution was determined by Jowett, 1904, and its synthesis accomplished by Stolz, 1904, Dakin, 1905, and Flachs, 1908. An extensive series of related amines, with similar sympathomimetic actions, has also been prepared (Barger and Jowett, 1903; Barger and Dale, 1910), and some of these, as well as the synthetic epinephrin itself, are marketed.

A good discussion of epinephrin is contained in Barger’s "Simpler Natural Bases," 1914.
Abel and Macht, 1912, have also found considerable epinephrin (along with the digitale Bufagia) in the "parotid glands" of the Tropical Toad, Bufo Agus. Crawford and Watanabe, 1915, believe that it (or a similar substance) exists in pituitary extracts and is partly responsible for their pressor effect.

Extracts of the extra-portal veins of the rabbit's liver, of man and mammals, also contain epinephrin or a closely related substance, having the typical action on intestinal and uterine muscle (Fulk and Macleod, 1916).

Chemical Structure.—Epinephrin is 3-allylphenyl (pyrocatechol) ethanol-methylamin, C\textsubscript{6}H\textsubscript{5}OH—CHOH—CH\textsubscript{3}—NHCH\textsubscript{3}, corresponding to the empirical formula C\textsubscript{9}H\textsubscript{11}NO\textsubscript{3} (first established by Aldrich, 1923.)

\[
\text{HO-CH(OH)CH}_3\text{NH.CH}_3 \quad \text{HO-}
\]

Its structure is rather closely related to that of tyrosin; and it may perhaps be derived from this or similar amins in the body.

Action of Isomers.—The natural epinephrin is levorotary. The synthetic base is racemic, and has been split into L and d. component by Flacher, 1908. The L component is identical with the natural base. The dextrorotary base produces qualitatively the same actions, but has only one-twelfth to one-eighteenth the activity; and the racemic mixture therefore has about half the activity of the natural base (Loewi and H. Meyer, 1907; Coshny, 1908 and 1909; Abderhalden and Muller, 1908; W. H. Schultz, 1909). Frolich, 1909, claims that the d.-base has a much more persistent action.

Related Sympathetic Substances.—Barger and Dale, 1910, found that the universal peripheral sympathetic stimulation (which they aptly call "sympathomimetic action") is not peculiar to epinephrin, but is shared by a large number of primary and secondary amins, the simplest being the primary fatty amines, such as acetylamin. The catechol nucleus is a rather unessential constituent, and the action of catechol itself is not related to that of epinephrin. However, the intensity and specificity of action increases as the amin approach the composition of epinephrin itself. It is noteworthy that the various sympathetic effects, and the augmentatory and inhibitory stimulations, vary independently in these various amines. Nor is there any parallelism between instability and activity.

Sympathomimetic Action of Epinephrin.—The correspondence between epinephrin and sympathomimetic stimulation was described on page 318; the organs and functions augmented and inhibited, on page 319; and the localization of the effects in the receptive substance, on page 320.

Effects on Circulation.—The intravenous injection of epinephrin into a normal animal, with intact vagi, produces the striking phenomena depicted in Fig. 14. The blood pressure rises sharply; as it approaches its maximum, the heart beats are greatly slowed and strengthened. The pressure is not sustained, but returns quickly to normal. The heart beats also return to their former rate; but, as may be seen from the tracing, more slowly than the pressure.

These phenomena are due to the interaction of three factors: vasoconstriction, vagus stimulation, and stimulation of the cardiac accelerator mechanism.

The blood pressure may rise to a very high level, especially if the vagi have been divided or paralyzed. In dogs, it may exceed 300 mm. of mercury. The extent of the rise increases with the dose, but not in simple proportion. The main element in the rise is ordinarily the intense vasoconstriction; for the volume of the organs diminishes as the blood pressure rises. The cardiac stimulation, however, is also an important factor, and sometimes it is the more important.

The cardiac slowing is indirect, due mainly to stimulation of the vagus center by the rise of blood pressure. The direct action of epinephrin would be to quicken the heart rate by stimulation of the accelerator end-
ings; this is the result with small doses ( Hoskins and Lovelette, 1914); or in excited hearts; or if the vagi have been divided or paralyzed; or if the heart escapes temporarily from the vagus control, as often happens. With the vagi cut, epinephrin stimulates the auricular, and still more the ventricular efficiency (Wiggers, 1916).

Effects with Different Methods of Administration. — Practically no systemic effect can be secured by administering epinephrin by mouth, and relatively little by hypodermic injection. This is explained by the limitation of absorption through vasoconstriction. The slow absorption permits the destruction of the epinephrin before it reaches the circulation. The response is considerably greater with intramuscular and peritoneal injection (Meltzer and Auer, 1905; Lapponi, 1915); but it is still much less, though more lasting, than with intravenous injection. Injection under pressure into the nasal submucoea is almost equivalent to intravenous injection (Flacher, 1914).

On the other hand, when it is injected (0.5 c.c. of 1:1000) into the root of a rabbit’s ear, strong contraction of the ear vessels persists for hours (Auer and Meltzer, 1917). The blanching is also quite lasting when epinephrin is applied to the scarified skin (Sümann and Flächer, 1917), and as intradermal injection.

Intraspinal injection, (for man, 3 c.c. of 1:1000) gives a slow but considerable and persistent rise (Auer and Meltzer, 1917, 1918). None is absorbed through nerves (Meltzer, 1909).

In man, the blood pressure response is also practically absent on oral administration. Hypodermically, 0.5 to 1.5 mg. (1/200 to 1/40 gr.) gives uncertain results, usually a rise of 10 to 12 mm., rarely higher (to 45 mm.). The same doses intramuscularly give more constant and higher rise, usually 8 to 25 mm.; but sometimes much higher, over 90 mm., so as to produce alarming symptoms (Halsey, 1909).

Relation of Dosage to Rise of Blood Pressure. — With intravenous injection and atropinized dogs, this is somewhat as follows (from the data of Hunt, 1901, and others):
0.0008 mg. per kilogram = rise of 5 mm.; 0.0025 = 7 mm.; 0.005 = 15 mm.; 0.007 = 20 mm.; 0.0097 = 25 mm.; 0.004 = 45 mm.; 0.005 = 65 mm.; 0.01 = 50 mm.

Influence of Dosage on the General Effects.—The effects of intravenous injection vary with the dose. The results of increasing doses may be tabulated as follows (Langley, 1902):

(a) Rise of blood pressure.
(b) Inhibition of bladder, mydriasis.
(c) Contraction of uterus, vas deferens, and seminal vesicles; salivation and lacrimation; inhibition of stomach and gall-bladder; increased bile secretion; inhibition or stimulation of internal anal sphincter.
(d) Contraction of erectors pilorum.
(e) Uncertain effect on tunica dartos and on sweat.

Cardiac Stimulation.—The perfusion of epinephrin through the excised mammalian heart (Hedbnom, Cleghorn, Gottlieb, Boruttat), or its perfusion or direct application to a frog’s or turtle’s heart (Lussana, 1913) quickens the rate, and increases the amplitude of the contraction. The tone is very markedly increased, often doubled. The oxygen metabolism of the heart is increased in proportion to its activity and rate (Barcroft and Dixon, 1907; Rohde and Ogawa, 1912; Evans and Ogawa, 1914). Existing irregularities are removed, and the effects of muscular depressants are counteracted (aconite, MacNider; strychnin, Januschke, 1910; phenol, chloral and chloriform, Gunn, 1913, 1915; potassium, etc.). A heart which has ceased to beat may often be revived by this drug.

The fact that epinephrin may start a heart many hours after excision, or when it has been depressed by chloral, goes to show that the heart may contract independently of ganglia; for the epinephrin action is pretty certainly not ganglionic (Gunn, 1915).

The cardiac acceleration is not due to vagus paralysis, for it occurs after atropin, and also in isolated strips of the cat’s ventricle (Lechham, 1913), or after the auriculo-ventricular bundle is cut. In complete heart-block, it quickens and strengthens the ventricles and auricles (van Egmond, 1911). From analogy, it may be assumed that the action is exerted on the receptive substance connected with the accelerator mechanism.

Normal Epinephrin Output and Cardiac Activity.—Stewart and Rogoff, 1919, found that temporary exclusion of the adrenal blood from the circulation sometimes influences the heart, especially when irregularities are present; and that in these cases, the disturbances disappear when the adrenal blood is re-admitted, or if corresponding doses of epinephrin are injected.

Auricular Tonus Waxes.—Excised sino-auricular preparations from turtles or frogs, when laid in Ringer’s solution, exhibit slow rhythmic variations of tonus. These are abolished by epinephrin, whilst at the same time the ordinary auricular contractions are strengthened (Gruber and Markel, 1918; Gruber, 1920).

Influence of Heat.—With the isolated frog heart, the amplitude is but little affected by epinephrin between 8 and 15°C., but increases from 24 to 45°C. The rate is decreased between 8 and 18°C., fairly constant between 18 and 28°C., and rapidly decreased between 28 to 35°C. (Spiricame, 1915).

Effect of Serum and Ions.—These have considerable influence on the response of the frog heart to epinephrin. The stimulant effects of epinephrin and serum are synergistic (potentiation, Moog, 1914); whilst in the absence of calcium, epinephrin produces depression and diastolic arrest (Burridge, 1912).

In birds, the cardiac effects of epinephrin, pituitrin and barium differ considerably from the mammals (Paton and Watson, 1912).

Use in Cardiac Failure.—The cardiac stimulant effects of epinephrin have been utilized in therapeutics to counteract acute cardiac failure in asphyxia, etc. It would be useless against persistent cardiac weakness, since its action is too fleeting, and can be obtained effectively only by intravascular injection.

Resuscitation of the arrested heart is most effectively accomplished by injecting epinephrin into the pericardial sac (Gunn and Martin, 1915); or more conveniently into the cardiac end of the carotid artery, flushing
it toward the heart by a stream of warm saline solution, and at the same time performing cardiac massage and artificial respiration. The chances of success diminish rapidly with the lapse of time after cardiac arrest; and after fifteen to thirty minutes, intracardiac clotting sets an end to all hope.

Intracardiac Injection.—E. Heydloff, 1930, advises for resuscitation the injection of the epinephrin directly into the heart through a hypodermic needle thrust through the thoracic wall.

Cardiac Dilation.—In using epinephrin for cardiac stimulation, the dose and the rapidity of injection—must be carefully controlled by the state of the heart. Overdoses of epinephrin kill by cardiac dilation, with pulmonary edema. The tendency to this increases with cardiac weakness. It may sometimes be relieved by artificial respiration (Emerson, 1907). Patients with cardiac disease generally react to 1 mg. hypodermically, byextrasystoles (D. Roth, 1914). Fatalities have occurred, especially in cardiac disease, from 0.4 mg. hypodermically (Fridericia, 1915).

Danger in Cardiac Insufficiency.—In this clinical condition, injection of 1 mg. generally produces distinct cardiac dilation, confirmed by radiography. Normal hearts were not changed by this dosage (M. Looper et al., 1918).

Epinephrin Pulmonary Edema.—This occurs more readily if the vagi have been divided, or if asphyxia is present; conversely, artificial respiration tends to prevent the occurrence of the edema (Gates and Auer, 1917).

In poisoning by cardiac depressants (i.e., chloroform, phenol or caffeine) the intravenous injection of epinephrin will temporarily restore blood pressure, and this may give the heart a chance to recover. But if the blood pressure is raised much above the normal, the heart may stop suddenly, and usually irrecoverably; and this may occur from doses of epinephrin which would be quite safe in healthy individuals (phenol, Solkan; chloroform, Levy and Lewis, 1912; Nobel and Rothberger, 1914).

Epinephrin on Heart Rate of Injunct Animals.—Epinephrin tends to have a twofold action on the heart rate: acceleration through direct cardiac stimulation; and slowing through reflex vagus stimulation. When the vagi are intact and in good tone, ordinary doses of epinephrin invariably slow the rate (Meck and Eyster, 1912). When the vagus tone is low, quickening may result (Hoskins and Loselette).

Injection of epinephrin may render the heart irrespnsive to vagus stimulation (Kanda and Kuno, 1917), by raising the muscular excitability. In the same way it removes the pilocarpine slowing and weakening in frogs (Ransohn, 1917).

Vagus Effects.—The vagus stimulation is purely central, since no slowing occurs when the vagi are cut. It is due mainly to the rise of pressure, for it is very slight if the pressure is kept from rising by hemorrhage, or by paralyzing the vasomotor endings; or by a compensating device (Brooks et al., 1918). However, there is some evidence that the vagus center is also stimulated directly (Biedl and Reiner, 1898; VerkORN, 1902).

This is confirmed by the slowing which may occur when epinephrin is perfused through the medullary centers (E. D. Brown, 1916). Perfusion of the medulla of turtles, however, does not seem to affect their heart-rate (Bush, 1920).

The degree of slowing varies much in different individuals, but it always tends to increase the rise of pressure, and this mounts much higher if the vagi are cut.

Vagus Sympathetic with Morphine.—Heinekamp, 1919 claims that the epinephrin slowing is generally absent unless the excitability of the vagus center has been raised by morphine.

A secondary increase of the pulse rate is sometimes seen, and is attributed to central and peripheral stimulation of the accelerator nerves (NeuJEN, 1909).

Electrocardiograms.—In human subjects, normal or with "irritable hearts," 0.5 mg. of epinephrin, intramuscularly, decreases somewhat the height of the T wave. The production time is not altered (Clough, 1910).

Electrocardiographic studies have been made on rabbits by F. R. Fraser, 1915.

The Vasocostriction.—Epinephrin is the most powerful vasocostricting drug known. It can be readily shown that this is the main factor in the rise of blood pressure, for the organ volume and the outflow of
blood from veins are diminished. The site of action is almost entirely peripheral, for the rise occurs if the central nervous system has been depressed; the perfusion flow through excised organs is slowed or arrested (Bier, 1897); and even rings of excised artery contract if placed in epinephrin solutions (A. B. Meyer, 1907). The vasomotor center is not usually affected directly; but it may respond indirectly, generally by constriction to the increased pressure; occasionally by dilation, when the increased blood supply relieves a preexisting asphyxial stimulation (Fitcher and Sollmann, 1915). Occasionally, there are doubtful indications of direct stimulation of the vasomotor center; E. D. Brown, 1916).

The constriction is most conspicuous in the smaller arterioles; but even large arteries (v. Frey, 1905) and veins participate. The maximum constriction occurs in the splanchic vessels, especially the kidneys; and in the vessels supplying the voluntary muscles and peristaltic areas.

The constrictor action is weak in the coronary, cerebral and pulmonary vessels; and in the intact animal these vessels are passively dilated by the displacement of blood from the more powerfully constricted areas. Epinephrin therefore would be harmful in cerebral or pulmonary hemorrhage.

The arterial muscle remains stimulated, in the susceptible vessels, as long as effective concentrations of epinephrin are present. Even very large doses of epinephrin (7,000 times the effective quantity) do not paralyze the vasomotor mechanism.

**Dilator Action of Epinephrin.**—This is the predominant response of certain vessels (Cow), but may also occur in others under special conditions, especially with very dilute concentrations; later in the course of perfusions; and particularly when the vascular tone is already high.

The vasodilator effects observed in living animals are due partly if not solely to direct action on the vascular muscles; for they may occur after complete degeneration of their nerves (Hartman et al., 1917 and 1918; Gruber, 1918; Dale and Richards, 1918). Hartman et al. believe that there is also a central factor, located in the sympathetic or dorsal root ganglia. This interpretation is not accepted by Gruber, and Dale and Richards.

In cats the dilator reaction is developed to the full degree only 11 weeks after birth. (Hartman and Kilborn, 1918.)

Brodie and Dixon often observed that the vessels were dilated by epinephrin. In the freshly excised kidney, supraparenal causes a powerful constriction; but some time after the excision, it dilates the vessels (Sollmann, 1903). The same phenomenon was observed in the postmortem perfusion of the dog’s leg. In the ear of the living rabbit, the constriction is also followed by dilatation (Meltzer and Auer, 1904). The vessels of the de-nervated ear dilate with doses that are constrictor for the normal ear (Enge- loch, 1912).

Ogawa, 1913, found that when very dilute solutions are perfused continuously through kidneys or legs, the constriction is eventually replaced by dilation; increasing the concentration again produced constriction. Intestinal vessels dilated directly when the solution was sufficiently dilute, whilst in kidney vessels the preliminary constriction was relatively prolonged. Relaxed vessels showed a greater tendency to constriction than those with good tone.

Increase of temperature diminished the contractor response, and at 41° to 45°C, reversed into dilatation. Frog’s vessels do not show dilatation with dilute solutions, nor with increase of temperature, but only in the absence of calcium or after degeneration of the nerves (March, 1911).

Cannon and Lyman, 1913, find that in living animals, small doses will either raise or lower the blood pressure, according to its previous level; and adduce evidence that the lowering is due to a direct dilator action on constricted arterial muscle. The fall occurs after ergotoxin. The dilator reaction is confined mainly to the peripheral vessels, for the fall of pressure which occurs with normal cats (0.002 mg.) occurs also if the splanchic vessels are ligated, but is replaced by a rise if the splanchic vessels are intact and the important peripheral trunks ligated (Hartmann, 1917). He therefore supposes that
vasoconstrictor nerves exist in the peripheral vessels, but not in the splanchnics. The dilator reaction fails if the vessels are already relaxed, as by hemorrhage or depressor stimulation. However, Swetschnikoff, 1914, on isolated rabbit's ear, observed the same constriction, whether the pressure was high or low.

Epinephrin sometimes produced also a central vasoconstrictor effect by action on the sympathetic dorsal root and mesenteric ganglia (Hartman et al. 1918).

**Double Peak of Blood Pressure.**—A typical blood pressure curve after large doses of epinephrin (5 to 1 c.c. of 1:20,000, by vein) shows the following outline (see Fig. 15):

The first rise (I) is due essentially to the peripheral vasoconstriction action. The first fall (2) is interpreted as a beginning relaxation of this peripheral constriction. The second rise (3) has been attributed to stimulation of the vasomotor center, superimposed on the residual peripheral vasoconstriction; for this peak does not occur after decapitation or ligation of the cord (McCulgan and Hyatt, 1918).

The final fall (4) is probably due to impurities (Weidelma, 1912), presumably mainly chloral (Hunt).

**Effect on Venous Pressure.**—Capra, 1911 and 1913, found in animals that this is not altered by small doses; it rises with large doses which embarrass the heart.

**Direct Effect on Veins.**—Gunn and Chavasse, 1913, showed that excited veins also react by constriction, although this does not apply to all veins (Crawford and Twombly, 1913). Segments of the superior vena cava, near the heart, enter into rhythmic pulsation. (Active contraction of the veins has also been demonstrated in situ by stimulation of the efferent nerves by reflexes, and by asphyxia (Hooker, 1928).

![Diagram of blood-pressure phases after intravenous epinephrin.](See text.)

**Portal Vessels.**—These are markedly constricted on perfusion, in mammals and dogs (Becquin, 1914), as also in intact animals (Burton-Opitz, 1915). The response is much greater than that to electric stimulation of the nerves (MacLeod and Pearce, 1914). Edmunds, 1915, confirmed the constrictor effect on excised portal vein; but attributes the changes in living animals to changes in the general venous and cardiac pressure, since the volume changes of the liver vary in different animals and with other conditions.

**Antagonistic Phenomena.**—The epinephrin constriction is prevented by drugs which paralyze the receptive substance, namely apoepinephrin (Brodie and Dixon, 1904), and ergotoxin (Dale, 1903; Sollmann and Brown, 1905). Mutual antagonism exists with caffeine (Sollmann and Filcher, 1912) and with nitrates. The pressor effect of 1:20,000 mg. of epinephrin is neutralized by 0.6 mg. of nitroglycerin (Cameron, 1909). After ergotoxin injection of epinephrin lowers the blood pressure, because the vasomotor mechanism is paralyzed, so that the vasodilator action of epinephrin on the peripheral is unopposed (Hartman and Fraser, 1917).

**Differences in Special Vessels.**—There is no question as to the typical response of the vessels which react strongly to epinephrin; but there is some difference of opinion as to whether the cerebral, pulmonary and coronary vessels respond by slight constriction, dilation, or not at all. In intact animals they are certainly dilated, but this might be, and in the main is, passive. The question can be solved only on excited organs and on excised arterial rings by the method of A. B. Meyer. The literature is reviewed by Barbour, 1912. The histologic structure does not affect the qualitative response (Barbour, 1913).

**Differential Reactions of the Arterioles in Animals.**—Those of the skeletal muscles are dilated by small and constricted by large doses. Those of the skin, bone, spleen and possibly the kidney, are not dilated by any dose (literature in Hartman, Kilborn and Fraser, 1918).

**The Coronary Vessels.**—Arterial rings respond by dilation in most mammals, but by constriction in man and monkeys (Barbour, 1912; Barbour and Prince, 1915; Park and Janeway, 1911; and others). Perfusion of the arrested heart may cause either dilation (Elliot, 1906) or weak constriction (Wiggers, 1909).
In the beating heart, the coronary flow is certainly increased in most species of animals (excised hearts, Wiggers; Rabé, 1912; Markwalder and Starling, 1913; Morawitz and Zahn, 1914; not in monkeys, Barbour and Prince, 1915) on account of the pumping action of the contracting cardiac muscle. In the intact animal, this occurs even if the blood pressure is kept level by hemorrhage (F. Meyer, 1913); and the increase would be still greater, if the blood pressure, and therefore the coronary pressure are allowed to rise (Bond, 1913). The heart-muscle would therefore be better nourished and thus better able to work against the high resistance. A vasocostrictor effect on the coronary vessels can be discerned in the excised heart only with doses which are too small to affect the cardiac muscle (Brodie and Cullis, 1911).

In the monkey, however, and therefore presumably in man, the conditions are different. All doses slow the coronary flow of the excised monkey heart, whether this is beating or resting (Barbour and Prince, 1915).

Pulmonary Vessels.—These show a weak vasocostriction (Plumier, 1904; Wiggers, 1909; Plumier and Clermont, 1912; Tribe, 1912). According to Tribe, negative effects (Brodie and Dixon, 1904; Burton-Optes, 1907; Hege and Phillipson, 1912; Bashe and Pick, 1913) are attributable to the dilator effect of the chloretone in certain commercial solutions. Cow, 1912, and Barbour, 1913, found that the reaction of arterial rings varied according to their situation; the intravascular portion of the artery did not react; the extravascular portion was constricted.

Macht, 1911, describes powerful constriction; Berezin, 1913, no action or dilatation.

Pulmonary Circulation in Living Animals.—Epinephrin generally causes a large rise of pressure in the pulmonary artery (Wood, Jr., 1911). The response is complex, depending on the species, as well as dosage and other conditions.

With rabbits, moderate doses, by vein may show either no effect on the pulmonary circulation, or may increase the pressure in the pulmonary artery, by constriction of the pulmonary arteries. With large dose, the predominant constriction of the systemic arterioles hinders the return of the blood to the heart, and thus lowers the pulmonary arterial pressure. The effects in any case are predominantly vasomotor (Schafer and Lim, 1915).

With dogs and cats, with fairly large doses, the cardiac stimulation tends to predominate, so that the pressure rises in both the pulmonary and systemic vessels. The rise of pulmonary pressure is not usually due to displacement of blood by the constriction of the systemic vessels, as has been suggested (Anders and Cloetta, 1910); for it may be absent when the systemic vasocostriction is strong (Schafer and Lim, 1915).

The increase of pulmonary pressure being largely cardiac, the volume of the blood in the lungs increases (Anders, 1911) and the pulmonary circulation is quickened, with moderate doses. Large doses delay the pulmonary circulation time (Langlois and Desbois, 1912), either by injury to the heart, or by constriction of the pulmonary vessels.

Pulmonary Hemorrhage.—This is increased by epinephrin. Due to the higher pressure and quicker circulation in the lung (E. Frey, 1900; Wiggers, 1909).

Cardiac Dilation.—When this occurs, the diminished efficiency of the heart causes a further rise of the pulmonary pressure with falling arterial pressure (Hallon and Nepper, 1911). This favors the production of pulmonary edema.

Cerebral Vessels.—In man, small doses of epinephrin first diminish and then increase the brain volume (Kapheil and Stanton, 1913). The dilation is probably passive.

In animals, Wiggers, 1907 and 1914, found constriction; Berezin, 1916, observed constriction, but requiring higher concentration than for peripheral vessels; Dixon and Halliburton claim dilation. Cow observed slight relaxation of arterial rings. Here again, there is undoubtedly passive dilation in the intact animal (Biedl and Reiner, 1905; Neujean, 1905). The vessels of the pia and retina are constricted (Hirschfelder, 1913).

(There is no mention of a paragraph beginning with “The cerebral vessels appear to have a much stronger vasomotor control in man than in the lower animals; for human brain plethysmograms, under the influence of emotions, show large oscillations that are disproportionate to the changes in the general circulation (Cavarazini, 1918)."

The Renal Vessels and Urine Flow.—The renal vessels appear to be especially sensitive to epinephrin, being constricted by doses which are too small to affect the general blood pressure; and with ordinary doses, the renal constriction outlasts the pressure rise (D. Jones, 1908).

Hoskins and Gunning, 1917, also confirm that both depressor and pressor doses in dogs generally cause constriction in the kidneys and decreased vein flow, the threshold dose being about the same as for blood-pressure. This vaso-constriction diminishes or arrests the urine flow.

Gunning, 1918, finds with intravenous injection that all doses diminish the urine flow.
flow. This persists until the blood pressure returns to normal, and is not followed by diuresis. Presumably the auris is vascular, although the proof is not complete.

These observations contradict the older claims, that very large doses dilate the renal vessels and thus increase the urine flow (Bardier and Fransen, 1899; Houghton and Merril, 1906). Freshly excised kidneys certainly do not show any dilation (Wiggers, 1907), until the nerve endings are killed by exposure (Sollmann, 1903). Hypodermic injections of epinephrine into rabbits (0.5 to 0.5 mg per kilogram) produces a strong diuresis, lasting several hours (Biberfeld, 1907). This is independent of the glycercina (Kanschegg, 1912; Gramenitzki, 1912). From experiments on perfused fresh kidneys, Richards and Plast, 1917, conclude that epinephrine has a constrictor effect on the efferent arterioles, and thus raises the glomerular pressure.

Excision of both adrenals is followed by rise of the blood-urea and diminished urine output of urea, creatinin and phthalain; thus indicating diminished permeability of the kidneys. This occurs even with normal blood pressure (Marshall and Davis, 1915). When only one of the adrenals is excised, the accompanying effects are merely those of the injury of the splanchic on that side: Increase of water, chlorid and urea, with unchanged phthalain and creatinin (idem, 1917).

Cow, 1914, finds a direct vascular connection between the suprarenal medulla and the kidneys. Through this, epinephrine could reach the kidneys directly, and thus diminish the urine flow, without its existing in discoverable quantity in the general blood streams.

Vesicles of Frog Foot.—The local application of epinephrin antagonizes the dilator action of sodium barbital (W. Jacob, 1920).

Skin Reaction to Epinephrin.—The intracutaneous injection of epinephrin (a drop of 1:100,000) produces intense blanching and "goose"-flesh, persisting for several hours (Sollmann and Pilcher 1916). Modifications of this reaction are said to occur in "hyperpyedism" (Goertschi), but this relation is doubtful (Boas, 1917).

Constriction of Capillaries.—The blanching of epinephrin occurs even if the circulation of the skin has been obstructed. Cotton et al., 1916, interpret this as an action on capillaries.

An action on the capillaries would be of very great general importance, since the maximum capillarity capacity may be 750 greater than the minimum (Krogh, 1919).

Circulatory Conditions on Perforated Response to Minute Doses.—The response is diminished by ether anesthesia or hemorrhage; and increased by transfusion (Rous and Wilson, 1919).

Epinephrin as a Local Hemostatic.—The powerful vasoconstriction makes epinephrin a most effective agent for arresting capillary hemorrhage in any situation to which it can be applied locally; especially in nasal and urethral operations. Solutions of 1:15,000 to 1:1,000 are used for this purpose. The dilutions must be freshly prepared, since they lose their activity in a few hours. The action persists as long as the epinephrin is present; but when this has disappeared, there is often secondary hemorrhage.

Even intravenous injection of epinephrin temporarily diminishes capillary hemorrhage from superficial wounds more effectively than any other drug (Hanilik, 1918).

Epinephrin is of little use against venous, and still less against arterial, hemorrhage (Hanilik, 1918).

Hemorrhoids.—Epinephrin may be used in suppositories; 1 mg (0.4 gr.) of the alkaloid (as Glaesel's Thrombina oil.

Use on Inflamed Mucous.—Epinephrin gives symptomatic relief to inflamed surfaces, by contracting the dilated vessels. It is thus used in catarrhal condition, e. g., conjunctivitis, and especially in hay fever. It is best applied in oily solution or ointment, containing 0.5 per cent. of the free alkaloid; oil prolongs the action. Epinephrin is non-irritant, but its action is too brief and it is claimed that its continued use has caused chronic hypertrophy of the mucous membrane (Poste, 1906; J. N. Hall, 1913).

Infantile Paralysis.—Meltzer, 1916, urges the intradural injection of epinephrin, to arrest and cause the absorption of the spinal edema, especially when the respiratory center is threatened. He advises 1 c.c. of 1:1,000 solution, every 4 to 6 hours. The suggestion has been tried on experimental poliomyelitis, with beneficial but not curative
results (P. F. Clark, 1912). Clinical trials by Frasor, 1914, have so far given equivocal results, but they were confined to advanced cases.

Marie, 1915, claims that epinephrine neutralizes the antitoxins of tetanus and diphtheria in vitro, but not in the presence of hemoglobin. It has been tried against puerperal, but without certain benefit. Engel, 1913, claims marked effects on rat tumors, not entirely explainable by ischemia.

Cocain-epinephrine Anesthesia.—The addition of epinephrine, in the usual concentration, enhances the anesthetic action and lessens the toxicity of cocain (Braun), by delaying its systemic absorption, by the anesthetic effect of anemia, and seemingly by a direct synergistic action.

Epinephrin and Cocain Synergism.—Cocain sensitizes to epinephrin, so that the mydriasis, vasoconstriction, etc., are more pronounced and this with doses of cocain which alone have no sensible effect (Fröhlich and Loewi, v. Fishel, 1915.)

Epinephrin on Absorption.—Meltzer and Auer, 1904, claim that intravenous injections retard absorption and transudation. Van Lier, 1907, showed that the absorption of sodium iodide from hypodermic injections is markedly retarded, unless very hypertonic (20 per cent.) solutions are injected. The local effect on intestinal absorption is constant for iodid, but more marked on phenol and especially alcohol (Hanzlik, 1910, 1912, 1913).

In non-corrosive poisoning (cyanid, strychnin, aconite, etc.) Jona, 1913, suggests the administration of epinephrine by mouth (16 to 15 c.c. of 1:1,000) to retard absorption. This would need to be supplemented by evacuation and chemic antidotes. It is probably useless.

The Effects of Epinephrin in Internal Hemorrhage.—Epinephrin is practically useless in internal hemorrhage; for although it constricts the vessels when it is injected intravenously, it also raises the blood pressure. The end result would not be reliable, and often harmful; especially in pulmonary hemorrhage (Frey, 1909; Wiggers, 1909) and in cerebral hemorrhages.

In intestinal hemorrhage, the results of Wiggers, 1909, were somewhat more promising: after a momentary increase, the hemorrhage was reduced, and this effect lasted the rise of pressure.

However, Hoskins and Gunning, 1917, find that small doses generally dilate the intestinal vessels (increased volume and vein-outflow). F. A. Hartman and McPhedran, 1917, also confirm this, but claim that still smaller doses constrict the vessels of the intestines, kidney, and generally also those of the spleen.

Spleen.—Hoskins and Gunning, 1917, state that effective doses, in intact animals, cause first a brief dilatation, followed by contraction of the vessels. The threshold is more sensitive than that for the general arterial pressure. Rhythmic contractions of the spleen are sometimes started.

Epinephrin in Circulatory Collapse.—The epinephrin constriction is able to restore the blood pressure in all forms of vasomotor depression, but the blood-pressure of shock (anaphylaxis or peptone) reacts very little to epinephrin (Simonds, 1916). Moreover, its action is too fleeting to make it of much use in any but purely temporary emergencies. If it is used, it must be injected intravenously, drop by drop, carefully watching the heart. The dangers are probably greater than the benefits.

Subdural lumbar injection is recommended by Auer and Meltzer, 1918. A high rise of blood pressure maintained over an hour is produced by 3 c.c. of 1:1,000 solution, in man.

Insufficiency of Epinephrin in Shock and Other Conditions.—This is due mainly to the deficiency of volume of circulating blood. Other conditions in which the pressor response to small doses of epinephrin is relatively poor are hemorrhage and other anesthesis; but in these, large doses of epinephrin are still effective (Rous and Wilson, 1919).
Clinical Toxic Symptoms.—The local application or hypodermic injection of epinephrin in ordinary doses does not normally produce any symptoms. Not infrequently, however, excitable or susceptible patients (and especially those with advanced Baselow's disease) respond in a few minutes by tremors, anxiety and nervousness, palpitation; precordial distress, increased rate of pulse and respiration; rise of blood pressure and temperature, and sometimes glycosmia (Seifert, Nebenwirk, 1915, page 234; Hewlett, 1918; Matsuo and Murakami, 1918).

With intravenous injections, there is danger of acutely fatal dilation of the heart.

Epinephrin Test of "Irritable Heart."—Susceptible individuals respond to the intramuscular injection of 0.5 c.c. of 1:1,000 epinephrin solution by a "positive reaction," consisting in a rise of the systolic blood pressure or pulse rate of more than 20 to 15 points; increased pulse pressure; flushing, sweating, tremor of the hands, restlessness, and often general nervousness. Sometimes the blood pressure may rise 30 to 40 mm., with the heart rate correspondingly quickened. The respiration is deeper, with undamped rate. Electrocardiograms may show various abnormalities.

The reaction begins in about 12 minutes, reaches a climax in about 1/2 hour, and is faded about an hour. Normal, vigorous individuals do not give a reaction with this dose. Of those who are "constitutionally inferior," with "irritable heart," neuroathenics, those easily irritated, etc., about 7/4 are positive and 3/4 negative (Peabody et al., 1918).

Fatal Effects in Animals.—Excessive doses of epinephrin produce vomiting, excitement, delirium, bloody diarrhea, hematuria, ascending central paralysis, great fall of temperature, occasionally convulsions, complete prostration, and death by respiratory (21) or cardiac (dog) paralysis.

Rabbits show multiple pulmonary hemorrhages, probably associated with edema (Leo Schmidt, 1910).

The fatal dose varies considerably (usually 0.1 to 0.6 mg. per kilogram intravenously, or 2 to 15 mg. per kilogram hypodermically), but about 200 times the therapeutic dose. A noticeable rise of blood pressure can be seen after 1/4 to 1/2 of the fatal dose. Caution is said to lessen the toxicity and glycosuria (Degregor and Durban, 1913).

Atropin is also claimed to decrease the toxicity (Leo Schmidt, 1910).

The toxic effects are the result of the peripheral actions: for as Cusenby, 1909, has pointed out, the ratio of activity of the different isomers is the same for the toxic as for the blood-pressure effects.

Epinephrin Atheroma.—If rabbits receive frequently repeated injections of large doses of epinephrin, atheromatous changes and calcareous patches are often observed in the aorta (Joseph, 1903) and other large vessels (d'Amato, 1903). These degenerations are never seen in dogs (Pearce and Stanton, 1900), or in monkeys, and presumably not in man. Dogs also give negative results with nicotine, lead, or toxins (Adler, 1914).

Identical lesions often occur spontaneously in rabbits which have never received epinephrin (Miles, 1907, Benneke, 1908, Hill, 1910, etc.). The frequency of these spontaneous lesions varies in different series from 7 to 30 per cent., but they are so markedly more frequent after epinephrin treatment, that this must at least exaggerate the tendency to the degeneration (I. Levin and Larkin, 1910). Success depends on frequent repetition of the epinephrin rather than on the size of the dose (Fleischer, 1909).

The injury has been attributed to high blood pressure, and to direct toxicity by epinephrin. The older experiments undertaken to decide between these views (summarized by L. Adler, 1908) did not take account of the spontaneous occurrence of the lesions (M. K. Meyers, 1909; M. C. Hill, 1911) and the question can not be considered settled. The toxic theory seems the more probable; although Dixon, 1913, still states that all pressor agencies, when repeatedly applied, produce degenerations of the middle coat. It is highly doubtful whether these atheromas of rabbits have any relation to human atheroma.

Atheroma is also produced by feeding cholesterol, cottonseed oil, the aldehydes of fatty acids, hydrochloric acid and by paracresol (Adler, 1914; Denney and Frothingham, 1914).

Epinephrin Myocarditis.—Rabbits also often show chronic myo-, endo-, and peri-carditis, after repeated epinephrin injections. This lesion—which is apparently independent of the atheroma—is much more frequent (50 per cent.) if a single intravenous injection of epinephrin (0.2 mg.) is combined with statin (12 mg.), cafest (15 mg.),
or strophantin (these drugs never cause the lesion if they are used without the ephinephrin). The changes in the heart-muscle start at once, progress for some seven days, persist about six weeks, and then regress completely by sixteen weeks (Fleisher and Leo Loeb, 1909; Strickler and Fleisher, 1910; Christian and Walker, 1911).

Fleisher and Loeb, 1910, attribute the lesions to "excessive mechanical strain," from excessive contraction of the muscle fibers; For the lesions are situated mainly at the base of the left ventricle, where the strain is greatest; the changes are analogous to those shown by striated muscle subjected to overexertion; and the lesions do not appear in the relatively stronger and more resistant hearts of dogs. H. A. Stewart, 1917, points to arteriosclerosis.

Hearts which show the microscopic changes are physiologically inferior to the normal; they are less able to cope with extra demands; and the animals appear more deposed to edema (edematous) and to bacterial infections.

**Bronchial Muscle and Use in Asthma.**—The bronchi are related, especially when spasmodically contracted, by stimulation of the sympathetic bronchodilator endings. Ephinephrin is therefore often very effective in *asthma* (Sch. c.c., 11,000 hypodermically, Kaplan, 1905; Matthews, 1910; Hoover and Taylor, 1915; v. Jagic, 1916).

The bronchodilatation has been confirmed in intact animals by Januszkiew Pollak, 1915, and others; on excised lung by Bucher and Pick, 1915; on excised tracheal muscle by Trendelenburg, 1913; on excised bronchial muscle by Titone, 1913. Gella and Symes, 1913, find differences between the bronchial and tracheal muscle, and claim that normal bronchioles are constricted by ephinephrin, and that it dilates only when the bronchioles are spasmodically contracted by pilocarpin, etc.

**Respiration.**—This changes with the blood pressure (Nice, Rock and Courtwright, 1915). It becomes deeper but irregular during the rise of blood pressure, and is generally arrested at its height (Langlois and Garrohe, 1910). In man, 1 mg. hypodermically is said (Fuch and Roth, 1912) to increase the respiratory volume by 8 to 10, mean 50 per cent.; the rate being unchanged or also increased. The effects on the perfused respiratory center are variable (E. D. Brown, 1916).

Vogtlin and Wiggers, 1916, tried ephinephrin against narcotic depression of the respiration, with doubtful results.

**Intratracheal Injections.**—Auer and Gates, 1915, found that the injection of ephinephrin into the lower trachea produces a prompt rise of blood pressure; presumably by aspiration and absorption from the alveoli. If the vagi have been divided, fatal pulmonary edema often follows. This may be prevented by atropine.

**Direct Central Actions.**—Lumbar injection of ephinephrin may cause muscular spasm and tremor. Injection under the dura or into the substance of the cerebrum produces an apparently catatonic sleep, lasting two to five hours, with regular respiration and reflexes, and fall of temperature (Bass, 1914). Bass does not believe that these effects can be explained by vasocostriction.

**Action on Pupil.**—Ephinephrin has a mydriatic effect. This occurs readily in frogs, but only under specially favorable conditions in mammals.

**Conditions for the Occurrence of Ephinephrin Mydriasis in Mammals.**—This may be procured by large doses intravenously. With local application, the mydriatic effect may be obtained if the oculomotor tone is low (weak illumination, W. H. Schultz, 1906); if the absorption is hastened (constrictivity, H. Straub, 1915); or if the excitability of the sympathetic is increased.

Such an increase is supposed to occur in Basdeo’s disease and in pancreasic insufficiency. O. LeoWe, 1907 and 1908, accordingly proposed a mydriatic response to ephinephrin as a diagnostic sign in these diseases (with certain limitations). Later works, however, showed that the increased mydriatic reaction occurs in all types of hyperemia; and that it can therefore be prevented in pancreatomegaly dogs by lowering the blood-sugar through phlorhizin (A. LeoWey and Rosenberg, 1914).

The mydriatic response to ephinephrin is also obtained a few days after excision of the superior cervical ganglion (Meltzer and Auer, 1904; Joseph, 1912; Githens and Meltzer, 1916), or after removal of the ciliary ganglion (Joseph, 1915). This may likewise be attributed to increased excitability of the sympathetic distribution, accompanying the degenerative changes which follow the excision (H. Straub, 1910). An analogous increase of excitability in degenerating structures to ephinephrin occurs in the ear vessels.
EPINEPHRIN GROUP

(Meier and Auer, 1905); and in other organs (Elliot, 1905); also in skeletal muscle on stimulation of the peripheral end of the divided splanchic nerves.

Sensitiveness of Different Mammals.—After excision of the superior cervical ganglion, cats are less sensitive than rabbits to the mydriatic action when the epinephrin is instilled into the eye; but they are more sensitive to intravenous injection. However, the response is more lasting in rabbits (Meltzer). On the other hand, the blood pressure response on intravenous injection is greater in rabbits than in cats, both as to height and duration (Gibbons, 1905).

Localisation of Mydriatic Action.—Lewandowsky, 1898, showed that the mydriatic effect occurs after degeneration of the sympathetic, so that the action must be peripheral to the endings (i.e., on the receptive substance).

The excised spleen of the mammalian iris is also relaxed by epinephrin. This is counteracted by physostigmin, with mutual antagonism (Joseph, 1915, 1917). Pituitary also counteracts the mydriasis in intact animals (Gibbons and Meltzer, 1917).

Further Evidence of Ocular Sympathetic Stimulation.—The mydriasis is accompanied by separation of the lids, protrusion of the eyeball, and withdrawal of the nicotinating membrane.

Intraocular Tension.—According to Rupert, 1900, this is first lowered, then increased.

Mydriatic Reaction in Frogs.—Frogs are especially susceptible to the mydriatic action; and this may be produced by systemic application (1 c.c., 1:100,000 into lymph as well as in the enucleated eye (1:2,000; Meltzer and Auer, 1904; Meltzer, 1909).

The dilatation is prompt and persistent, submaximal, indifferent to light.

Epinephrin Muscis.—After repeated injections or local instillations, epinephrin may produce constrictions of the pupils, in mammals. This altered response is attributed to a change in the pupil-dilator muscle (Kato and Watanabe, 1920).

Spleen.—This apparently may respond either by relaxation or contraction. Hartman and Lang, 1910 (literature), obtained active dilatation by action on the dorsal part of the spleen and some gastropeltic constriction by ganglionic or more peripheral action.

Action on Intestines.—Peristalsis is inhibited and the tone relaxed by an action on the myenteric junction (see general section on Autonomic Poisons). Very dilute solutions increase the contractions (Hoskins, 1912).

The ileo-colic sphincter differs from the ordinary intestine, being contracted by epinephrin or splanchic stimulation (Elliot, 1904).

Excised Stomach.—This is relaxed in most mammals, but contracted in some. The pylori sphincters are always contracted (M. Smith, 1918).

Gall-bladder.—This is relaxed (Lieb and McWhorter, 1915).

Action on the Uterus.—The effects correspond to stimulation of the hypogastric nerve (see general section on Autonomic Poisons); in pregnant cats it produces contraction; in non-pregnant cats relaxation (Cushny, Kehrner, Dale); in non-pregnant guinea pigs, relaxation; in dogs, contraction followed by relaxation; in rabbits, increased tonus (Brag, 1903). Surviving human uterus is stimulated (Ruchsmann and Kliegmann, 1912), whether pregnant or not (Lieb, 1915). The Fallopian tubes are also stimulated to contraction (Gunn, 1914).

Epinephrin could be used locally to arrest postpartum hemorrhage; not intravenously, since the increased blood pressure would increase the bleeding.

Keratosis of Epinephrin Inhibition by Pituitary Extract.—The uteri of guinea pigs and non-pregnant cats are ordinarily relaxed by epinephrin. If, however, they are first treated with pituitary solution, the epinephrin produces contraction. The effect in the normal response of different uteri to epinephrin may therefore depend on the content of pituitary. This sensitizing action seems to be in the peripheral nervous mechanism, and not in the muscle itself (Cow, 1910).

Vagina; Male Genitalia Organs.—The effects are similar to those on the uterus (see section on Autonomic Poisons for details).

Excised Ureter.—Epinephrin (1:500,000) increases the rate and tone, or starts the contractions. The effect is reversed by ergotoxin (Macht, 1916).

The response of the epinephrin isomers differs only quantitatively, the levo being much more stimulant than the dextro (Macht, 1918).

Urethral Bladder.—This was discussed in the general section on Autonomic Poisons.

Effect on Secretions.—Epinephrin may provoke secretion of the salivary and lacrimal glands (Langley, 1901); and of the skin glands of frogs (Ehrmann, 1902). These would not be suppressed by atropine. The increased secretion of the submaxillary glands is accompanied by increased blood flow (Solem and Lommen, 1915). In most
glands, however, secretion is diminished or arrested through the vasconstriction. This is notably the case with *pancreatic secretion* (Benedictini, 1906; Edmunds, 1906). This is apparently due to diminished blood supply; for the volume of the pancreas is decreased by small doses, and independently of the general blood pressure (Mannis McLaughlin, 1917).

*Sweet.*—This is increased in animals (Muto, 1916). (He finds that the sweat glands are innervated by both the sympathetic and parasympathetic. The sympathetic predominates in horse and sheep; whereas man, cattle and cats are more subject to the parasympathetic.)

The action is peripheral, for Dieder, 1916, found that the injection of epinephrine into a cat's paw produces sweating when the sciatic or posterior nerve roots have been divided. Injection at a distance or intravenously was ineffective.

*Bile Secretion.*—Downs and Eddy, 1914, claim that this is increased by epinephrin. Confirmation is needed.

*Cerebrospinal Fluid.*—The secretion is not affected, the pressure varying merely with the blood-pressure changes (Dixon and Haliburton, 1915).

*Lymph Secretion.*—The thoracic lymph flow increases parallel to the rise of arterial pressure; the effect, therefore, being apparently circulatory (Yanayaw, 1910).

*Skeletal Muscle.*—Epinephrin, when applied to excised skeletal muscles, has practically no effect on their contraction, even in concentrations up to 1:15,000 (Kato, 1915; Takayasu, 1916). However, the injection of epinephrin into living animals increases the efficiency (height of contraction and irritability) of their muscles, the increase persisting after the muscle is excised (Oliver and Schaefer, 1893). The improvement is particularly marked if the muscles (of cats) had been previously fatigued, or weakened by acids (Gruber, 1914; Gruber and Kretschmer, 1915). The epinephrin effect is also noticeable when post-mortem changes have started (Gruber and Felles, 1913).

The increased efficiency is probably an indirect effect of the epinephrin, attributable to improved circulation through the muscle whilst this is still in the body (Cannon and Nice, 1916; Hoskins et al., 1916; Gunning, 1917).

The *creation formation*, which is considered an index of a tonic function of skeletal muscle controlled by the sympathetic system, is increased by epinephrin, even after curare (Kieser, 1910).

*Nerve trunks* are not affected.

The *pigment cells* in the frog's skin are contracted into spheres (Lieben, 1906). This also occurs in the metanephros of fishes, the effect being reversed by ergotinin (Spaeth and Barbour, 1917).

*Epinephrin in Amnensis.*—Chromaphil material exists in the ganglia of a number of species, including the earthworms and leech. These possess vascular systems whose contractions are accelerated by epinephrin (Gaskell, 1910).

*Protozoa.*—The pulsations of the varieties of paramaecum are accelerated by epinephrin, putratory and pinelin extracts (Feather, 1910).

**Epinephrin Hyperglycemia and Glycosuria.**—The injection of large doses of epinephrin (much beyond the therapeutic) into animals produces marked hyperglycemia and glycosuria by converting the hepatic glycogen into sugar. The effect is analogous to asphyxial glycosuria, diabetic puncture, or stimulation of the hepatic, splanchic or sensory nerves; it acting probably on sympathetic nerves controlling the glycogenic function.

In human subjects, clinical doses of epinephrin (1 mg, hypodermically) do not produce glycosuria; but it increases the sensitiveness to alimentary glycosuria (Landau, 1914); and in epinephrin-sensitive patients it produces hyperglycemia.

**Clinical Response.**—In epinephrin-sensitive patients, the intramuscular injection of 0.5 mg increases the blood sugar to 0.041 per cent., whilst in “negative” patients it is 0.01 per cent. (Peabody et al., 1918). The hyperglycemia is accompanied by decreased reserve alkali in the blood (Peters and Geyelin, 1917).

**Historical.**—The occurrence of glycosuria after hypodermic injection of large doses of epinephrin was discovered by F. Blum, 1907. Intravenous and intramuscular administration are less effective, even if larger doses are used (Pollak, 1909; Underhill, 1911). The phenomenon was investigated by Herter and Wakeman, 1908; Neil Paton, 1909, and many later observers. An extensive discussion of the literature
is given by G. M. MacKenzie, 1917. The glycosuric action of other sympathomimetic drugs is described by Morita, 1915.

**Mechanism of the Glycosuria.**—The glycosuria is generally proportional to the hyperglycemia (Granetitzki, 1912). It is also increased even after excision of the kidneys (Ziecler, 1901; Metzger, 1902), showing that it is not renal.

There is conclusive evidence that the glycosuria is due to increased glycogenolysis in the liver. The degree of hyperglycemia and glycosuria depends upon the glycogen content of the animal; they are more intense in well-fed animals (Vorburgh and Richardson, 1901), or in animals rich in glycogen; and conversely there is no glycosuria in animals whose glycogen has been completely removed by phlorizin; and an existing phlorizin glycosuria is not increased by epinephrin (Klinger, 1912).

The evidence indicates the hepatic origin of the glycosuria also connecting the liver and kidneys. The blood of the hepatic vein contains more sugar than that of the portal; sugar formation is increased on perfusion of the excised liver, and conversely, there is no glycosuria when the function of the liver has been injured by phosphorus (E. Frank and Isaac, 1931).

**Habituation.**—The glycosuria response diminishes and finally disappears on continued administration of epinephrin, in proportion to the exhaustion of the glycogen stores. Hyperglycemia persists somewhat longer than the glycosuria, so that continued injection of epinephrin evidently decreases the permeability of the kidneys for glucose (Pelak, 1909, 1911; Komscheg, 1912); perhaps by vasocostruction. At this stage, diabetie puncture also produces only hyperglycemia, and not glycosuria. Phlorizin, however, still causes glycosuria (Biberfeld, 1916).

**Paradigms of Vasocostruction and Glycosuria.**—The results of Straub, 1909, and Rittmann, 1909, show that both effects are strictly parallel, and proportional to the rise of injection (intraeavenous). Smaller doses suffice for the glycosuria than are required for the rise of blood pressure (Granetitzki, 1912); and Kamsom believes that the pressor and glycosuric action are connected with different groups in the molecule. This is supported by the observation that, with partial oxidation of epinephrin, the glycosuric action is lost first (McGuigan and Mostrom, 1915).

**Interfering Factors.**—Epinephrin glycosuria is prevented by ergotoxin (Losel), which lessens the hyperglycemia and also the permeability of the kidney for sugar (Husken, 1916; McCulloch, 1911; Milicich); by lymphogogues (peptone, hirudin; Milicich); and by repeated hemorrhage (Wienko, 1913). Urathene increases the activity (Underhill, 1911).

Epinephrin glycosuria is suppressed by antipyrhetics (Starkenstein). Since the hyperglycemia is not diminished, the action of the antipyretics must be on renal permeability (Mannfied and Purjes, 1915).

**Relation of Adrenals to Other Glycosurias.**—Removal of the adrenals prevents the usual glycosuric response to diabetic puncture (A. Mayer), theobromin (Milicich, 1911) and splanchic stimulation (MacLeod et al., 1911, 1912). This seems to indicate that these glycosurias occur through the mediation of the adrenals glands. Later work, however, indicates that these results were the result of shock. Stewart and Bogd, 1919, abolished practically the total epinephrin output by removal of the adrenal and denervation of the other. This had no effect on the liver glycogen; nor did it interfere with the production of hyperglycemia by diabetic puncture either or asphyxia. Also, they could find no evidence that diabetie puncture increases the output of epinephrin.

**Suprapranules and Pancreas.**—The fact that both glands may affect the sugar-metabolism led to theories of a special inter-relation between them. These lack all real foundation. The glycosoric mechanisms of epinephrin and of the pancreas are absolutely different; the epinephrin lacking entirely the metabolic disturbances that are characteristic for pancreatic diabeties—the inability to use sugar, the altered urea-sodium ratio (Underhill and Clusson, 1906; Rosenbloom and Weinberger, 1942); the increase of acetone substances, etc.

Neither is there any other good evidence for the theory of Eppinger, Falta and Rüdinger, 1900, that epinephrin inhibits the internal secretion of the pancreas. The observation of Ziecler, that injection of pancreas abolishes the epinephrin glycosuria, can be explained simply by irritation (presumably reflex spasm of the renal vessels); for the same results follow the intraperitoneal injection of simple irritants, such as turpentine (Fouret and Schmidt, 1931). Removal of the pancreas has no definite effect on vasomotor irritability; nor is there any other good evidence that the pancreas normally exerts a depressing influence on the sympathetic system (Hoskins and Gunning, 1935).

Removal of the adrenals results in changes of the pancreas; but these are attributable to the low blood pressure and otherudynamie phenomena (Mann and Drips, 1935).
Some of the earlier work on epinephrin glyceremia was done by painting the pancreas with the drug; and it was supposed that there was a direct action on this organ. This was erroneous, for no effect is obtained unless there is absorption of the epinephrin from the peritoneal cavity (Kleiner and Meltzer, 1917).

Gaseous Metabolism.—This is invariably increased by intramuscular injection of therapeutic doses (1/2 c.c. of 1:1,000) in man. In normal subjects, the increase is less than 15 per cent.; in those who are hypersensitive to epinephrin, it exceeds 20 per cent. The respiratory quotient often rises (Peabody et al., 1918; Tompkins et al., 1919a). There is no relation between this reaction and thyroid disease (Sandiford, 1920; Boothby and Sandiford, 1920).

The increase is apparently not due to excitement, but more probably to the hyperglycemia, or improved circulation. Wilenko, 1913, claims that epinephrin increases the consumption of glucose in the perfused heart; and believes that the glycosuria is due to some indirect disturbance of the consumption of sugar. This conclusion would require more experimental evidence. Lusk, 1914, finds that it does not influence the oxidation of ingested glucose, nor protein metabolism.

Heat Regulation.—Excision of the suprarenals lowers temperature (Hultgren and Anderson, 1903); while the injection of epinephrin (and other internal secretions) produces fever (Freund and Marchand, 1913). Hirsch, 1914, found, presumably under different conditions, that the injection of epinephrin or pancreas lowers temperature by decreasing heat production. Cloutet and Waiser, 1915, describe rise of brain temperature and cooling of skin, with 0.2 mg. in rabbits, intravenously. Intracerebral injection acted similarly. The rise was not prevented by ergotoxin.

Nitrogen Metabolism.—Epinephrin, by vein or hypodermically, has little or no influence on the nitrogen excretion (Kraus and Hirsch; Puest, 1908; Lusk, 1913). In dogs, large doses, hypodermically, increase the excretion of uric acid and especially of allantoin (Furth, 1914).

Urea Excretion.—Addis et al., 1918, believe that the hypodermic injection of epinephrin into rabbits increases the urea-excretion capacity. Maximal doses, however, diminish the output. The efficiency is smaller if the uric acid concentration of the blood is high.

They believe that the increase is not related to the circulatory changes, and suggest a “sympathetic receptive substance” in the kidney cells. They also claim antagonism with epinephrin.

Further work is needed to make the conclusions convincing.

Coagulability of the Blood.—This is not affected by the direct addition of epinephrin, but when epinephrin is injected into an animal, the coagulation time is shortened by small doses (0.002 mg. per Kg.) and retarded by large doses (0.05 mg.); (Cannon and Mendenhall, 1914). If the abdominal organs were removed from the circulation these effects do not occur, so that the epinephrin acts presumably on the liver cells. Gräfelfeld, 1916, finds that the increased coagulability with small doses is due increased prothrombin; and Howell, 1914, refers the diminished coagulability after massive doses to diminished prothrombin, analogous to hemophilia.

Polythemia.—Intravenous epinephrin injection raises the blood-count by diminishing the volume of plasma (Lamson and Kelly, 1916 Brainbridge and Trevor). The increase of erythrocytes does not occur if the hepatic artery is first ligated, but sets in when the ligature is removed (Lamson, 1916). This indicates that the action occurs through the liver.

Hemolytic Action.—Epinephrin is strongly hemolytic for beef-blood and to a less degree for other animals. It also produces methemoglobin. Serum weakens the action (Kleiner and Tietze, 1912 and 1913).

Interrelation of Internal Secretions.—There can be little doubt that the functions of the various endocrine glands are interrelated, just as are all the other functions of the body. However, the subject is as yet but little understood; and superficial speculations have far outrun the slender positive knowledge.

As concerns epinephrin, there is apparently some sensitization by thyroid secretion; the suggested relations with the pancreas, pituitary, etc. have not been confirmed.

Thyroïd Sensitization of Epinephrin.—Thyroid secretion does not produce any direct changes in the caliber of the blood-vessels, but sensitizes them to the pressor action of epinephrin, as also to the dilator action of depressor nerve stimulation. (Asber and
Flack, 1910 and 1911; Santesson, 1911,1918). The action is produced in perfused organs (Aller, 1910) and is therefore peripheral, presumably on the myoneural junction.

The augmentor action of epinephrin on the excited mammalian heart is also sensitized by thyroid (Asher et al. 1916); but the vagus excitability is not affected (R. L. Levy, 1918), since it is parasympathetic.

The sensitization occurs on the injection of thyroid extract (Asher and Flack); of iodothyroacetic acid (Oswald, 1915, lasting 17/2 hours); and of Kendall's crystalline iodine compound (Levy); but not after iodthyroacetic acid (Asher and Flack).

It may also be produced by stimulating the thyroid secretion through the superior hypoglossal nerve (Asher and Flack), or through the cervical sympathetic (R. L. Levy, 1916).

The sensitization does not extend to other effects of epinephrin; for instance, it does not sensitize to the pupillo-dilator action; nor to the accelerator response (Levy).

There is no reliable evidence that thyroid injection or depressor stimulation alters the secretion of epinephrin; the statements of Gley and Quinguio, 1913, and Richards and Wood, 1913, date before the introduction of adequate methods.

Epinephrin on Thyroid Glands.—The thyroid vessels are highly sensitive to constriction by all doses of epinephrin (Gunning, 1917).

Cannon and Cattell, 1916, find some evidence of stimulation of the thyroid (action-current) on the injection of epinephrin and by splanchic stimulation.

Epinephrin Sensitivity as Test for Thyroid Disease.—The quantitative reactions of the skin, of metabolism, etc., to epinephrin have been proposed as tests of "hyper- thyromism." However, no constant relations have been established.

Thyroidectomy was erroneously supposed to influence epinephrin glycosuria. The apparent results can be explained by the natural variations in the intensity of the glycosuria, which occur even in the same animal under apparently identical conditions (Underhill, 1921).

Epinephrin on Depressor Stimulation, Nicotin, etc.—Epinephrin diminishes or abolishes the response to depressor stimulation (Oliver and Schaefer, and others), and is added to all kinds of vasomotor stimulation, pressor or depressor; electric, nicotine, etc.; and this independently of the level of blood pressure (Hoskins, 1912). This depression of vasomotor irritability occurs more slowly than the direct pressor effect of epinephrin; so that, if both measures are started simultaneously, the results are strictly additive; but if epinephrin is started first, the addition is imperfect. Curiously, a similar diminished reaction to nicotine occurs in from one to eight days after the excision of one-half to seven-tenths of the adrenal tissue (Hoskins, 1915).

Sensitization to Pituitary.—Kepinow, 1912, claimed that doses of pituitary which on themselves inactive increase the vasomotor effect of epinephrin. Rischbieter, 1912, and Hoskins, 1915, were unable to confirm this, finding only simple summation.

Bömer, 1915, found some increase, but attributes this to more prolonged sojourn of the epinephrin in the circulation, due to cardiac depression; for the "potentiation" occurred only in rabbits, in which pituitary depressed the heart; and not in cats, in which depression is absent. A similar "potentiation" was produced by other cardiac depressants, histamin, nicotin, etc.

Pituitary injection does not increase, but rather diminishes the epinephrin hypertonia (Stenroos, 1914).

Cause of the Brief Action of Epinephrin.—When epinephrin is injected intravenously, the effects are of very short duration, disappearing within a few minutes after the injection ceases (Fig. 14). This goes parallel with the disappearance of epinephrin from the blood, and is due to the rapid destruction of the substance. Epinephrin is readily oxidized and thus rendered inactive. The oxidation occurs presumably in all tissues, including the blood, but with very different velocity. The blood vessels and liver probably have the largest share.

On the other hand, the vessels continue to respond practically uniformly and indefinitely to whatever epinephrin may be present in the blood. Its effects may therefore be repeated by repeating the intravenous injection and they may be rendered continuous by continuous infusion. A uniform infusion will maintain a uniform moderate rise of blood pressure for a considerable time.
Persisttence of Action if the Concentration of Epinephrin is Maintained.—In excised kidneys, the perfusion flow may be arrested for a long time, sometimes for hours, by a single injection of epinephrin. This illustrates that epinephrin is not destroyed (at least the presence of oxygen) in the tissues (blood vessels) or any other tissue, during its action. It also shows that the stimulation can be continued indefinitely, and that it does not give way to "fatigue," or to depression, no matter how much epinephrin is used. This corresponds exactly to what is observed in the living animals: Repeated injections of the same dose, on the same animal, give quantitatively the same pressor effect (Bayaz, 1905), for at least 20 successive injections (Kretschmer, 1907). Sufficient time must elapse between injections for the circulation to return to normal; otherwise, there will be superposition.

Kretschmer also found that if the injection be made continuously, the pressure rise is maintaineduniformly so long as the rate of injection is uniform. The blood-pressure level rises as the rate of injection is increased, from the minimal effective dose until a maximum is attained. In rabbits, this occurs when the rate of injection corresponds to about 0.01 mg. per kilogram per minute. Up to this point, the destruction must keep step with the injection, else the rise would be progressive. Further injection produces no further rise, but, when the injection is arrested, the return to normal is inverse to the rate at which the epinephrin has been introduced, since it will take a longer time to destroy the excessive epinephrin.

The Uniformity of Response is not Unlimited.—Froehlich and Pick, 1912, found that if large doses are given in rapid succession, the rise becomes less pronounced and finally disappears, although the blood pressure may remain normal. This is perhaps due to an altered distribution of the blood; for Froehlich, 1910, found that a single dose of d-epinephrin, which has a much more prolonged action, may abolish the response to ordinary l-epinephrin.

Epinephrin is not an Antigen.—No antibody is produced, even if the (hypodermic) injections are continued over three months (Elliott and Durham, 1910); nor is there any habituation (Pollak, 1910). Halpern, 1913, claims that intraperitoneal injections of suprarenal extracts (not of epinephrin) leads to the production of a dilator substance.

The Return to Normal Pressure Coincides with the Disappearance of the Epinephrin from the Blood.—The direct investigation of this question yielded contradictory results in the earlier investigators (Weiss and Huch, 1908), who worked with methods which at present would not be considered adequate for the purpose. The recent work (De Vos and Kochmann, 1903; D. E. Jackson, 1909; Trendelenburg, 1910) shows that the disappearance of epinephrin from the blood goes perfectly parallel with the return of the blood pressure.

The Disappearance of Epinephrin is not Due to Excretion.—Furth found that the urine contains at most traces, even after large injections; and the pressor effect disappears even when access to the excretory organs is excluded by clamping the aorta (Jackson, 1909). This experiment also shows that the visceral organs are not necessary for the destruction of epinephrin.

Artificial Destruction of Epinephrin.—Epinephrin is readily oxidized, especially in dilute and alkaline solutions (B. Moore, 1893), with complete loss of activity. Through its amino-group, it is also promptly inactivated by formaldehyde (Cramer, 1911). Artificial oxidation does not destroy all the activities at the same rate (McGuigan and Mostrom, 1912). Blood in vitro has a curiously slow destructive effect, so that the activity is preserved for many hours (Oliver and Schafer, 1895; Emden and Fuhr 1905); indeed, small quantities of serum retard the destruction materially (Schwabach, 1905). The oxidation proceeds much faster in the presence of blood vessels (Tatum, 1912): Cerbro-spinal fluid destroys epinephrin much more rapidly than does serum (Meltzer, 1914).

Detection in Tissues.—Gioffredi, 1907, found that when epinephrin was perfused through the liver, it was rapidly destroyed; more slowly in skeletal muscle; not appreciably in the kidney, lung and brain. The destruction is therefore a special vital function of the liver.

This explains the vastly more lasting effects of epinephrin when it does not come into contact with the liver, as in perfusion of the excised kidney. It also explains the observation of Meltzer that epinephrin retains its activity for several hours when it is confined in the tissues by a ligature. When the epinephrin is injected into a rabbit's ear, where the destruction and absorption are evidently slow, an extreme constriction action may last for hours (Auer and Meltzer, 1927).

Kretschmer, 1907, found that the destruction is hastened (i.e., the action is shortened) by lowering the alkalinity of the blood by the injection of acids; and vice versa. This appears to be impermissible to epinephrin injected into the medulla (Shimidzu, 1920).
Physiologic Functions of Epinephrin.—The striking actions of epinephrin invite the theory that it plays an important rôle as a hormone for maintaining the tone of the sympathetic system, particularly the blood pressure; and that it is concerned in pathologic conditions of the sympathetic system. Basedow's disease, diabetes, arterial hypertension, etc. However, not enough epinephrin passes into the blood normally, to exert any effect on blood pressure, or even on the much more sensitive intestine; although it can be demonstrated in the blood of the adrenal vein by the blood pressure and by the ouill test (Stewart and Rogoff, 1916).

The output of epinephrin may be increased by stimulating the sympathetic nerve supply of the adrenal glands, directly, or through a dorsal center (idem); the increase, however, is never sufficient to affect the blood pressure. In fact, the output of epinephrin is limited even under the most favorable conditions, that it may be doubted whether it has much physiologic significance; nor has the causation of any pathologic condition been definitely connected with altered epinephrin content of the blood.

Epinephrin secretion is certainly not essential to life; for animals, including monkeys, live without noticeable disturbance when their output of epinephrin has been practically suppressed by excision of one adrenal, and section of the nerves of the other (Stewart and Rogoff, 1917, 1919).

It is possible, but scarcely probable, that epinephrin is mainly a waste product temporarily stored and perhaps destroyed in the adrenal glands. The very high blood-flow of the suprarenals, which is surpassed only by that of the thyroid. (Burton-Otto and Edwards, 1917) indicates that the gland has important functions; but these might be quite apart from the epinephrin.

Chemical Control of Body Functions.—The organism of animals as well as plants produces, as direct or by-products of its activities, chemic substances of decided pharmacologic actions. Some of these are probably waste products; but others serve to regulate important functions. In this way, the body is under the constant influence of "drug therapy," and the correction of faulty functions by "drugs" is not an artificial but a natural process of the body. A striking instance of such regulation is the carbon dioxide (Bayliss and Starling, 1906), with its controlling effect on the respiratory and osmoregulators, etc.; and there are numerous other instances of the importance of the "hormones" of internal secretion, such as the regulation of the pancreatic secretion by secretin; the chemical control of the sexual functions; etc. (Starling, Harvey Lectures, 1918).

Constrictor Substance of Serum.—Normal serum has a constrictor effect on blood vessels. This was at first attributed to epinephrin (Trendelenburg); but it was shown by G. N. Stewart, 1911, and confirmed by others, that serum stimulates all smooth muscle directly, and lacks the sympathomimetic inhibitory action of epinephrin, for instance, on the intestines. This constrictor substance has therefore no relation to epinephrin. It is formed mainly in the process of clotting (O'Connor, 1912) and in cases with the age of the serum (Handovsky and Pick, 1913).

Presence of Epinephrin in Blood.—Epinephrin can be demonstrated in the blood of the adrenal veins; under special conditions and by especially sensitive methods also in the vena cava. The normal discharge in the cat is about 0.0003 to 0.001 mg. per minute per kilogram of body weight (Stewart and Rogoff, 1916).

Epinephrin Output and Blood Pressure.—The concentration in the blood never reaches the level where it could affect the blood pressure. Hoskins and McClure, 1912, point out that if epinephrin persisted normally in the circulation, it would result in inhibition of peristalsis, since the intestines are much more sensitive than the blood vessels. Trendelenburg, 1915, also finds that the concentration in normal blood could not be over 1 in 1 or 2 billions, and is probably smaller—too small to affect the blood pressure or intestine. Further, Hoskins and McPeek, 1912, emphasize that the small quantity which could possibly reach the circulation would distil instead of constricting the blood vessels.

The fact that the adrenal glands do not normally contribute to the maintenance of blood pressure is shown by temporarily interrupting the baroreceptor relation; the blood pressure does not fall while the clamp is applied (within 40 hours; Austmann & al.,
1917); but only as death approaches (Trendelenburg, 1914); nor does it then rise when the clamp is removed (Hoekstra and McClure, 1912). The positive results of Stehle and Weiss are attributed to obstruction of the vena cava or stimulation of afferent nerves; however, Hoekins and McPeek, 1913, also found positive results in pregnant cats.

**Response to Splanchnic Stimulation.**—While it is thus certain that the amount of epinephrin ordinarily secreted is below the physiologically effective limit, there is evidence of some secretion, especially on splanchnic stimulation, direct or reflex.

Older methods gave deceptive results; partly because they did not really measure epinephrin; and partly because they overlooked the important influence of the rate of the blood flow through the adrenals. If the epinephrin output is constant, as is ordinarily the case, then the concentration must vary with the rate of the blood flow through the adrenals. This is indeed the case (Stewart and Rogoff, 1917).

However, an actual discharge of epinephrin from splanchnic stimulation is shown by the mydriatic and blood-pressure reaction in the animal itself (Stewart et al., 1916). It occurs very promptly, and is not prevented by attempts to exhaust the epinephrin store through fright or morphin.

**Rise of Epinephrin in Splanchnic Pressor Response.**—A part of the blood-pressure changes on splanchnic stimulation is due to the discharge of epinephrin. Asher, 1911 and 1912, found that splanchnic stimulation in eviscerated animals does not raise the blood pressure if the suprarenal vessels are clamped. The splanchnic rise under these conditions must therefore be due to secretion of epinephrin. The rise can be made continuous, showing that the epinephrin is secreted and not merely washed out.

With normal animals the pressor effect of splanchnic stimulation is ordinarily interrupted by the temporary "dip," soon after the stimulation is started. This dip is absent if the adrenals are clamped and is therefore due to the discharge of epinephrin. The earlier observers (V. Anrep, 1912; Burton Opitz and Edwards, 1916) believed that the epinephrin discharge caused the pressure to rise, when the direct stimulation of the vessels by the splanchnic had begun to fade; but Perlman and Vincent, 1910, propose the more probable explanation that the dip itself is due to the discharge of vasodilatation concentrations of epinephrin, acting mainly on the skeletal and splanchnic vessels. The phenomena are not constant in all cases. Gley and Quinquaud (1914) and afterward by the anesthetist (Parsons and Vincent, 1917) and are sometimes abolished by caffeine curare and morphin (Perlman and Vincent).

**Spinal Center.**—In cats, epinephrin is liberated after section of the cord as low as the last cervical, but not after section of the mid-dorsal region (Stewart and Rogoff, 1917). This may be interpreted as an "epinephrin center" in the thoracic spinal cord.

**Influence of Drugs on Epinephrin Output.**—This is increased by strychnine, depressed by nicotine and curare; unchanged by stryphanthin (Stewart and Rogoff, 1910). The effects are augmented under these drugs.

**Low Blood Pressure and Shock.**—It has been claimed that the epinephrin output is increased in conditions of low blood pressure, however induced, presumably in an effort to compensate the falling pressure. These claims were based on faulty methods.

Stewart and Rogoff, 1914, have shown definitely that the output of epinephrin and its concentration in the general circulation is not altered by low blood pressure. The concentration in the adrenal vein rises, but merely because the blood flows through the glands with the blood pressure, and the epinephrin is therefore less diluted.

**Emotional States.**—Impoet methods of epinephrin estimation also led to claim that excitement, fright, etc., increase the epinephrin output (Cannon et al.), and diminish the epinephrin store (Elliot, 1912). Exact methods again failed to confirm these claims (Stewart and Rogoff, 1917).

**Total Amount of Epinephrin in Glands.**—In man, this is normally about 4 to 5 mg per gland (Goldziher, 1910; Elliot, 1914); in dogs, 2 to 7 mg; in cats, 0.15 mg (Marchetti, 1915); in sheep, 10 mg; in cows, 0.10 mg (Foehn, Canny and Dines, 1913). The percentage is about 0.1 per cent. of the moist weight, in all animals. The content does not vary with the seasons (Sedel and Fenger, 1914).

In glands obtained from autopsy material from various diseases, the epinephrin content is generally somewhat low, about 0.35 per cent. of the dry weight, in place of the normal 0.4 per cent. (Luckisch, 1917).

Epinephrin is present very early in fetal animals (Fenger, 1912; McCord, 1915). In the human fetus, it is absent at six months, but present at full term (J. H. Lewis, 1910; Moore and Purinton, 1900).

Elliot (1905) believes that epinephrin is also present in special cells in other situations, but always closely associated with sympathetic ganglia (f.e., in the intercarid body). This has been taken to indicate that sympathetic stimulation is effected by both a chemic and a nervous mechanism.

**Cholin.**—Suprarenal extracts contain some cholin. This is responsible for the
depessor effects produced by such extracts after the removal of their epinephrin (Hunt, 1900).

The adrenal cortex contains no epinephrin, and is supposed to have relations to growth and sexual development. Voegtlin and Macht, 1914, announced a crystalline, liposoluble constrictor principle.

Addison's Disease. This is associated with destruction of the suprarenal glands.

The therapeutic administration of preparations of the glands has therefore been tried; cf. in rickets, diabetes insipidus, etc. The results have not been very good, which is scarcely surprising when the rapid destruction of the substance is considered. Erection of both suprarenal glands produces death in a few days (Brown-Sequard, 1859). This is not due to the removal of the medulla but of the cortex, which is not connected with the epinephrin (Wheeler and Vincent, 1917).

There is fall of blood pressure, muscular weakness, decrease of metabolism, fall of temperature, central paralysis, death by failure of respiration. The blood pressure changes are the effect rather than the cause of the asthenia; for the pressure and vascular response do not begin to fall until the asthenia is far advanced. The asthenia probably depends on the failure of the cortical rather than of the medullary function of the glands (Hoskins and Wheeler, 1914).

The injection of the blood of the moribund animals into a normal specimen is said to cause analogous symptoms. Unilateral excision has usually little effect. Transplantation of suprarenal tissue has been accomplished by Busch and co-workers, 1906 and 1908.

Feeding of Suprarenal.—With normal white rats, the ingestion of suprarenal for 1 to 9 weeks resulted in some hypertrophy of the testicles. The growth of other organs was not affected (Hoskins and Hoskins, 1916).

SUPRARENAL TESTING

Commercial preparations of epinephrin vary greatly in activity (Hunt, 1900; Schmitt, 1900; W. H. Schultz, 1910). This is partly due to the ready decomposition of solutions, but even the dry commercial base is often far from pure (Schultz, 1909). Assay is therefore desirable. Quantitative methods are also needed for scientific problems. Gravimetric and volumetric methods are not applicable and recourse must be had to colorimetric and physiologic methods. For fairly large quantities, the effect on the blood pressure of mammmals is commonly used. A standard procedure is described in the U.S.P., IX, and in the Reports, Council of Pharm. and Chem., 1911, page 111. The Trendelenburg method of frog perfusion has also been widely employed. Various other methods are discussed in the papers of Crawford, 1907; Schultz, 1909; E. N. Stewart, 1911; Fifeineau, 1911.

Colorimetric methods also give good results. A process is described in the U.S.P., IX and by Seidel, 1915 (with critical discussion). Folin, Cannon and Denis, 1913, describe a simple colorimetric test, which gives good agreement with the blood-pressure method. The method of Kraus is unsatisfactory (Hale and Seidel, 1913). The various color reactions are described by Barger, Simpler Natural Bases, 1914, page 89.

PREPARATIONS—EPINEPHRIN

*Epinephrin, N.M.R.; Adrenalinum (Adrenal.), B.P.; Epiéphrin, Adrenalin 8-Suprarenal., etc.; C₁₉H₁₈NO₃·H₂O—Microcrystalline powder. The free base is practically insoluble, and is therefore marketed as an aqueous 1:1,000 solution of one of its salts, generally the hydrochlorid. The solutions usually contain a small quantity of preservative (often sulphite) and thus keep fairly well. On dilution they deteriorate in a few hours, by oxidation, acquiring a pink to brown color. This is favored by alka
dey, delayed by acids. The alkaloid is a reducing agent and gives a pink or red color with oxidizing substances such as iodin (Ewins, 1910). Ferric chloride produces an eberal green color, which turns purple and carmin on adding an alkali. Diss. 0.5 c.c. in 1,000 solution. Maximum dose, 0.5 mg. 10 gr.

Liquor Adrenalinii Hydrochloricus (Liq. Adrenal. Hydrochl.), B.P.—0.1 per cent., preserved with chloriform. Diss. 0.5 to 0.0 c.c. in 10 to 30 minims, B.P.

Suprarenalum Secusum (Supraren. Sicc.,) U.S.P.; Dried Suprarenals.—The suprarenal glands of such animals are as used for food by man, cleaned, dried, freed from fat, and powdered, and containing not less than 0.4 per cent. nor more than 0.6 per cent. of epinephrin, the active principle of the suprarenal gland. One part of Dried Suprarenals represents approximately 6 parts of fresh glands, free from fat.” The epinephrin is determined colorimetrically. Diss. 0.25 Gr., 4 gr., U.S.P.
This African drug—the root of an Asclepiadaceae plant—resembles epinephrine closely in its peripheral effects, except that these are more gradual and lasting. It is used by the natives against dysentery, and seems to be effective in amebic dysentery and other diarrheas (Merck's Report, 36:464).

**Constituents.**—The drug contains neither alkaloids nor tannin; its antidiarrheal action is therefore not astringent. The active constituents are a series of glucosides the most important being the crystalline Uzarin (Hennig, 1917). This is very easily hydrolyzed by acids into glucose and the inactive uzaridin. It is therefore much less effective by stomach than by rectum. **Uzaron** is a purified extract of secret composition.

**Actions.**—Güterbock, 1912 and 1914, found a variety of actions: Central stimulatory proceeding to convulsions; a peripheral sympathomimetic action (dilatation of pupils; inhibition of intestines, uterus, stomach, bladder; vasoconstriction); and a digital effect on the heart. Tiiperstedt and Airila, 1915, find that it slows the heart and blood stream, but raises the blood-pressure through vasoconstriction. The cardiac slowing is prevented by atropin. In intact animals, the systemic actions are much less with oral than with hypodermic or intravenous administration. It may be amebicidal in dysentery (Jost, 1914).

The intestinal movements are inhibited by the sympathetic stimulation (Hin, 1913), both in situ or when excised. It is very effective against the physostigmin e- pilocarpin movements. The diminished peristalsis lessens the excretion of uric acid (Abl, 1913).

(Pick and Wasicky, 1916, believe that uzara acts by paralyzing smooth muscle.

**COTOIN (METHYL-TROIXY-BENZOPHENONE)**

This has been used in diarrhea. It is not antiseptic nor astringent, but decrease the tone of excited intestines and uterus (Impens, 1913).

In transfused frogs, it contracts the blood vessels and diminishes reflex excitability (Iodbauer and Kurz, 1916). It is not toxic to rabbits, nor to guinea pigs. Its excretion occurs by the urine, partly as benzoic acid (Iodbauer and Kurz).

It is used in cholera; also to check the night sweats of phthisis. **Dose.** 0.06 to 0.1 Gm., 1 to 10 gr.

It is a glucosid, derived from Coto, the bark of an unknown Bolivian plant. This and the related "paracoto" barks also contain other related trioxymphenols, differing by the number of methyl groups (Iodbauer and Kurz, 1916).

**PITUITARY EXTRACT**

**General Statement.**—Extracts of the posterior (infundibular) lobe of the pituitary gland have a strong stimulant effect on smooth muscle, leading to considerable and rather persistent vasoconstrictor rise of blood pressure; reflex slowing of the heart; diuresis; augmented contractions of the intestine, uterus and bladder, etc. The effects resemble those of histamin (Fuehner, 1912) and are quite distinct from those of epinephrine (Dale, 1910; Bayer and Peter, 1918). They have no relation to the nerve supply, and are probably exerted directly on the muscle. The complexity of actions is probably due partly to the presence of several active constituents.

Therapeutically, extracts have been used hypodermically with success to accelerate labor, to check uterine hemorrhage and in paresis of the bladder; and with more doubtful results in intestinal paresis and in collapse conditions. Oral administration is practically ineffective.

A review of the literature of pituitary is given by Simpson, 1914.
Active Constituents.—It is probable that pituitary extracts contain several active principles, perhaps closely related to histamin, or to histamin derivatives, in protein combination. Several investigators have isolated crystalline substances; but these are probably cleavage products which do not fully represent the actions of the extracts.

Solubility and Stability.—The active constituents are soluble in water, are not affected by boiling or by peptic digestion, but are easily destroyed by trypsin, by incipient putrefaction and by hydrolytic agents in general (Dalé, 1910). This explains the inefficiency of oral administration.

H. S. Adams, 1917, claims that the oxytocic principle is rapidly destroyed by boiling with a weakly acid reaction (pH = 5); but not if the acidity is higher (pH = 3).

Isolation of Constituents.—Schaefer and Herring, 1906, believed that the various activities are due to separate constituents. Fuchsner, 1913, isolated four basic fractions, which are concerned to a varying degree in the blood pressure, respiratory and uterine effects. A 0.1 per cent. solution of this mixture is marketed as Hypophysin. Bandoni, 1913, also claims to have isolated a crystalline active principle. Most of the other workers doubt whether any of these really represent the active substances in pure form (Banger, "Simpler Natural Bases," 1914, p. 168).

Abel and Macht, 1919, identified the presence of histamin. Dudley, 1919, prepared a crystalline principle of high oxytocic and pressor efficiency, but differing chemically from histamin. Abel and Nagayama, 1920, identified histamin; a substance yielding histamin; and an unidentified pressor or oxytocic principle. Fenger and Hall, 1920, claim that the oxytocic principle does not occur in free form in the fresh gland, but is there linked to a protein complex, from which it is split in the preparation of the extracts.

Guggenheim, 1915, suggested that the active principle might be allied to acetyl cholin.

Crawford, 1920, claims to have isolated a pressor principle in impure form. This principle is related to epinephrin (Crawford and Watanabe, 1916).

Effects on Circulation.—The active principle appears very early in fetal life (McCord, 1915). Absence of Iodin.—Iodin is not present in any part of the pituitary gland, even after excision of the thyroid (Simpson and Hunter, 1917; Seaman, 1920).

Intravenous injection of pituitary extract raises the blood pressure (Oller and Schaefer, 1895). This may be preceded by temporary fall of pressure.

The rise is not as high, but is more sustained than that of epinephrin, lasting ten minutes to one-half hour. It is due mainly to widespread vasconstriction, from direct stimulation of the arterial muscle. The kidney vessels, however, are passively dilated in the intact animal. The heart is generally depressed and this produces usually a primary fall of pressure before it is overcome by the vasocstriction. The heart rate is usually slowed, at first from reflex vagus stimulation, and later by direct cardiac depression. Repeated injections of large doses produce less and less rise, and finally a fall.

Method of Administration.—Intravenous or peritoneal injection is much more effective and typical than hypodermic (Pankow, 1912) or intramuscular; but the last acts longer (Klotz, 1913). When given by mouth, there is practically no effect.

Cardiac Effects.—In intact animals, these are complicated by the interference of the vagus and muscular actions. The total result is generally slowing and weakening of the beat.

Rate.—This may be unchanged or even quickened, but is slowed in most cases. The slowing is much less if the vagi have been divided, and is due largely to stimulation of the center by the rise of blood pressure (Heyo and Plunket, 1913). Some slowing
occurs even after atropin and in excised hearts (Cleghorn and others) and this part must be ascribed to direct muscular depression. Werschchin, 1913, believes that the peripheral slowing is due to increased vagus tone; and Claude, Porak and Routier, 1915, attribute it to slowed auriculo-ventricular conduction by an action on the His bundle.

Strength.—The excursions of the mercury manometer are increased, but this is due simply to the slower rate. Direct cardiac tracings show decreased excursions and increased tone. These and the slowing diminish the output, occasionally with a preliminary increase (Wiggers, 1911). The decrease occurs even when the blood pressure rises showing that the rise is purely vascular. The ventricular efficiency is diminished (Wiggers, 1916).

The pressure in the pulmonary artery falls, by weakening of the right ventricle (Wiggers, 1921); or it may be unchanged (Anders, 1915). The rise in pressure is not affected by moderate doses; it rises with large doses by cardiac dilatation (Capps and Matthews, 1913).

Oft-repeated injections are said to produce cardiac hypertrophy, with lasting rise of pressure (Etienne and Parisot, 1908).

Excised Mammalian Heart.—This also reacts with decreased rate and amplitude (Wiggers; McCord, 1913). Einhorn, 1913, however, attributes this to the chloroform in the solutions; with pure solutions he describes primary slowing and weakening with subsequent quickening and increasing excursions.

Isolated Frog's Heart.—The excursions are generally increased; small doses quickly large doses slow to final standstill (Einon).

Evidence of Vascular Action.—Oliver and Schafer, and subsequent workers, have shown that the rise of pressure is accompanied by diminished organ volume (except in the kidneys), so that it can not be cardiac and must be vascular. Tigerstedt and Airila, 1913, also found that the aortic blood flow decreases with the rise of pressure (and still more in the fall). The vasomotor center is not affected directly; but may be somewhat depressed or more often moderately stimulated, by the rise of blood pressure or respiratory embarrassment (Pilcher and Sollmann, 1915; McCord, 1911). The vasoconstriction must therefore be general; and accord with facts after the cord has been cut; and perfusion of excised organs shows direct constriction (Rischbieter, 1913). Segments of excised arteries and veins are also constricted (de Bonis and Susanna). Unlike epinephrin, the effect is not abolished by ergotoxine, so that it is probably direct on the arterial muscle.

Application of pituitary solution to the scrotal skin produces a local blanching (Sollmann and Pilcher, 1916). This is a distinction from histamin, which produces flushing and urticaria.

Human Blood Flow.—The changes in the pulse-dow of the arm, after intramuscular injection of 1 c.c. of pituitary solution, indicate some vasokonstriction (Hewlett, 1917).

Specific Differences in Vessels.—These are quite unlike those of epinephrin. Pituitary contracts the pulmonary, cerebral, and coronary areas which are warily affected by epinephrin. The coronary circulation is therefore slowed, notwithstanding the rise of blood pressure (Morawitz and Zahn, 1914).

The brain-volume in man is increased (Raphael and Stanton, 1916).

Injection at the root of the ear, in rabbits, produces blanching, but less intense and less persistent that with epinephrin (Auer and Metzler, 1919).

When rings of surviving excised artery are exposed to the pituitary, J. Pal, 1904 and Cow, 1911, found the following: The carotid and its branches and the crural and mesenteric were constricted. The intercostal and cerebral showed no response. The gastric and renal dilated, the dilation of the renal increasing, the nearer the kidney the ring was taken. Proximal pieces of the renal may constrict. The hepatic and splenic constricted near their origin, but dilated near the organ. The coronary was sometimes constricted, sometimes dilated. The vessels of frogs are dilated (Froehlich and Phd. 1911).

Renal Circulation.—Magnus and Schaifer, 1907, observed that the kidneys in intact animals dilate during the rise of pressure, whilst other organs generally are contracted. The kidney volume diminishes during the fall. Hallion and Carrion described vasokonstriction followed by dilation. Both effects are probably mainly passive; for perfusion of excised kidneys generally produces constriction (McCord, 1911), sometimes followed by dilation. The ureter flow follows the volume-curve (Sollmann). The larger renal arteries are dilated (Cow).

Duration and Repetition of Action.—The rise of blood pressure lasts for about half an hour after intravenous injection. (Mummery and Symes.)
PITUITARY EXTRACT

1908, state that it persists for several hours if the brain and cord have been destroyed.) The effect may be repeated after one-half to three-fourths of an hour, or more frequently if small doses are used (0.05 to 0.1 c.c. of pituitin for dog; Hoskins and McPeek, 1915). In this way, the blood pressure rise may be utilized for bio-assay (Hamilton, 1917).

Frequently repeated injections of large doses, however, become less and less effective (Howell, 1908) and may finally lower the pressure (Schäfer and Vincent, 1908). The secondary depressor action does not occur as easily in dogs as in cats or rabbits (Hamilton, 1912). The mechanism of this action has not been established.

It is not due to cardiac effects, for these remain constant; nor is it due to fatigue of the vessels, for it does not occur in perfusion experiments (McCord, 1911). This observer believes that a new dilator substance is formed by the action of blood on the pituitary principles; for he claims that mixtures of blood and pituitary have a dilator effect when injected or perfused.

Action on Depressor.—Pituitary injection decreases the efficiency of depressor stimulation, especially in rabbits, less in cats. The action is stronger than that of epinephrin, and occurs even when the blood pressure does not rise (Auer and Meltzer, 1913).

Synergism with Epinephrin.—This has been reported by Kepinow (Gottlieb, 1911). The pituitary rise is due to stimulation of epinephrin secretion; for it is not modified by injection of the adenal vessels (Hoskins and McCord, 1913).

Primary Fall of Blood Pressure.—This is cardiac, but not vagal, for it occurs after section of these nerves (Paskow, 1912). The fall is more pronounced with large doses (Solmann; Auer and Meltzer, 1913). Schäfer and Vincent, 1909, believe that it is due to a distinct depressor constituent.

Circulatory Effects in Birds.—These are different than in mammals. There is a swift fall of blood pressure by peripheral vasodilatation, antagonized by epinephrin or brxin. The venricular and auricular contractions are stimulated (Paton and Watson, 1910).

Different Portions of Pituitary Gland on Blood Pressure.—Howell, 1908, showed that the pressor effect is confined to the posterior lobe of the gland. The hypophyseal portion (which has a structure resembling the thyroid) produces a distinct fall of blood pressure, usually accompanied by acceleration and weakening of the heart (W. W. Hamburger, 1904 and 1910). The Pars Intermedia also produces a fall preceded and followed by rise (Lewis, Miller and Matthews, 1911). The pituitary gland does not contain iodin, even after excision of the thyroid (Simpson and Hunter, 1911). The active principles appear very early in fetal life (McCord, 1915).

CLINICAL USE IN SHOCK AND COLLAPSE

Mummery and Symes found experimentally that the pituitary rise of pressure is more pronounced and sustained if the pressure has previously been lowered, as by hemorrhage, traumatic shock, cholim, peritonitis, etc. Blair Bell, 1911, claimed similar beneficial results in patients. The usual dose (1 c.c. of the commercial solution = about 0.01 gm of the moist gland, intramuscularly) may raise the blood pressure 10 to 40 mm. in an hour, with slightly slowed heart rate (Heck and O'Mally, 1909; Klots, 1912); but the response is uncertain. This may explain why the drug has not commanded confidence. The slowing might be useful in cardiac irregularities (Werchbin, 1913). Lewis, 1914, finds that the intramuscular injection of 1-5 c.c. converts the dicrotic pulse into a normal pulse, with diminished pulse volume, but without definite change in blood pressure or blood flow in the arm; these changes corresponding tovasoconstriction.

H. B. Schmidt, 1917, confirmed that the intra muscular injection of 2 to 1.5 c.c. of the commercial extract produces no change in the systolic pressure of feline' patients; but that the diastolic pressure often shows a slight rise, reaching its maximum in about one-half hour.

Local application is effective against capillary hemorrhage, ranking next to epinephrin. Intravenous injection is uncertain (Hanzlik, 1918).

Dugger, 1911, believes that it may be of some use in pulmonary hemorrhage by depressing the heart.
URINE FLOW

In man, pituitary administration tends to diminish the daily urine output; this effect being marked in diabetes insipidus (see below).

In animals, the injection of pituitary generally produces a temporary increase in the urine flow, perhaps by increasing the tubular flow; the effect, however, is inconstant. The daily output is not changed, but the capacity for extra urea excretion is depressed.

The diuresis was described by Schaefer and Herring, 1908. It occurs generally but not always (Becro and Plumier, 1913), and is of short duration. V. Konschegg and Schuster, 1915, find that small doses cause temporary diuresis, followed within ten minutes by diminished urine flow. Larger doses diminish the flow from the start. Injection during the inhibition again starts diuresis.

The daily output of urine and its specific gravity are not altered. (M. H. Rec., 1918.)

Mechanism of the Pituitary Diuresis.—Knowlton and Silverman, 1918, found an increase in the oxygen consumption of the kidneys. This speaks strongly against direct stimulation of the renal cells, and suggests that the diuresis is the mechanical result of vascular changes and increased filtration pressure. Accordingly, they found that the diuresis was always accompanied by increased renal blood flow. The earlier observers had also noted that the diuresis was generally accompanied by renal vasodilatation (Harrison and Carrion; King and Stoland); but since there was no constant relation between the diuresis and the blood-pressure or kidney volume (neither of which give a complete picture of the vascular circulation), a direct effect on the renal cells was suggested; possibly due to a distinct constituent (Schaefer and Herring, 1908; Hodkins and Means, 1913).

Urea Excretion.—Addis et al., 1918, claim that the hypodermal injection of pituitary into rabbits markedly lowers the capacity of urea excretion; and that this constitutes a mutual antagonism with epiephrine.

Pituitary Factor in Water Diuresis.—Cow, 1915, found that injection of extracts of duodenal mucous membrane increases the urine flow. He attributes this to stimulation of the pituitary gland; and believes that water diuresis is due to absorption of the duodenal pituitary stimulant. Further confirmations are needed for this theory.

Urinary Response in Normal Human Subjects.—With ordinary doses, the diuretic response seems to be small and uncertain; the chlorid excretion is increased (Frey and Kumpf, 1914).

Konschegg and Schuster, 1915, claim that 1 to 2 c.c., hypodermically, in normal individuals, diminish the volume and solids of the urine, the effect lasting sixteen hours. J. L. Miller, 1917, also states that in man, pituitary injection always diminishes the urine.

The transformation of benzoic into hippuric acid, in nephritis, is reported to be increased by pituitary, independent of any diuresis (Paris and Ceccaroni, 1917).

Uric Retention.—The administration of dried pituitary (02 Gm. per day, for 5 weeks) to normal human subjects increased the urate content of the blood, presumably by diminishing the permeability of the kidneys (Hammett et al., 1920).

Use of Pituitary in Diabetes Insipidus.—Hypodermic injections of solutions of the posterior lobe greatly diminish the thirst, and the volume of the urine, and increase its specific gravity and the percentage of chlorids and nitrogen (Velden, 1913; Grau, 1913; Klauert; Konschegg and Schuster, 1915; G. Hormay-Seyler, 1915; Motafeldt, 1916). The kidneys resume the power of concentrating the urine considerably (Christie and Stewart, 1917). The action is confined to the posterior lobe. It requires at least two injections a day; the ordinary extract of the posterior lobe, six hours apart. Oral administration is inefficient (Barker and Mosenthal, 1917).

RESPIRATORY CENTER

This is affected, both directly and through the circulatory changes. With intravenous injection, Paukov, 1912, describes a primary arrest during the fall of pressure, then an increase and a second stoppage during the rise. Nice, Rock and Courtneight, 1914, describe the characteristic effects as primary increase of depth, followed by shallow and generally slow, but sometimes quickened respiration. These disturbances set in with the circulatory changes, but are not as lasting. They fail to occur after few injections have been made. In frogs, tadpoles and fish, the center is paralyzed (Hepner, 1915).
PITUITARY EXTRACT

BROCHIAL MUSCLE AND ASTHMA.—Froehlich and Pick, 1913, found fatal bronchial stenosis in guinea pigs. This is peripheral, i.e., preventable by atropin, but not by section of vagi. It occurs also in the surviving lung of dead animals (Baehr and Pick, 1913). Lane, 1913, observed no effect on isolated bronchial muscle.

Pituitary has been tried clinically in asthma (Brochardt, 1913); but the results are not promising. Laniart, 1915, even reports a patient in whom pituitary provoked asthmatic attacks.

UTERUS

In the body and on the excised organ, even very small doses of pituitary have a marked augmentary effect, and increase the excitability to hypogastric stimulation (Dale, 1907; Frankl-Hochwart and Froehlich, 1910). This occurs in all animals, pregnant or non-pregnant (Fuehner, 1913; Gunn and Gunn, 1914). The action has been used for a bio-assay (Dale and Laidlaw, 1912; Roth, 1914; U. S. P. IX).

Human uterus, non-pregnant or pregnant, in vitro or excised, is also thrown into extreme contraction.

Lieb, 1914 and 1915, described differences between pregnant and nonpregnant uterus, but was evidently in error (Gunn, 1914; Charteris, 1917; Webster; Solimana). The tubes are not contracted by pituitrin, in distinction to epinephrin (Gunn). The round ligament also does not respond (Webster).

Excessive concentrations of pituitary (also of histamin) depress the excised uterus of mice and guinea pigs; but rats' uterus is not depressed by pituitary in any concentration (Abel and Macht, 1920).

Interaction of Epinephrin and Pituitary.—Epinephrin normally relaxes the excised uterus of guinea pigs and of non-pregnant cats; but if these uteri are first treated with pituitary, the addition of epinephrin causes them to contract (Cow, 1929).

USE IN OBSTETRICS

This was introduced by Bell, 1909. Its efficiency for hastening delivery and checking postpartum hemorrhage has been generally confirmed (also in animals; Lescohier and Closson, 1913). It fails in some cases (Boight, 1911). Excessive doses are dangerous, the powerful contractions closing the cervix, preventing delivery and producing local necrosis (Gumann, 1913), and sometimes even rupture of the viscous (Espeut, 1913; Zuelig, 1915; also J.A.M.A., 1914, 62: 1421). It may also prevent delivery if injected during the first stage of labor. After this, and in proper doses (1 c.c., repeated in an hour if necessary) it is not dangerous to mother or child. It does not produce abortion before term, and is most effective when the os begins to dilate (Malinowsky, 1914).

Duration of Action.—The uterine stimulation becomes apparent within 15 minutes after intramuscular injections, reaches its maximum in half an hour, and then fades out rapidly. Further injections of 5 c.c. may be made whenever the stimulation fails to fade, every half hour if necessary, without cumulation (Watson, 1910).

Rather high fatality of mother and fetus was tabulated by Mundell, 1916 and 1917. He considers that the single dose should be reduced to 1/2 c.c., but this may be repeated more frequently.

Curency Webster injects a few drops of pituitary extract directly into the uterine muscle, to secure a firm and bloodless field for incision, f.s. in Cesarean section.

URINARY BLADDER

The vesical muscle is stimulated and the excitability increased to the pelvic, but not to hypogastric stimulation (Frankl-Hochwart and Froehlich, 1910). This has been utilized in postoperative paralysis of the bladder (Hoffstätter, 1911; Fellenberg, 1911).
INTESTINES

These show primary inhibition of contractions through sympathetic stimulation central to epinephrin; followed by increased contractile through stimulation of Auerbach’s plexus and its postganglionic fibre (Bayer and Peters, 1911). The stimulant effect has been used clinically in paralytic distention of the intestines, especially after operations (Bea and Hick, 1909). Its efficiency is still under judgment; Bidwell, 1910 claims a limited usefulness.

Shamoff, 1916, and Hoskins, 1916, found that the intestinal action varies greatly: different preparations, some even relaxing, like epinephrin. “Hypophysis” was especially relaxing, but extracts of fresh glands also gave this result. The blood-pressure tests of these preparations gave the normal response.

Roth, 1917, finds that this depression is at least in part due to the action of chloretone, when this preservative has been added.

The muscle (both circular and longitudinal) of the frog’s esophagus is depressed by a pituitary (Waddell, 1916).

PUPILS

Pituitary, on intravenous injection, constricts the pupil, in normal rabbits or after ganglionectiony. It counteracts epinephrin dilatation (Gibbons and Meltzer, 1917). Frog respond to pituitary by dilatation. (Ott and Scott, 1909, claimed that he pupil’s ganglionectionized mammals are also dilated; ovary, thymus and mammary have no effect on the pupil).

INVERTEBRATES

Paremodon.—Pituitary extract increases the pulsation-frequency of the contractile vacuole.

LACTAL SECRETION

Ott and Scott, 1910 and 1912, discovered a marked galactagogue effect in goats a number of other gland extracts, especially of the sexual apparatus, had a similar less weaker action. The observations were confirmed by Mackenzie, and by all subsequent workers. The increase occurs within fifteen minutes after the intravenous or hypodermic injection; but there is a corresponding decrease at the next milking, so that the milk output of milk is not changed (Hammond, 1913; Hill and Simpson, 1914). The fat content is increased at the first milking, without decrease at the next. The non-fat solids are not affected (Hill and Simpson, 1914). If the injections are repeated over long periods, the effect is lost (Simpson and Hill, 1913). No increase of milk is said to occur in cows (Gadin, 1913) or human (Schaefer, 1913); but Hill and Simpson, 1914, found that intramuscular injection of 1 c.c. of pituitary solution in the fifth month human lactation was followed by marked increase of milk and fat.

Mechanism of Action on Milk.—The fact that the response (in goats) is perceptible within half a minute, as also the secondary decrease, suggest that the increase is due to secretion, but merely to the more complete expression of stored milk by contraction of the smooth muscle of the gland (Simpson and Hill, 1914). The increase of milk fat would agree with this. Galves, 1913 (full discussion of the subject), presumes a mammary secretion of such contraction in lactating glands (non-lactating glands not respond). Simpson and Hill, 1915, point out that barium does not increase milk, although it stimulates the muscle powerfully; but this would be counteracted by the intense vasocostriction.

OTHER SECRETIONS

Saliva.—Intravenous injection into dogs diminishes the flow of saliva, partly decreased blood flow, partly by direct depression of secretion. The response to pancreatin is also diminished (Silen and Loomsen, 1913).

Pancreatic Secretion.—This is decreased (Pemberton and Sweet), through vascular constriction (Edmunds).

Cerebrospinal Fluid.—Pituitary affects the pressure merely through its circulatory changes (Dixon and Halliburton, 1913 and 1914).

Cow, 1915, believes that the pituitary principle occurs sometimes in the cerebrospinal fluid; especially after injection of extracts of the duodenal mucosa, which considers as a stimulant of pituitary secretion.
PITUITARY EXTRACT

Toxic Actions.—Aside from the accidents arising from actions on smooth muscle, such as rupture of the uterus or asphyxiation of the fetus, toxic effects are rare and generally unimportant. Selbert (Nebenwirk, 1915, page 206) cites the following: Tachycardia; anxiety; albuminuria; unconsciousness; eclamptic attacks; mydriasis, anamnestic, diarrhea.

Metabolism.—Excessive and long-continued doses are said to produce ataxia; and new symptoms, emaciation and disturbances of carbohydrate metabolism, Weid, Cushing and Jacobson, 1913, believe that this is influenced by the posterior lobe. Lachrymations of pituitary lower the assimilation limits for carbohydrates, and cause glycosuria and glycosuria. Stimulation of the hypothysis in dogs produces hyperglycemia, even when proper precautions are taken against asphyxia, neighboring structure, etc. No result is obtained after section of the splanchnics (Keeton and Becht, 1917).

STANDORIZATION

Some extracts are seven or eight times as active as others. In view of the powerful effect, they should therefore be standardized. Various methods have been proposed, and their results are not parallel (Roth 1917). The contractor effect on the excised tissue (Roth’s method) was adopted by the U.S.P. IX. Hamilton, 1917, contends for a fixed pressure method.

Speth, 1918, proposed the use of the chromatophores of fish scales (lundulius), with KCl as standard.

PREPARATIONS—PITUITARY

Pituitary extract, U.S.P.; Desiccated Hypophysis.—The posterior lobe of the pituitary body of the ox, cleaned, dried, and powdered. Dose, 0.03 Gm., 1/4 gr., U.S.P.

Alcohol is not a solvent for the active principle; nor does it destroy it (Hamilton, 1918).

(The pituitaries of carnivorous and omnivorous animals furnish more active extracts than those of herbivora (G. B. Roth, 1917).

Anterior Pituitary Lobe.—General Statement.—The actions of this are quite distinct from those of the posterior lobe. It has but little effect on smooth muscle; but appears to influence metabolism, growth and sexual development. The effects on growth appear to be due to a peculiar hormone, "tethelin."

Excision and Disease.—Total removal is followed by death in a short time (Paulosco, 1917; Reford and Cushing, 1909; Crowe, Cushing & Homans, 1910. Partial removal or disease leads to retarded growth or infantilism, obesity, and other abnormalities. Hypertrophy (as in acromegaly; P. Marie, 1886) is characterized by accelerated adolescent growth and abnormal growth (gigantism).

Fed with Anterior Pituitary Lobe.—Confirming results have been reported; the results being apparently influenced by the maturity of the animals, the stage of the gland, and other unknown conditions. It has been claimed that feeding with the fresh or dried gland in the pre-adolescent period retards growth (as judged by weight and length of bones), but stimulates sexual development. In fully grown animals, it accelerates growth, including the replacement of tissue lost by inanition; the healing of granulating wounds, etc. (T. B. Robertson, 1910). Since then, Robertson, 1910, defines the effect on mice as temporary retardation, and later compensatory acceleration of growth.

J. A. Larson, 1915, claims some acceleration of growth and prolongation of the life of rats, on feeding anterior pituitary lobe. The effect appeared to be greater on males than on females. The most striking results were obtained after thyroidecay, when the pituitary prevented the usual fatal issue.

Gestational Trait.—R. T. Frank, 1910, failed to obtain any definite effects from feeding the anterior pituitary of rabbits. Egg Production of Chickens.—S. Simpson, 1920, failed to confirm the older claims that this is increased.

Growth of Tadpoles.—Feeding with anterior pituitary accelerates growth and prevents the growth retardation that normally ensues after excision of the anterior pituitary (P. E. Smith, 1910).
Metamorphosis of Tadpoles—Allen, 1919, observed that this does not occur if either the pituitary or thyroid are removed; but that it occurs in the absence of both glands if sodin is administered.

Therapeutic Uses—These are in the experimental stage. Improvement has been reported following the administration of the dried anterior lobe (0.05 to 0.25 Gm., to 4 gr., in powder or tablets) in the later stages of acromegaly; in dystrophic adhesion; and in certain cases of obesity. It is contraindicated in early stages of acromegaly.

TETHELIN

General Statement.—This is a lipoid, isolated from the anterior pituitary lobe by T. B. Robertson, 1910, and considered by him as the constituent responsible for the influence of the gland on growth. It retards growth on systemic administration but local application stimulates the growth of epithelium and of carcinoma.

Effects on Growth.—When fed to young animals (mice), tethelin considerably retards growth (as also do cholesterol and egg-lecithin). After puberty, this effect is largely lost, so that there is a compensatory acceleration of growth, even if the tethelin feeding is continued, but more rapidly if the tethelin is omitted. The acceleration of growth is therefore not a direct effect of the tethelin but is merely compensatory (Robertson and Ray, 1910).

Duration of Life.—The tethelin-fed mice live about 12 per cent, longer than the control animals. This is probably connected with the slower growth. A special cause for increased longevity is the delayed incidence and growth of cancers (Robertson and Ray, 1910).

Carcinoma.—Feeding of tethelin tends to retard the growth of cancer; but its local injection in rat carcinoma increases the growth of the tumor and tends to metastasize analogous to anterior pituitary. Lecithin retards (Robertson and Burnett, 1910).

Application to Wounds.—Local application appears to hasten the healing of ulcers, fractures, etc. The therapeutic application of this action is still in an experimental stage.

Toxicity; Excised Uterus.—Tethelin is non-toxic. It does not affect excised uterine (C. A. Schmidt, 1917).

THYROID PREPARATIONS

General Statement.—The administration of thyroid gland is highly successful in combating the phenomena of thyroid deficiency—myxedema, cretinism, etc.—whether the deficiency be congenital or acquired by disease or operations. The benefit persists practically only as long as the administration is continued. Metabolism is increased also in normal individuals, first the nitrogen, then fats. Thyroid is therefore used against obesity. However, it is a dangerous remedy, excessive doses causing nervous symptoms. Thyroid administration alters the susceptibility to certain poisons. Acute effects are slight and inconstant, even on intravenous injection.

Active Constituent.—This has been isolated by E. C. Kendall and named “thyroxin,” to emphasize the importance of its oxygen content. It also contains a considerable percentage of iodin, which is thus characteristic of the gland.

The active principle is confined to the colloidal material of the gland where it occurs presumably in combination with the chief protein component of the colloid, “thYRO-globulin.”

Structure and Properties of Thyroxin.—This was split off in crystalline form by Kendall in 1913 and 1916, and first named “alpha-iodin,” to distinguish it from non-crystalline active forms of iodin, “beta-iodin” which are contained in the gland in about equal amount.

Kendall, 1918, has definitely established the chemical structure of thyroxin by synthesis as:
Structure and Action.—Kendall, 1910, believes that the oxindol group is the essential part in the action on metabolism, for this is abolished if the H in the imino group is replaced by acetyl.

The indol ring is easily opened by hydration:

This change appears to be connected with energy production, acting perhaps as a catalyst.

The iodin is considered by Kendall as of subsidiary importance. He assumes that it behaves merely as an activator. It is, however, a fair index of the thyroxin content of the glands. It is concerned specifically with the action on the metabolism of tadpoles, which appears to be independent of the imino group.

Relation of Activity and Iodin Content.—The relatively large percentage of iodin in thyroid gland early fixed the attention of investigators. When criteria of thyroid activity were developed, such as the therapeutic efficiency, increased nitrogen excretion, acetonitrile test, tadpole test, etc., it was found that these are roughly proportional to the iodin content of the thyroid preparations (Hunt, 1912; Marine, 1913); although the correspondence is not absolute (Rogoff, 1917).

Specificity of Thyroxin Iodin.—The characteristic thyroid actions are not produced by the inorganic and most of the organic iodin compounds, not even by most iodized proteins, except after they are assimilated by the thyroid.

Thyroxin, on the other hand, produces all the effects of thyroid administration, although its proportion in the fresh gland is generally only 1 : 10,000, at most 1 : 4,000. The inert B form is perhaps an intermediate stage. Glands practically devoid of iodin may also possess a slight activity.

Thyroglobulin.—Oswald (1890, 1908, and 1909) recognized that the activity of the thyroid is confined to its iodin containing colloid, thyro-globulin. The iodin content of this globulin averages about 0.35 per cent, but varies from 0 to 1.3 per cent. It was therefore assumed that the globulin may either take up various amounts of iodin (Hunt, 1912), or that the gland contains a mixture of iodinized and iodine free globulin (Oswald).

Thyroid also contains nucleo-proteins; mainly in the nuclei, and therefore in inverse order to the colloid (Beebe, 1917).

The iodin is confined to the colloid; practically none is present in the cells of the thyroid (Tatum, 1910).
Cleansing Products.—The iodized thyroglobulin has been further fractionated by F. C. Koch, 1913, finds that the full activity is contained in the metaprotein fraction of the thyroglobulin; the simpler cleansing products showing less and less activity per unit of thyroidoid. Pick and Phillips, 1905, also claim that completely digested thyroid is less efficient in myxedema. Both statements appear to conflict with the universal experience that oral administration is effective, although it may be assumed that complete cleavage occurs before the tissues are reached.

Iodothyron.—This is the cleansing product prepared by Baumann, 1896, containing from 4.5 to 15.3 per cent. of iodin (Oswald; Koch, 1903). It does not give the protein reactions, and is very resistant to heat and reagents. Baumann and Roos, 1886, and Hildebrandt, 1896, claimed that it has the therapeutic actions of thyroid; but most later observers have obtained rather negative results. The commercial product contains much less iodin (as little as 0.014 per cent.; Hunt and Seidell, 1910), sometimes in loose combinations.

Iodin Content of the Glands.—This averages about 0.25 to 0.5 per cent. for dry, and 0.01 to 0.06 per cent. for moist glands. (The average percentage for moist glands is given by Aldrich, 1914, as 0.025 for sheep; 0.036 for beef; 0.047 for hogs.) It is subject to great variations, particularly in goiter. In hyperplastic goiters, the percentage of total iodin are both greatly diminished, proportional to the histologic changes. In colloid goiters the percentage is diminished to a less degree (Marine and Williams, 1908). Iodin is said to be absent in wild carnivorous animals, and sometimes in domestic (Ross, 1899), but this must be rare. Contrary to older statements, Fenger, 1913 and 1915, found it in the fetus of domestic animals long before birth. Its asserted absence from the human fetus therefore seems to require further confirmation.

The iodin undergoes marked seasonal variations, the percentage being three times greater (with smaller glands) in June to November, than in December to May. It diminishes gradually from about September till March or April, and then increases abruptly until September. The changes appear to be connected mainly with the prevailing temperature; although diet and the reproductive season are not definitely excluded (Seidell and Fenger, 1913 and 1914). The iodin is also decreased by stimulation of the nerves going to the gland (Rahe, Rogers, Fawcett and Beebe, 1914), but this is due to aam constrictorion (Watts, 1915).

Organic.—It is noteworthy that organic iodin compounds cannot be demonstrated in any other mammalian tissues than the thyroid (Blum and Gruenert, 1914).

Effect of Administration of Iodin Compounds.—These, whether organic, or organic, materially increase the iodin content of the gland, with corresponding increase of its activity, and characteristic anatomic changes (involution of hyperplasia (Marine)). The selective affinity of the thyroids is very high, relative to the other tissues (Marine, 1915). Hunt, 1907, points out that part of the pharmacologic action of ordinary iodids may be explained by their conversion into thyroid secretion; and this is obviously their effect in thyroid disease.

When iodin compounds are fed, iodin is taken up by the thyroid tissue to the point of saturation, which averages about 5 to 6 mg. of iodin per gram of dried thyroid. The selective affinity is so strong that as high as 18.2 per cent. of a given intake (oral) of iodin was recovered from a thyroid whose ratio to the body weight was 1:587 (Marie, 1915).

The iodin content can also be increased by the injection of blood of hyperthyroid, and decreased by that of thyroidectomized animals (Jones and Tatum, 1915). Elaboration of Active Iodin Compound.—This has been investigated by Marine and Kogoff, 1916. Inorganic iodin was injected into the veins of dogs; the thyroidoids were excised after various intervals, and tested chemically and on tadpoles. The iodin is fixed by the gland within five minutes after injection; but the active compound is not formed until 8 hours, and is not complete for 20 hours. This is about the time when the histologic changes start, supporting the view that the iodin elaboration and the evolution are connected.

The rate of the formation of the active iodin compound varies in different dogs, independent of the total iodin or histologic condition of the gland, of age, sex, etc. It is suggested that this may depend on differences in the quantity of a hypothetical "mother-substance."
Artificially Iodized Proteins.—Rogoff and Marine, 1917, obtained a positive tadpole test from artificially iodized ox serum. The activity was less than that of thyroid, and was destroyed by alkaline hydrolysis.

Perfusion of Thyroid.—Fresly excised thyroid takes up and fixes potassium iodid from the perfusion fluid, presumably in an organic form, so that it can not be washed out by Ringer’s solution. The amount fixed is independent of the iodid concentration of the perfusion fluid, but is larger for hyperplastic than for colloid glands, and is about equal to the amount fixed in the living animal, in the same time (an hour), with intravenous injection. In neither case does the iodid absorbed by the thyroid produce the specific effect on tadpoles; so that a further elaboration in the gland is necessary (see above). The iodid fixation of perfusion does not occur when the gland becomes disorganized by autolysis; nor does it occur on perfusing other organs than the thyroid (Marine and Feiss, 1915).

Passage of Active Thyroid Secretion into the Circulation.—It must be supposed that the thyroid secretion is distributed by the blood; however, the concentration in the blood is too small to be demonstrated even by the tadpole test (Rogoff, 1918).

Ede of Thyroxin.—When large doses are administered, nearly two-thirds are rapidly excreted especially by the bile (to 60 per cent.) and urine (to 8 per cent.). About a third is retained in the body for longer periods (Kendall, 1916).

Thyroid Deficiency.—Complete excision of the thyroid apparatus (Cachexia strumifi ca) causes a series of acute effects, motor, nervous and metabolic, which are more or less rapidly fatal in most animals, especially in carnivores. (These results were first described by Schiff, 1856; Reverdin, 1862; and especially Kocher, 1883; the literature is reviewed by Vincent, 1912.) If the parathyroids are spared, the motor symptoms and lability are much less; and the metabolic disturbance, though no less severe, runs a more chronic course. In man, thyroid deficiency, when occurring in adults, results in Myxedema, with the conspicuous skin changes and nervous disturbances ending in mental deterioration. Congenital deficiency produces the condition of Cretinism.

Experimenal Cretinism.—Complete thyroidectomy in young rabbits is said to be followed by typical cretin phenomena, such as dry, rough hair, retarded growth, skin changes, etc. These are perfectly controlled by feeding dried thyroid or its cleavage products if the hydrolysis has not gone too far. Kendall’s “B” compound was ineffective; so was transfusion of normal blood; whereas the serum of thyroid-fed animals was moderately efficient (H. R. Basinger, 1916).

Therapeutic Results of Thyroid Feeding.—The deficiency symptoms are more or less completely relieved by the administration of thyroid by mouth (Howitz, Mackenzie, Fox, 1892), as well as by intravenous injection (Colzi, 1884; Murrey, 1891) by thyroxin, or by implantation of thyroid tissue (Schiff, 1884).

Administration.—The dried gland is the most convenient form, either as powder or tablets. The latter ordinarily contain 0.15 Gm., 2 gr. of dried gland. The treatment must be practically continuous, but overdoses must be avoided.

It may be begun with 0.15 Gm. per day, increasing by this amount every few days to a maximum of 0.25 Gm., 4 gr., three times daily, best on an empty stomach. If “side” effects appear, the dosage must be temporarily reduced. When the full therapeutic action has been reached, the dose may be reduced to 0.25 Gm., 0.75 gr. daily, and then every second day for a month. The administration may then be interrupted for a time and resumed in a similar way when the indications again arise. It is claimed that arsenic (10 to 15 drops of Fowler’s solution daily) increases the tolerance.

Means and Aub, 1914, found that the basal metabolism in hypothyroidism is restored to normal by daily doses starting with 0.2 to 0.25 Gm. (1 to 4 gr.) of the dried gland, later 0.05 to 0.1 Gm. (1 to 3 gr.). In view of this, the usual dosage appears unnecessarily high.

Overdosage.—This is denoted by circulatory, nervous, digestive, and splanchnic disturbances, resembling superficially those of Graves’ disease.

Symptoms.—These are: palpitation; rapid and often irregular pulse; vascular congestion; headache and muscle pains; tremors of extremities; nervousness; insomnia; tremor; diaphoresis; irritation of skin; hyperpyrexia. Polyphagia, or loss of appetite, 22.
necæa, vomiting and diarrhoea. Sometimes albuminuria and glycosuria. Scotoma has been described (Snydacher, 1911). In fatal cases, uncontrollable vomiting, collapse and coma. Creatins are said to be more susceptible to the toxic effects (Bausinger, 1916).

**Administering Thyroid Hormone.**—The administration of thyroid hormone produces similar effects, but the resistance varies greatly in different animals, carnivores being less susceptible. The most constant features are emaciation, gastroenteritis and diarrhoea; but no tachycardia, nervousness or exophthalmos. Death may occur with convulsant or depressant symptoms. Fresh, dried, or stale glands produce the same effect (Carlson, Kook and McKie, 1912; French, 1913). Hypertrophic thyroid is less toxic than normal, in accordance with its lower iodine content (Stokland, 1912).

The effects of thyroxin are produced so slowly that they are in large part indirect; for a single massive injection is generally almost inactive; whereas the same dose may be fatal when divided over a number of days (Kendall, 1919).

Gudernatsch, 1915, found that small doses of thyroid fed to rats tend to prevent conception. If pregnancy occurs, the young either abort, or die early, or grow less than normals. The detrimental results are the same whether the feeding has been to the mother or father alone.

**Synergism with Amino-acids.**—Kendall, 1916, found that thyroxin also produces symptoms analogous to exophthalmic goiter, but has no direct effect on the pulse rate, even on intravenous injection. If, however, amino acids are injected at the same time, there are marked disturbances of the pulse rate and of metabolism, which may even be fatal. Kendall (1917) believes that this involves also the suprarenal and parathyroid glands, but the evidence is not convincing.

**Experimental Hyperthyroidism.**—Cannon, Binger and Fritz, 1915 and 1916, aimed to produce this condition by fusion of the phrenic with the cervical sympathetic nerve, believing that this would result in continued stimulation of the sympathetic structures, including the thyroid.

They obtained symptoms which they interpreted as "hyperthyroidism." However, careful repetition of the work by others (Troell, 1916; Burget, 1917; Marine, Regd and Stewart, 1918) gave uniformly negative results, although electric stimulation proved perfect functional union. The effects described by Cannon et al. must, therefore, have been accidental (perhaps diastemad). The cats showed tachycardia (to 260), falling of hair, sclerosis, pruritus, excitable temper, greatly increased metabolism enlarged pupils, exophthalmos and hypertrophy of the adrenal glands. Removal of the thyroid on the fused side arrested the progress of the disturbances, and restored the metabolism to normal.

**Innervation of the Thyroid.**—The gland is abundantly supplied with non-medullated fibers, probably derived from the cervical sympathetic, and going to the cells as well as to the blood vessels. An action-current develops in the gland on stimulation of the sympathetic, high in the thorax, even when the superior and recurrent laryngeals have been cut. Vagus stimulation or pilocarpin does not generate the action-current (Cannon and Cattell, 1916).

On the other hand, autographs of thyroid show evidence of growth and function, so that the nervous connections are not indispensable (Massey and Marine, 1916).

**Sensitization to Autonomic Stimulation.**—Injection of thyroid, or increased secretion secured by stimulation of the superior laryngeal nerve, does not produce any characteristic autonomic stimulation directly; but it increases the response to epinephrin, splanchnic, and depressor stimulation (see Literature under Epinephrin); and to the depressant action of histamin (Oswald, 1915).

The sensitization to epinephrin would be situated at the myo-neural junction (Asher, 1916).

There is also a synergism with epinephrin on the excited heart. Here again, the heart is not affected by thyroid alone (Asher et al. 1916).

**Epinephrin on Thyroid Secretion.**—Injection of epinephrin, 0.001 to 0.002 mg., evokes an action-current in the thyroid. The same result follows stimulation of the cut splanchnic; but it is absent if the adrenal blood is prevented from reaching the circulation (Cannon and Cattell, 1916).

**Temperature and Drugs on Thyroid Functionation.**—Judging thyroid activity mainly by morphologic criteria [higher cells and decreased collar], C. A. Mills finds increased activity by exposure to high temperature and the reverse with low temperatures. Large doses of morfin or quinin also appear to diminish thyroid activity, presumably as the
result of diminished metabolism and heat production. Conversely, strychnin in just sub-convulsive doses increases the thyroid function.

Animals fed on thyroid die more rapidly when kept in a warm temperature than when kept cool (Stoland and Kinney, 1919).

Cocaine.—The symptoms of cocaine poisoning resemble those of “hyperthyroidism,” since both involve sympathetic stimulation. There is no causal connection. Often repeated injections of cocain do not produce any histologic changes in the thyroid (Mills, 1910).

Effects on the Circulation.—These vary, and are probably indirect, due to increased excitability of the sympathetic and parasympathetic nerves (Oswald, 1915). Usually the intravenous injection produces fall of blood pressure and slowing of the heart, probably due to its choliner content (Lohmann; Fuhr and Schwarz, 1908; Fuhr 1909; Schoenborn, 1909). Pressure juice produces little effect in dogs and cats, but marked collapse in rabbits (Caldwell, 1912). These effects are not specific but due to proteins, enbium, etc.

Blackford and Sanford, 1913, claim that the pressure fall is much more marked with extracts from toxic goiter; and that the sera of such patients also produce marked cardiovascular depression. These claims await confirmation. Pawlett, Rogers, Lark and Beebe, 1913, find that the coagulable portions of thyroid extracts (which contain most of the iodin) have no effect on blood pressure. The fall is confined to intravenous injection of the non-coagulable portion, and has no relation to the iodin content. It therefore appears unconnected with the specific constituents of thyroid (they also review the contradictory literature).

Cardiac Vagus.—The response of the heart to vagus stimulation is not affected by thyroid (R. L. Levy, 1918). Complete excision of the thyroid-parathyroid apparatus lowers the vagus excitability (Coronelli, 1915).

Secretion of Cerebro-spinal Fluid.—This is said to be inhibited by thyroid and increased by brain extract, independent of blood-pressure changes. Other organ extracts act only mechanically, through the circulation (Frazier and Peet, 1911).

Bile Secretion.—This is not affected by thyroid administration (Downs and Eddy, 1910).

Thyroid in Exophthalmic and Other Goiters.—The administration of thyroid is often beneficial in goiter; but the active “toxic” stages are especially susceptible to the toxic effects of thyroid, so that only very small doses should be used. The same effects can be produced by iodids, which are elaborated into the active substance by the thyroid of the patient. Caution should therefore be used in prescribing iodin compounds in goiter, especially where nervous symptoms exist (Oswald, 1915; history; description of symptoms and cases).

Nature of Goiter.—Anatomically, this may consist in overgrowth of the epithelium (hyperplasia), or of the colloid. The investigations of Marine, 1927 to 1913, indicate that the first change is hyperplastic, the epithelium proliferating to meet some physiologic deficiencies, such as an inadequate supply of iodin; or experimentally the excision of a part of the gland. When the deficiency is met, f.t., by the administration of iodin, the glandular changes revert into the colloid type. Transplanted thyroid tissue reacts in exactly the same way, by hyperplasia or involuted, to removal of thyroid tissue or iodin; so that the changes are evidently independent of the nerve supply (Manley and Marine, 1915).

The relation of these changes to the “toxic” symptoms of Basedow’s disease is not understood; for the symptoms do not occur typically in animals. It is commonly assumed that these “toxic” symptoms are due to excessive or perverted secretion of the thyroid (hyperthyroidism, dysthyroidism). The evidence for this theory is not conclusive, for it is based mainly on the resemblance of the clinical nervous symptoms in those of thyroid feeding; and on the beneficial results of partial thyroidectomy. These may have other explanations, and are opposed by the fact that improvement also follows the graduated administration of iodin. (Blackford and Sanford, 1913, assert the presence of a powerful depressor substance in the blood and thyroid of Basedow patients.)

Iodin Administration as Preventive of Simple Goiter.—Since simple goiter appears to be a reaction to deficient iodin, occurring especially in adolescent girls, it should be prevented by systematic administration of this substance. This has been confirmed
by the brilliant results obtained with school girls in an endemic goiter district (Martin and Klimball, 1917, 1918, 1920).

Sodium iodid was employed in these experiments, given twice a week (May and December) in courses of ten days each. Up to 10 years, the daily dose was 0.2 Gm. from 10 to 16 years, 0.4 Gm.; taken in a teaspoon of water.

The iodid prevented the appearance of goiter in over 99 per cent. of the girls, an almost equal number in the control group. The goiter was removed in one year in 11.5 per cent., and in 2 years in 33 per cent. The goiter recurred in less than 15 per cent., and was always mild.

Antithyroid Serums.—These were introduced on the hyperthyroidism theory of Graves' disease as substitutes for operative removal, but only had a short popularity.

On the theory that Baselow's disease consists in a thyroid intoxication, Balfour and Enriquez (1894) attempted its treatment by the administration of the serum of thyroidecimized dogs, supposing that these produced substances antagonistic to thyroid secretions. Moehlman Serum, Rodenhan and Thyroidin are prepared on this principle generally from sheep. Their oral administration sometimes has a palliative effect on the nervous symptoms in mild cases, but probably no more than simple rest and diet. Brebe, 1906 and 1915, introduced a cytolytic serum. Encouraging results were reported at first, but these reports have become less frequent.

Increased Metabolism.—This is one of the most constant effects of thyroid administration, occurring in normal animals, but much more marked in the low metabolism of thyroid deficiency (Magnus-Levy, 1897; DuBois, 1914). The heat production in Baselow's disease is also much above the normal. The metabolic effects of thyroid administration are shown by increased excretion of nitrogen (Ord and White, 1853; Mendel, 1893), and carbon dioxide and increased consumption of oxygen; with improvement of appetite and rapid loss of weight (Leichterstein, 1893). The first effect is on fat, the proteins being drawn upon when the fat has been reduced to a certain minimum. On a meat-free diet, the nitrogen increase concerns especially the uric acid and creatinin, whilst the uric acid and creatinin are very little changed (Krause and Cramer, 1912).

Total Nitrogen Excretion.—In dogs fed only on sugar, thyroid administration (0.2 to 0.15 Gm. of, the dried gland, per Kg) increased the nitrogen output about 30 per cent. in a 5 to 7 day period (Rohde and Stockholm, 1910).

Nitrogen Partition.—Jazey and Isaacson, 1918, found the ratio of urea and ammonia to total nitrogen unchanged by administration of thyroxin. Creatinin excretion was unaffected, even when there was extensive tissue destruction. Purin excretion was diminished after excision and in cretinism; increased after thyroxin and in Baselow's disease.

These results differ markedly from those of Krause and Cramer, 1912. These found that on a meatless diet, the nitrogen increase concerns especially the urea, ammonia and creatinin, whilst the uric acid and creatinin are very little changed.

Studzinski and Kamienski, 1915, state that thyroid administration increases the urine excretion in hypo-thyroidism, but not in normal subjects.

Basal Metabolism.—This is increased about 4 per cent. by 1 mg. of thyroxin, in adults of 150 lb.; and more by larger doses. In myxedematous patients, 20 mg. may produce an increase of 30 per cent. (Kendall, 1918, 1919).

Manner of Action.—It is doubtful whether the increased metabolism of carbohydrates is due directly to stimulation of oxidation, or whether it is an indirect result, perhaps of increased mobilization of liver-glycogen (Cramer and Call). The evidence is incomplete and contradictory.

Cramer and Cramer, 1918, found in rats that total removal of the thyroids and parathyroids does not impair the power of the cells to oxidize carbohydrates as judged by the respiratory quotient. This would indicate that the increase of carbohydrate metabolism in hyperthyroidism is not due to a direct influence of the thyroid on cell oxidation. They consider that the action of thyroid consists in mobilization of the liver-glycogen.

It is claimed that thyroidectomized animals do not utilize sugar on parenteral administration as well as normal animals (Underhill and Saikl, 1908); and that they do
not react with glycosuria to some of the procedures which are ordinarily effective (King, 1900).

Jammy and Isaacs, 1918, excised the thyroid from dogs, leaving the parathyroids. This resulted in hypoglycemia, with increased sugar tolerance. Similar findings have been recorded for myxedema and cretinism.

Increased Metabolism in Basedow’s Disease.—Du Bois, 1916, considers this the most definite feature of the disease. Heat production is 50 per cent. above the normal in severe, and 75 per cent. in very severe cases. The excessive heat production accounts largely for the tachycardia, cardiac enlargement, emaciation and mental irritability. This feature also throws light on the efficiency of treatment: Rest in bed for a week diminishes the excessive heat production by 10 per cent., or more; psychotherapy was also of value. Negative results were obtained with thyroidin, X-ray, thyroid "residue," ergot, quinin, and Beece serum.

The high metabolism means that the patients need 1 1/2 to 2 times as much food as normally expected.

In cretinism, the heat production was found 20 per cent. below. This was corrected in a few days by thyroid administration.

Similar results are reported by Means and Aub, 1919.

Halverson, Bergheim and Hawk, 1916, have also made a study of the effects of thyroid and thymus treatment on metabolism in exophthalmic goiter.

Use in Obesity.—Thyroid administration is often strikingly effective in reducing the fat in constitutional obesity (menopause, etc.), much less so in superalimentation. In any case, the result is not permanent and is connected with the sometimes dangerous effects described under over dosage. Only small doses should be used, under strict medical supervision.

The protein income should be kept high to compensate the loss (v. Noorden, 1915).

Other Therapeutic Uses.—Thyroid has been tried in the following conditions, but the inconsistent results indicate that it is probably useless: Skin diseases; porosis, eczema, lupus, chronic rheumatism, gout, arteriosclerosis, rickets, infantile cachexia, nephritis, etc.

Eppinger and Hofer, 1918, claims that local application of thyroid extract to bald spots promoted healing and especially the proliferation of epithelium. This too requires confirmation.

Uteral Growth and Development.—Guderensch, 1912, made the important discovery that feeding thyroid to tadpoles checks their growth, but at the same time hastens their development into frogs. This has been abundantly confirmed. The action probably consists in increased autolysis and phagocytosis.

The effect of the tadpoles is due to the thyroxin (Marine and Rogoff, 1916), specifically to the iodin component. This is in contrast to the effect on oxidative metabolism in mammals, which is due to the iodoxy group (Kendall, 1919).

The tadpole effect is therefore roughly parallel to the iodin-content of the gland (Levart, 1913), but the correspondence is not complete (Rogoff, 1917), since the B-Iodin fraction is inactive (Marine and Rogoff, 1916).

Rogoff, 1917, utilized this method for the standardization of commercial thyroid preparations. He found considerable variations in their activity.

Exposure to X-rays increases the efficiency of thyroid feeding on the tadpole metamorphosis (McCord and Mariboux, 1918).

Our Thyroid Constituents and Iodized Products Tested by Tadpole Method.—Morse, 1914, found that the nucleoproteins, lipoids, etc., of the thyroid are ineffective. Positive results are produced by iodothyroin, iodated tyrosin, iodized Witte’s peptone and iodin serum proteins; not by inorganic iodin or iodids, iodized starch, iodized lecithin, or agar algae. The activity therefore appears to be due to iodized amino-acid derivatives.

The insufficiency of inorganic iodids, however, seems to be of only quantitative; for these does not influence the metamorphosis of thyroidectomized tadpoles, which does not take place without this stimulus (Swingle, 1919).

Proteins.—The presence of thyroid tissue increases very markedly the multiplication of paramecium (Nowick and Shumway; Rudington, 1917).

Plant Growth.—Thyroid, when added to the culture medium, produces remarkable retardation of the root-growth of onion bulbs. This effect is not produced by potassium iodid, nor by pituitary or supraenal.
Susceptibility to Poisons.—The metabolic disturbances alter the destruction of poisons in the body. In mice, f.i., the toxicity of acetanilide is greatly diminished, whilst that of morphin is increased.

It has been suggested that many symptoms of Graves' disease may be secondary, due to lowered resistance against metabolic, intestinal, or other accidental poisoning.

Acetonitrile Test.—Hunt (1925, 1927, 1928) found that the administration of thymol to white mice, for a few days, markedly increases their resistance to acetanilide. The toxic effects of the latter are due to the liberation of HCN. Thyroid feeding does not affect the toxicity of HCN when administered as such; so that its protective influence must be due to a retardation of the metabolic processes which convert acetanilide into HCN.

In rats and guinea pigs it has the opposite effect, increasing the toxicity of the nitrile.

The acetanilide response is a delicate and nearly specific test by which a milligram of active thyroid tissue can be readily detected. It may also be used for comparing the relative activity of different thyroid products. This is found to go parallel with their iodin content. The administration of iodin therefore renders dogs' thyroid non-active. The prompt increase argues that the storage of iodin is the cause, rather than the result, of the activity. Thyroid in which no iodin can be detected by the ordinary chemical tests, as well as certain other organs, show a very feeble activity (Hunt and Seidel, 1928), and this may be due to traces of iodin compound, which are not revealed by the ordinary test.

Trendelenburg, 1910, and Lusky, 1912, claim that the blood of cats gives the test even after removal of the thyroids. This removal does not seem to alter the response of the mice. Application of the test to the blood of Básedow's disease has not given conclusive results.

Effect of Diet.—Certain diets, dextrine, oatmeal, liver, or kidney, also increase the resistance of the mice to the nitrile, as compared with cracker, milk, cheese or egg diet. This seems to be due to an action on the thyroid; for the difference is diminished if the thyroids are excised; and these glands present anatomic changes (Haut, 1910, 1911).

Thyrotropic Iodin Compounds.—Other iodin compounds also have some protective action, presumably by being converted into the thyroid compound. None reach the same activity, but they present interesting differences. The iodin of the seaweed, bladderwrack, is about 100 times as active as the iodin of potassium iodid (Hunt and Seidel, 1920); and a diet of seaweed increases the iodin content of the glands (Hauter and Simpson, 1915). Iodothyrtin has a varying activity (none, Trendelenburg, 1910).

Resistance to Morphin.—Thyroid feeding lowers the resistance of mice, rats and guinea pigs to morphin (Hunt). Gottlieb, 1931, claims to have demonstrated that this is due to lessened destruction of the morphin; and that the serum of a Básedow patient had a similar inhibitory effect, whilst normal serum hastens its destruction.

According to Olds, 1910, the resistance to morphin is not increased by excision of the thyroids, as might perhaps be expected.

PREPARATIONS—THYROID

*Thyroidum Siccatum (Thyroid, Sicc.,). U. S. P., B. P.; Dried Thyroid.—The dried and powdered healthy thyroid glands of sheep (and other animals used for food, U.S.P.). One part of the dried corresponds approximately to 5 parts of the fresh gland. The U.S.P. requires 0.17 to 0.23 per cent. of thyroid iodin. Dose, 0.1 Gm., 0.25 Gm., U.S.P.; 0.03 to 0.25 Gm., 0.5 to 4 gr., B.P. Raw or boiled glands (1/2 to 1/3 gland) have also been used, but have no advantage.

PARATHYRoids

These small glands were often excited with the thyroid, and their removal was responsible mainly for the convulsive symptoms and the fatality. Their function is apparently quite distinct from the thyroid; f.i., they are usually normal in cretins (Roussy and Clunet, 1910). They were discovered by Sandstroem, 1888, and their physiologic importance pointed out by Gley, 1892.

Actions.—Excision of the parathyroids from dogs produces tetany. This is temporarily relieved by the injection of parathyroid extract or nucleo-protein (Beibe, 1900), and also by calcium. This suggested that the glands are concerned with calcium metabolism (MacCallum and Vogtlin, 1909); but this does not seem to be the case (Coburn, 1910). The antagonism is merely due to the depressant action of calcium. Streptolysin
and sodium chlorid are similarly protective. The ammonia of the blood is increased by depression of the functions of the liver (Carlson and Jacobson, 1911). It is doubtful whether the ammonis increase is an adequate explanation of the symptoms. W. F. Koch, 1913, finds that the removal of the parathyroid leads to the appearance of toxic bases (guanidin, histamin, etc.) in the urine, which may be partly responsible for the symptoms.

D. M. Pátron et al., 1917, believe that the parathyroids regulate guanidin metabolism, preventing the formation of undue amounts; and thus regulating muscular tone.

The carbohydrate tolerance is lowered by excision of the parathyroids (Underhill and Bidlitch, 1909). Injection of the nucleo-protein produces polyuria and dilatation of the pupils (Ott and Scott, 1909 and 1910).

The administration of parathyroid extract also increases the 
vasoconstrictor response to nicotine, epinephrin and pituitary, involving therefore the most peripheral vasomotor mechanisms. This effect is also counterbalanced by calcium (Hokin and Wheelon, 1914).

Parathyroid hyperplasia is produced in foals by feeding with maize or wheat. This is hindered by calcium, increased by sulphuric acid and neutral sulphur (Marine, 1914).

Interrelation with Thymus.—Uhlenhuth, 1918, found that mammalian thymus produces convulsions when fed to the larvae of salamanders. This occurs only before their parathyroids have developed. Apparently, thymus contains tetanic poisons, which are antagonized by the parathyroids. Calcium and magnesium also check the thymus convulsions, but much less perfectly.

Therapeutic Uses.—Parathyroid has been administered in tetany resulting from removal or disease of the gland, perhaps with some benefit. It has also been tried in paralysis agitans (Berkeley, 1909), in infantile and gastric tetany, eclampsia and chorea, but the results are so inconsistent that it is probably useless.

Toxic Actions.—Morris, 1915, describes mental symptoms in a patient which he is inclined to attribute to the prolonged administration of large doses of parathyroid.

Desiccated parathyroid gland consists of the dried external parathyroids of the ox, representing about 6 parts of the fresh tissue. Average dose, 6 mg., 1/6 gr., four times daily. Fresh glands or hyperemic injections of fresh glands have sometimes given better results.

PINEAL GLAND

This is a vestigial remnant of a primitive dorsal eye, but presents some evidence of glandular structure, with sympathetic innervation. It begins to involute early in life, between the seventh year and puberty; but its degeneration is never complete.

The literature of the pineal gland abounds in apparently contradictory results (an extensive bibliography is given by McCord, 1917). The phenomena seem to be confined to the prepubertal years, i.e., before the gland has undergone involution.

Epiphysias of the pineal gland are said to be often associated with precocious physical, mental, and sexual development, and general overgrowth of the body. Only a few cases are on record, and the reliability of the connection is not established.

Epiphysial experiments have not yielded conclusive results. The early effects are comparable from traumatism. There are no late changes in adults; in young animals, slalion is said to lead to precocious development (Sarteschi, Foal), but the effects, at best, are not very striking.

Intravenous injection of extracts does not have any pronounced action on the circu-

lation (Dixon and Haliburton, 1909). It is also practically inactive on excited heart and uterine or intestinal muscle (Fenger, 1916). Ott and Scott, 1912, claim that it increases the milk secretion in goats. This would need to be confirmed.

Continuous Oral or Hypodermic Administration.—Hardened growth and development of young animals has been reported (Dana and Berkeley; McCord, 1914); but these seem to have been experimental accidents, since the careful experiments of Sisson and Finney, 1912, failed to show any effect, at any period.

Toadpole.—Feeding with pineal histens growth and differentiation. There is also a second constituent which contracts the pigment under the skin, thus rendering the color much lighter (McCord and Allen, 1917).

Protocere.—Paramecia fed with pineal divide twice as rapidly as controls (McCord, 1917). Pineal extracts increase the pulsation frequency of the contractile vacuole, as do also ephedrin and pituitary solution (Weather, 1916).
PHLORHIZIN

General Statement.—This glucosid produces a unique glycosuria by forcing the kidneys to the excretion of dextrose, with polyuria and acetonuria, leading to loss of sugar, and thus to the production of sugar from proteins, greatly increased excretion of nitrogen, etc. The phenomena are of great scientific but of no therapeutic importance (Critical Review, G. Lusk, 1912).

Phlorhizin was isolated by Koninck, 1835, from the root-bark of apple, pear and similar trees. Stas, 1839, showed it to be a glucosid, decomposed by acid hydrolysis into dextrose and phlorin; and the latter again into phloretinic acid and phlorhizin. The characteristic glycosuria was discovered by Mering, 1886. It has been produced in all vertebrates tried: mammals, birds, frogs and reptiles. The phlorhizin is injected for the most part unchanged (Pietkiewicz) within two days (Fraunheit). The glycosuria outlasts the excretion.

The amount of glucose in the urine may be very high, above 12 per cent. It persists for several hours after a single injection, but may be prolonged indefinitely at its highest degree, by administering 1 Gm. of the glucosid per kilo of body-weight, by mouth, three times a day. Larger doses do not increase the glycosuria.

The Glycosuria is not Pancreatic.—The symptoms after phlorhizin resemble those of pancreatic diabetes, but their mechanism is in fact totally unrelated. The net striking fact is the absence of hyperglycemia. With phlorhizin, the sugar of the blood is diminished (Mering); if the kidneys are excised, or the ureters tied, the blood sugar remains normal (Minkowski; Schabad, 1892. According to Underhill, 1911, it may rise, indicating overproduction of sugar, but this plays at most a minor part.

The Action is Renal.—It is evident from these experiments that the glycosuria is due essentially to more ready elimination of sugar by the kidneys. The effect is peripheral, for it occurs after destruction of the medulla and cord, and after section of all renal nerves (Frey). If the phlorhizin is injected into one renal artery, glycosuria occurs in this kidney and not in the other (Ganz). Mosberg, deduced by the Neubauer arrangement that the sugar excretion occurs in the tubules, but the evidence is not conclusive. Nishi found that the cortex contains more sugar than the medulla, while the reverse holds normally. Histologic changes have also been described in the ureter epithelium. Carmin and methyl blue, which are also excreted by the tubules, may suppress the glycosuria.

The excretion of sugar is proportional to the activity of the kidneys; it is diminished, for instance, when one kidney is excised, and increases again as the remaining kidney hypertrophies (Schilling, 1904). The glycosuria is suppressed in severe nephritis, and the injection of phlorhizin (phlorhizin test, 5 mg. in warm water, hypodermically) has been proposed as a means of diagnosis. The result, however, is not decisive in either sense.

Other Renal Functions.—Diuresis occurs (Frey, 1906; Loewi and Neubauer, 1908), presumably as a result of the glycosuria, but is relatively small. The excretion of the other solid constituents, salts, protein, etc., shows no constant abnormalities. The oxygen consumption of the kidneys is largely increased. The milk after phlorhizin contains the normal amount of lactose, and no dextrose. Traces of sugar appear also in the saliva and gastric and pancreatic juice (R. G. Pearce, 1916).

Nature of the Action.—The evidence is unsatisfactory and contradictory. Cunby, 1917, considers that it tends to prove that the glycosuria is due to inability of the tubules to absorb sugar from the glomerular filtrate.

The glomerular membrane of perfused frog kidneys is normally impermeable to certain concentrations of glucose (Hamburger). This impermeability is destroyed by phlorhizin (Brickman, 1910). This is in line with Mering's original assumption that the phlorhizin action consists in increased permeability of the kidneys. It appears, however, that this is not the whole explanation for living animals. Levene, *i.e., four* more sugar in the blood of the renal vein than in that of the renal artery. Minkowski
PHLOHRHIZIN

suggested that the phlorhizin acts as a glucoidal vehicle, splitting off its sugar in the kidneys, and again taking up sugar from the tissues; but the quantity of sugar excreted when phlorhizin is injected into the renal artery speaks against this view.

Pavy, Brodie, and Slau (1903) have shown that the quantity of sugar which is excreted when the other abdominal viscera are excised exceeds the quantity of sugar which disappears from the blood, and that which could be derived from the limited glycogen deposits of the muscle.

This indicates that phlorhizin causes the kidneys to assume the function of forming sugar from the proteins of the blood, and of secreting this into the urine, i.e., a function analogous to that of the mammary glands. They supposed that the sugar of the blood rises in loose and firm combination with the blood proteins; the phlorhizin causes the kidney to secrete first the loosely combined sugar; and when the supply of this fails, the firmer combination is attacked. The stock of carbohydrates in the body therefore disappears first, although some glycogen is retained very persistently (Mering), even in fasting (Sanson and Woodyatt, 1915). With persistent administration, the sugar is derived from the carbohydrates of the food; and if these are excluded, from the proteins. Eduction of the liver (Eck's fistula) does not influence the glycoursia (Foster, 1912).

In complete phlorhizin poisoning the ability to oxidize sugar is also impaired, so that dextrose, when injected hypodermically, is completely excreted (Stiles and Linsk).

Liver-glycogen.—Phlorhizin does not mobilize the glycogen directly, but only as a result of the hypoglycemia. On the contrary, when the kidneys are excluded, phlorhizin leads to a re-accumulation of hepatic glycogen. Since there is no hyperglycemia, it appears that phlorhizin stimulates directly the synthesis of glycogen. When the kidneys are intact, this action is overcome by the glycoursia (Eptin and Baehr, 1915).

D + N Ratio.—In the urine of depancreatized dogs, fasting or fed on meat or fat, Mikowski found that the weight of dextrose divided by the weight of nitrogen gave a constant ratio of 2.8. This signifies that 45 per cent. of the protein molecule is excreted as dextrose. A ratio greater than this shows that some of the sugar ("extra-sugar") is derived from other sources. Phlorhizin produces the 2.8 ratio in fasting rabbits, cats, and goats, after the "extra-sugar" has been flushed out. In dogs, the ratio is 3.67, so that 38.7 per cent. of the protein is excreted as dextrose. This ratio is also found in cattle, sheep, and other domesticated animals.

Sources of the Sugar.—Feeding with meat or gelatin increases the dextrose excretion, but leaves the ratio unchanged, showing that their conversion into sugar takes the ordinary course. Glycocol, alanin, leucin, asparagin acid and glutaminic acid are more or less completely converted into dextrose. The following are also converted and tested as dextrose, and therefore raise the D + N quotient: levalose, lactose, d-lactic acid, glyceral, lactic acid, propyl alcohol. Feeding with fat, ethyl or butyl alcohol and tannin have no influence, so that no dextrose can be formed from these sources.

Total Metabolism.—The calories lost by the glycoursia are compensated by increased nitrogen metabolism, the fat metabolism remaining unchanged. In fasting animals the N excretion may be increased to four or five times above hunger alone (Reilly, Nolan and Linsk).

Acidosis.—In starving animals phlorhizin produces fatty changes in the liver, with increased excretion of ammonia, beta-oxybutyric acid and acetone substances (Mering). This is prevented if plenty of carbohydrates is given (Moritz and Praunzitz). It is increased by the ingestion of butyric acid or butter-fat. These changes are analogous to those caused by other agents producing inordinate protein metabolism.

Phlorhizin Test of Renal Function.—This is described in N.N.R. It has not maintained itself, although it is still recommended by some (for instance, Krotoszyner and Strom, 1917). These authors use 0.01 gm. in 2 c.c. of saline intravenously. Carris, 1913, has also suggested glycoursia after lumbar subdural injection as an indication of meningitis. Normal meningitis being impermeable to it, no sugar appears in health.

KIDNEYS

There is no good evidence for or against the formation of an internal secretion by the kidney (Critical Review, Pearce, 1906). Injections of kidney extracts produce blood-pressure changes (Pearce) corresponding to the urine in them. Therapeutically, the administration of kidney preparations has been tried in chronic nephritis, without convincing results. A few apparently favorable cases are described by Formanek and Riedel, 1907.

Foster, 1912, claims to have isolated a crystallizable toxic substance from the blood of uremic patients, which is not present in normal blood.
RED BONE MARROW

This contains lecithin, hemoglobin and other organic iron compounds. Glycerine extracts have been tried in anemias, to stimulate the production of corpuscles. The results are not convincing. The extracts also contain pressor and depressor principles (G. H. Brown and Guthrie, 1925; Brown and Joseph, 1926).

THYMUS

General Statement.—This gland has been credited with relations to the thyrotoxic apparatus, and to growth. However, careful experiments failed to demonstrate any detectable alteration in any body structure and function after its extirpation (E. A. Park and McClure, 1910). The older results were probably accidental consequences of bad hygiene.

Effects of Injection.—Intraperitoneal injections of thymus extracts into guinea pigs result in muscular spasm, dyspnea and convulsions. Smaller doses lead to loss of weight (Olken, 1918).

Ott and Scott, 1912, described increased milk secretion in goats, following the administration of boiled extracts.

Frog Larva.—Feeding with thymus hastens growth and retards metamorphosis (Gudernatch); but only as does any other food (Swingle, 1917; Uhlenhuth, 1917).

Salamander Larva.—Thymus produces convulsions when fed to salamander larvae that are devoid of parathyroid; see Parathyroid (Uhlenhuth, 1918).

Therapeutic Uses.—Thymus administration has been tried, but with very doubtful results, in Graves’ disease, rickets, tuberculosis, hemophilia, infantile atrophy and marasmus. Other lymph glands, spleen, etc., have also been employed in obscure conditions.

ERGOT

General Statement.—Ergot (Secale cornutum) is a fungus (Claviceps purpurea) growing in the grain of cereals; the official being obtained from rye. The fungus goes through several stages of development, the resinous stage (sclerotium) constituting the drug. It is used mainly to contract the uterus (by peripheral action) and thus check postpartum hemorrhage. It also stimulates other forms of unstriped muscle, especially the intestine and blood vessels. The consumption of grain infested with ergot leads to gangrene and spasmodic effects. Epidemics of this “ergotism” were formerly frequent and must have occurred in antiquity, although the causal connection was not recognized. It is now very rare in civilized countries, the ergot being removed by the modern methods of treating the grain. The uterine effect was learned from midwives and is first mentioned by Lonicer, 1565. Its use in regular medicine dates practically from Stearns, 1807 (N. Y. Med. Repository).

Active Constituents.—The composition of ergot is complex; several active constituents have now been isolated in pure form. The most important are: the alkaloid Ergotoxin, several aromatic amins, especially Tyramin and Histamin, and cholin derivatives. The numerous names applied to these and to impure mixtures render the literature very confusing.

Ergotoxin or Hydroergotin, C_{33}H_{43}N_{6}O_{5}, an amorphous alkaloid occurring in alcoholic extracts. It is responsible for the characteristic action on the cock’s comb and is concerned in the uterine and vascular effects. It is rather unstable and by loss of H_{2}O changes into its lactot: Ergotnin or Ergotin, C_{32}H_{42}N_{6}O_{6}, a crystalline alkaloid with very weak actions.
Both alkaloids exist ready-formed in ergot, but can be easily converted into each other by chemical means (Barger and Ewings, 1910). Both are insoluble in water and petroleum ether, sparingly soluble in ether, and readily soluble in most other organic solvents. Ergotoxin is easily soluble in cold alcohol; ergotinin but sparingly. They dissolve in dilute NaOH, but the ergotinin is partly converted. Their salts form colloidal solutions with water, but these are precipitated by electrolytes (salts or mineral acids).

**Tyrnamin.** Ergotamin, uteramin, or para-hydroxyphenylethlyamin; this is closely related to epinephrin in structure and action. It is mainly responsible for the pressor effect, and is not important in the uterine action.

**Histamin.** Ergotidine, Ergamin, beta-iminazolyl-ethylamin, 4-beta-aminoethylglyoxyalin: lowers the blood pressure, and stimulates the excised uterus powerfully.

A number of other aromatic amines occur casually; such as *agmatin*, guanidobutyralam (Engelhard and Kutscher, 1910), which has a weak stimulant action on the excised uterus; isoamylamin, etc.

These aromatic amines are also produced in the putrefaction of meat, and in the intestinal tract, and have been prepared synthetically. They are generally insoluble in ether or chloroform, readily soluble in water; precipitated by phosphotungstic acid. Chemically, they are derived from the amido-acids by the elimination of CO₂.

\[
\begin{align*}
R & \quad \text{thus becomes} \quad R \\
\text{CH}_{2}\text{NH}_2 & \quad \text{CH}_2\text{NH}_2 + \text{CO}_2 \\
\text{COOH} &
\end{align*}
\]

In this way, Tyrnamin is prepared from Tyrosin; Histamin from Histidin; Agmatin from Arginin; Isoamylamin from Leucin. An authoritative discussion is contained in Barger's "Simpler Natural Bases," 1914.

**Acetyl Cholin.**—This was found in ergot by Ewings, 1914. It is responsible for the cardiac inhibition.

**Investigations of the Composition of Ergot.**—A large number of *constituents* has been described in ergot: Alkaloids, amines, resinsous acids, glucoses, betain, and cholin, fat (5 per cent.), some peculiar sugars, coloring matter, etc. The red pigment (Sideroythrin) is important for discovering the presence of ergot in bread.

There has been much animated discussion as to the rôle of the several constituents in the action of the drug, and the matter is not yet altogether decided. The confection of the older literature is explained partly by the instability of the principles, but mainly by the difficulty of isolating them pure. The impurities alter their characters sufficiently so that successive investigators have repeatedly described the same principle, somewhat differently contaminated, as different substances. Physiologic actions have been ascribed to substances which these owed solely to their contaminations.

The modern conception dates mainly from the work of Barger, Carr and Dale, 1906 and 1907, on the isolation of the ergot alkaloids. Their papers also give the historical data. By the discovery of the crystalline phosphate of ergotoxin, they succeeded for the first time in preparing this principle uncontaminated; and in determining its properties and its relation to ergotinin, which Tanret had isolated in 1874. Kraft, 1906, arrived independently at the same results. Dale found that the ergotoxin produces the characteristic effects of ergot. Barger and Dale also showed that the alkaloidal and resinsous principles (spahcellinic acid, spahcelotolin, etc.), isolated by earlier investigators, contain large proportions of this alkaloid; and that their apparent activity can be fairly attributed to the latter. On the other hand, they pointed out that the methods of preparing extracts of ergot tend to eliminate this alkaloid; and that it is therefore necessary to assume the presence of other, water-soluble principles. In 1906, Barger, Dale and Dixon found these to consist of tyramin and histamin (1910).
Impure Principles.---These are still important for understanding the older literature. They are classified by Barger and Dale as follows, in chronological order:

Wenzel, 1864: Echoline and Ergotine = mixtures of the alkaloids, containing choline (Meichenhoff, 1890).

Tanzet, 1872: Amorphous Ergotinine = impure mixture of ergotin and ergotoxin.

Dragendorff, 1877: Pteridineline = ergotin, possibly mixed with some ergotoxin.

Fedwysztiek, 1883: Sclerotineline = ergotin.

Kobert, 1884: Sphenelocinic Acid = inactivated resin with adherent alkaloids.

Corusin = alkaloidal resin, probably containing some ergotoxin, and perhaps some active alkaloidal decomposition products.

Ergotinic Acid = a sapotoxin.

Keller, 1896: Corusin = impure mixture of ergotin with ergotoxin.

Jaccobi, 1897: Chrysosulin = inactive yellow coloring-matter with small proportion of adherent alkaloid.

Selotineline = mixture of ergotin and ergotoxin.

Sphenelocin = impure ergotoxin.

Selolin = impure ergotin.

Kraft, 1906: Hydroergotin = synonym for ergotoxin.

Vahlen, 1906 and 1908: Celosin = inactive mixture, consisting of nearly equal parts of leucin, isoleucin and valin (Van Slyke, 1909).

Marino-Zucchi and Pasquero, 1911: Clavispin: claimed to be an active glucosid; not yet confirmed.

Ergotin is a name applied to a variety of pharmaceutic extracts, generally prepared in such a way that they must contain mainly the amines, and relatively little of the alkaloids.

ACTIONS OF ERGOT

The effects of the various ergot constituents are so much modified when they are present together, that it is advisable to describe first the actions produced by ergot itself.

Uterine Actions.---The most important use of ergot is in obstetric cases. The clinical effects are well described by Sharp, 1911. In labor, the ordinary doses improve the uterine tone, and collect small irregular and non-effective pains into larger effective contractions. Small doses may inhibit the contractions. Excessive doses produce prolonged tonic contraction.

When proper doses are used during labor, with the os fully dilated and no obstruction, they tend to hasten normal delivery. Really effective doses, however, are rather dangerous to mother and child. The firm contraction may hinder delivery, and compress and asphyxiate the fetus; even rupture of the uterus has been reported; but these accidents are very rare.

The most extensive employment of ergot is after the delivery, to hasten and sustain the normal retraction; thus obliterating the open sinuses, and checking postpartum hemorrhage. In early pregnancy, its effects are much less certain. Contrary to popular opinion it is not abortifacient unless dangerous doses are long continued.

The uterine effects are due mainly to ergotoxin and histamin side somewhat by tyramin. Ergotoxin has been used therapeutically and acts more promptly (four minutes after hypodermic injection, Sharp). Pituitrin is now being employed considerably.

Ergot has also been used in other forms of uterine hemorrhage and in chronic metritis; but is probably of little value apart from obstetric conditions.

Administration.---The usual dosage is 2 to 5 c.c., 1/4 to 1/3 of the fluid extract, or the equivalent of the solid extract, which is eight times as
strong. They may also be used hypodermically or intramuscularly. The response to ergot is quite prompt even when taken by mouth; it appears in fifteen to thirty minutes and lasts half an hour (Brady, 1910). Opium delays but prolongs the effects; moderate chloroform anesthesia does not modify them (Sharp).

**Mechanism of Uterine Action.**—The action is peripheral, since it occurs also in the eroded uterus (Kurkdjrovski, 1906; Feller, 1906; human, Ruebeamen and Kligermann, 1912). Moderate concentrations increase the tone and the automatic contractions; high concentrations produce tetanus of the uterus. (François, 1912, cautions about the interpretation of the phenomena.)

La Torre, 1912, found interesting histologic changes in the uteri of dogs treated with ergot. They consist in contraction of all the muscular uterine layers and of the arterial muscle; being especially marked in pregnancy when the muscle is hypertrophied. The retraction of the muscle is so great that muscle seems almost absent. The smaller vessels going through the muscular layer to the mucosa are greatly compressed, while the larger vessels are dilated. Paradoxically, it appears as if the volume of muscle were diminished, and the lumen of the uterus increased. The interpretation is difficult.

**Blood Pressure.**—This is practically unchanged, in man (Sharp, 1911), or animals, unless the ergot is injected into a vein. This produces considerable, but inconstant and complex changes. The variability is largely explained by the conflicting actions of the different constituents, and by dosage and other conditions.

Sometimes there is a large but brief fall from direct cardiac depression, followed by a slight but prolonged rise from direct cardiac and vascular stimulation (Sollmann and Brown, 1905). The fall is presumably due to histamine and acetyl-choline; the rise to ergotoxine and tyramine. Other experimental authors (Cronyn and Henderson, 1909; Edmunds and Hale, 1911) found the same. The rise is greater if the vasomotor center has been destroyed, and it is therefore due to a direct peripheral action on the vessels (Jacob, 1897; Wood and Hofer, 1910). Excised arteries (except the pulmonary) are also constricted (Cow, 1911). The vasoconstriction occurs also in calcium-free solutions (Pearce, 1925), and is due to ergotoxine and tyramine. The vasomotor center is not affected by ergot or ergotoxin (Pflichter and Sollmann, 1915).

The pressure in the pulmonary artery is increased, whether the carotid pressure is rising or falling (Wood, 1911). Mellin, 1904, Plummer, 1905, and Andreae, 1915, attribute the rise to constriction of the pulmonary vessels; Dixon to increased output of the right ventricle. Wiggers, 1911, showed that ergotoxine produces both effects.

Very large doses of ergot paralyze the vagus center, and the vasomotor endings (epinephrin becoming ineffective, whilst barium is still active) (Sollmann and Brown, 1905). This “vasomotor reversal” is due solely to the ergotoxin (Dale, 1905).

**Ergot as General Vasoconstrictor.**—The efficiency of ergot in postpartum hemorrhage, and the vasoconstriction observed in animal experiments, have led to its use against hemorrhage in other situations. However, the conditions here are altogether different; for, as ordinarily administered, it does not affect the blood vessels or blood pressure. Its use is therefore irrational (Bradford and Dean, 1894). It is also useless in pulmonary hemorrhage (Frey, 1909). It has been praised rather uncritically in a great variety of other conditions, which it would be useless to enumerate.

**Cyanosis of the Comb of the Fowl.**—When ergot preparations are administered to roosters, in about an hour the tips of the comb and wattles become blue and cold, the effect lasting several hours. It may be preceded by temporary blanching. This reaction is used for testing the quality of ergot (see below). It is due to ergotoxin; histamin produces a similar but much prompter effect (Crawford, 1913); tyramin is ineffective. The mechanism of this cyanosis is not understood.
It has been attributed to vasoconstriction; but the cyanosis does not occur after other vasoconstrictor drugs; whilst it is produced by paraesthesia which lowers blood pressure (Crawford), by capsaicin (Ellinger, 1908) which injures capillaries; and by other drugs which cause vascular injury (large hypodermic doses of cane-sugar, pipera- xin, chronic acid, etc.).

**Gangrene Action.**—This is a characteristic feature of chronic ergot poisoning in man and in many animals. It is most readily studied in roosters.

If ergot is given repeatedly to roosters, the bluing persists in the tips of the comb, and gradually involves the entire comb and the wattles. Eventually, these appendages undergo gangrene and may drop off. The extremities may also be involved; in one experiment, the entire wing fell off after a few days.

**Histologic Changes.**—V. Recklinghausen, 1881, showed that the larger arteries, but not the veins, of the gangrened comb are occluded by baseline thrombi. The capil- laries are congested with red corpuscles. These results were confirmed by Gruncel, 1890. They are generally referred to very violent constriction of the small arteries, interrupting the blood stream. This explanation is entirely hypothetical. Kraynak observed formation of thrombi in a variety of conditions; and it is probably a result of a toxic effect on vascular endothelium. No histologic changes are found in the acute cyanosis.

**Susceptibility of Different Animals to Gangrene.**—Pigs are quite susceptible to the gangrene action of ergot. They react especially by purulent eruptions on the skin; the ears are particularly susceptible. Horses and cattle show similar changes. Horses is quite subject to the gangrene, which begins in the extremities. The fingers, toes, or an entire member may slough off. Dogs and rabbits do not seem to be susceptible to this action.

The cause of the varying susceptibility has not been demonstrated. It may be due to physiologic peculiarities, or merely to anatomic differences. The gangrene always begins in those situations in which the circulation is weakest. It differs in no essential from gangrene produced by any other cause. It may be dry or wet, according to whether liquefying bacteria are absent or present.

Salant and Hecht, 1924, describe a habituation tolerance to the action of ergot on the cock’s comb and to the fatal dose.

**Alimentary Canal.**—Injection of ergot or ergotoxin (10 mg. for rabbits, intravenously) results in marked increase of peristalsis through the whole alimentary tract, and increased intestinal motor response to vagus stimulation (Meltzer and Githens, 1908). This produces violent diarrhea and vomiting. The emesis, however, is largely central (Engleston and Hatcher, 1915).

In chronic poisoning, these direct effects are aggravated by vascular stasis, advanced cases showing ecchyrosis, ulcer formation, etc. The ulcers involve particularly the lymph follicles, in which the blood supply is poorest. The stasis may lead to effusion of blood into the lumen of the intestine. The appetite is lost. This action on the al- mentary canal is also most marked in the animals mentioned, but occurs in others. The liver of roosters shows peculiar degenerations, resembling amyloid.

**Isolated Bronchial Muscle.**—Ergot has no effect (Titone, 1913).

**Central Nervous System.**—This is affected both directly and indirectly, and the effects are correspondingly variable. With moderate doses, the flow through the cere- bral vessels is increased. Small doses may cause mediatory stimulation (vagus slowing, increased respiration, convulsions, etc.). Large doses of ergot cause death by medullary paralysis. It has a narcotic effect for roosters.

**ERGOTINIC ACID**

This has a typical sapotoxin action. Taken by the mouth it produces no effect beyond local irritation, as sapotoxins are not absorbed. If injected subcutaneously or intravenously, it will produce paralysis of the central nervous system and of protozoa generally. It causes peripheral paralysis of blood vessels, and thereby lowers the blood pressure.

**ACUTE ERGOT POISONING**

This is rare in man, but may occur by attempts at abortion. The symptoms are vomiting, diarrhea, vertigo and confusion, precordial distress, dyspnea, muscular pain, paresthesias and anesthesias, disturbances of vision and speech, epileptic convulsions.
small pulse, loss of consciousness. In pregnancy, uterine hemorrhage and abortion if the dead fetus are frequent. Recovery after severe poisoning may take several days.

Rosenbloom and Schildmeer, 1914, have isolated ergotin crystals from a patient end of acute ergot poisoning.

**CHRONIC ERGOT POISONING, “ERGOTISM”**

This is now mainly of historic interest. The initial symptoms are

-**Historical.**—Ergotism was formerly very frequent endemically in consequence of the presence of ergot in flour, and the population of large tracts of country have been poisoned. The last large epidemic in the United States occurred in New York in 1872, since the cause has been recognized these epidemics have been less frequent, but in mauls they still play quite an important role (Schnack, 1897). A comprehensive account of the history of ergot is given by Kober, 1869.

-**Symptoms.**—The initial stage is ushered in by disturbances of the peripheral sensory apparatus. There is formication in the skin and various other disturbances of cutaneous sensation. Hypoesthesia and anesthesia exist at the same time in different parts, or even in the same part, the skin being hypoesthetic to some forms of stimulation and anesthetic to other forms.

These disturbances of sensation begin at the extremities and spread upward. This distribution favors the view that they are manifestations of changes in the circulation, since these would make themselves felt first of all in the extremities. The disturbance in sensations also involves the alimentary canal. There is apt to be at once nausea, hunger, and loss of appetite. Digestion is much impaired on account of the disturbed circulation. Diarrhea and vomiting are very common. The vomiting is partly due to the disturbed circulation and partly to the action on the center. The central sensory apparatus also shows changes at this time. There is violent and persistent headache and central disturbances of the special senses. The motor system also begins to show abnormal symptoms, such as twitchings and tremors, most marked in the extremities and in the tongue.

In all these effects of ergot it is extremely difficult to say to what extent the phenomena are caused by the central, and to what extent by peripheral, actions. They are probably largely dependent on disturbances in circulation, and these may in some cases be more prominent in the central nervous system; in others, peripherally.

At this point the sensory symptoms have reached their acme, and do not become any worse, but persist as they have been described. But the motor phenomena go on increasing; the twitchings pass into spasm, and then into permanent and often very painful contractions. Always beginning at the extremities, they involve the terminal phalanges of the fingers and ascend to the other joints. The facial muscles also participate. The type of these contractions shows that their origin is central. They are not absolutely persistent, but last for about half an hour; then pass off for a time, and reappear. This is very different from spasms of peripheral origin, such as those of lead-poisoning. The smooth muscles also may participate in these contractions; especially that of the bladder; so that there may be involuntary evacuation of the urine, tenesmus, etc.

The pulse is always hard and small, pointing to a high blood pressure. Its frequency, however, is variable. It is usually slow, due probably largely to the high pressure.

So far the symptoms, the initial stage, are common to all the different forms of ergotism; they can be accounted for partly by the changes in the circulation and partly by the direct action of the ergot principles themselves. In the second stage the circulatory disturbances become more marked. The phenomena already seen—the disturbances of sensation and the contractions—persist; but to these are added secondary effects due to the prolonged slowing of the circulation. These may be most marked in the central nervous system or in the extremities. The former give rise to the so-called spasmomorphic form of ergotism. The predominance of stasis in the extremities produces the gangrenous form. Why one action should predominate in some individuals, and another action in others, is not explained. Perhaps there may be some differences in the anatomic arrangement of the blood vessels or extent of the innervation.

(A) The gangrenous form may have been indicated somewhat earlier. Pustules may have formed in the skin, which are due to this defect of circulation. In more
marked degrees it affects the extremities. The entire member may be involved in the gangrene, which differs in no respect from any other gangrene; it has its line of demarcation, and may be wet or dry according to bacterial infection. The finger, toe, or limb may slough away without bleeding. (B) In the spasmotic form the contractures pass into tonic and clonic convulsions or epilepticform spasms. Since any part of the central nervous system may be affected, the exact symptoms may be extremely variable. It may be repeated that they are due to a defective circulation in the central nervous system, which leads to stimulation and then to paralysis. Both forms, the gangrenous as well as the spasmotic, are therefore due to changes in circulation, and are determined by the ergotoxine.

The treatment of ergot poisoning can be only symptomatic.

DETERIORATION

The ergot alkaloids and amines are rather unstable substances; and it has long been observed that ergot loses its activity with age. Ergotism is said to have occurred only during the first four months after harvest (Poulsson). Many pharacopoeias therefore direct that ergot must not be older than one year; but the fluidextracts on which the reputation of ergot is mainly based have probably all been aged for a year before being sold (Eldred, 1913). The alcoholic preparations probably keep better, but no exact data are available. The activity of ergot should therefore be ascertained, at least qualitatively, by bio-assay.

Using the cock’s-comb test, Haskell and Eckler, 1917, found that the activity of the fluidextract remained practically unchanged for two and one-half years, then deteriorates gradually, so that it has fallen to about one-half in three and one-half years. Special proprietary preparations are very unreliable.

BIO-ASSAY

The complex composition of ergot makes chemical assay practically out of the question. The same objection, but to a lesser degree, holds for the bio-assay (Edmunds and Hale, 1914). The idea would be to measure the therapeutically desirable effects; but it is not certain that any of the present methods accomplish this result. The cock’s-comb test is the most widely employed and probably the most satisfactory. This reaction was described by Lorinser, 1854; used experimentally by Greenfield, 1892 and 1895, under Kobert; and applied commercially by Houghton, 1898. The details are described by Edmunds and Hale, 1917, and in U.S.P. IX. It estimates mainly the ergotoxine, but is also affected by the histamin. Its results agree very closely with the more complex uterine method of Edmunds, 1908. Another uterine method is described by F. E. Stewart and Fittenger, 1913. Dixon, 1905, and Wood and Hober, 1910, propose the blood-pressure rise as a test; but this gives conflicting results, as might be expected from the opposing actions of the constituents.

PREPARATIONS—ERGOT

Ergot. U.S.P., B.P.; Ergot1 (Secale cornutum).—A fungous growth, Claviceps purpurea, from rye.2 Generally collected in Russia or Spain. Should not be older that one year. Dose, 2 Gm., 30 gr., U.S.P.; 1 to 4 Gm., 25 to 60 gr., B.P.

Ext. Ergot. U.S.P.—A pilarul extract, prepared by defatting ergot with benzol, extracting with acidulat alcohol, and evaporating. Dose, 0.25 Gm., 4 gr., U.S.P.

Ext. Ergot., B.P.; Ext. Ergot, Purif. (Ergotina Bonjean).—A soft watery extract, purified by partial precipitation with alcohol. Dose, 0.12 to 0.5 Gm., 2 to 8 gr.

Ergotina.—This name has been applied to very different preparations.

Those that occur most extensively in the older literature are:

Ergotina Bonjean: Aqueous solid extract, purified with alcohol.

Ergotina Wurmac: Dialyzed extract, marketed both as a liquid, and as a soft extract.

Ergotina Wiggers: Dried, alcoholic, purified solid extract.

Ergotina Yeom: Fluid extract prepared with dilute solid tartaric acid.

Haskell, 1914, found that “ergotin” and powdered extract produced all the typical effects of ergot; but that the effects on the uterus are weakened much more than those on blood pressure.

1 From the French, “ergot,” a cock’s spur, which it resembles in appearance.
2 Claviceps purpurea growing on a Southern forage grass. Pastureum, produces toxic effects on seeding. They have not been studied in detail (H. B. Brown, 1920).
*Vindemia* *Ergot* (Fl.: *Ergot*), U.S.P.—Prepared with aciddulatated dilute alcohol. *Dose*, 0.2 to 0.6 c.c., 30 minutes, U.S.P.

*Ext. Ergot., Liqu.*, B.P.—An aqueous solution, preserved with alcohol. *Dose*, 0.6 to 1.5 c.c., 10 to 30 minutes, B.P.

*Inf. Ergot.*, B.P.—1 per cent. *Dose*, 30 to 50 c.c., 1 to 2 ounces, B.P.

*Fæce* Ergot., B.P.—33 per cent. of *Ext. Ergot.*, B.P., preserved with 1 per cent. of phenol. *Dose*, 0.2 to 0.6 c.c., 3 to 10 minutes, B.P.

*Tr. Ergot, Ammon.*, B.P.—25 per cent., with dilute alcohol and ammonia. *Dose*, 2 to 4 c.c., 1/4 to 1 dram, B.P.

Ergotitoxus Citrinus, N.N.R.—The weaker alkaloid of ergot. *Dose*, 0.3 to 0.6 mg., 1/4 to 1/8 gr., hypodermically, N.N.R.

Ustilago Maydis.—Corn Smut.—A fungus analogous to Ergot, found on the corn plant. Little is known about its composition or action, although it has been employed by the negroes for abortion, and stock-raisers have also observed that it has an ecbolic effect. Kobert states that it does not produce the ergot action on the cock's comb. He must have worked with old samples, since the author obtained the typical darkening from several different samples. However, the action is quite weak, and the drug does not deserve much attention unless it should be possible to isolate the principles in more active form. It contains resin.

**ERGOTOXIN**

This is concerned in the stimulation of the uterus; the vasoconstriction; the bronchial constriction; the intestinal irritation; the gangrene; and the vasomotor reversal. It produces a powerful and prolonged peripheral stimulation of smooth muscle, particularly in the arteries and uterus. Large doses paralyze the augmentary sympathetic endings (myoneural junction) which are stimulated by epinephrin (Dale, 1905, 1906 and 1913). Very massive doses paralyze the muscle.

**Excised Human Uterus.**—This is contracted, but requires higher concentrations than can be used clinically (Lieb, 1913). Kebohet, 1911, found 1 to 2 mg. hypodermically quite inoperative. Sharp, 1910, however, claims that 0.6 mg. contracts the uterus more promptly and powerfully than ergot extracts, but that the action is too brief.

**Vascular Effects.**—The rise of blood pressure with ergotoxin is purely vascular (diminished organ volume). The constrictor action is exerted directly on the arteries, for it occurs after the medulla has been divided, and the vascular ganglia excised or paralyzed by nicotine.

If now, during this rise, the vasomotor nerves be stimulated—either electrically, or by epinephrin or nicotine—a fall of pressure results, instead of the customary rise. The ergotoxin has therefore paralyzed the peripheral sympathetic vasoconstrictor mechanism, leaving the central dilator mechanism active. This *vasomotor reversal* is obtained in pitched cats by 0.5 mg. per kilogram, intravenously. Since ergot itself and fein are still capable of producing vasoconstriction, the arterial muscle can not be paralyzed; and the constrictor paralysis would be referred to the myoneural junction. This also proves that the constrictor action of ergotoxin is more peripheral, i.e., directly on the muscle fiber. Very large doses finally paralyze this also.

The antagonism of ergotoxin and epinephrin can also be demonstrated on excised arteries (Macht, 1915) and on the stomach (M. Smith, 1915).

Ergotoxin also reverses the expanding action of epinephrin on the melanophores of fish (Speath and Barbour, 1917). The central actions of epinephrin, i.e., the fever, are too antagonized (Cloetta and Waser, 1915).

**Cardiac Effects.**—These are slight. In the excised mammalian heart, Wiggers, 1911, observed diminished systolic contraction and increased tone with decreased amplitude and output. In intact animals, the heart is mainly affected indirectly by the vascular changes; the amplitude being first diminished and then increased.

**Bronchiol.**—These are scarcely affected (D. E. Jackson, 1914).

**Praetor.**—Ergotoxin inhibits or reverses the epinephrin stimulation, but does not interfere with the parasympathetic stimulants (Macht, 1916).

**Pupi.**—In cats, these are contracted (Dale). With rabbits, the intravenous injection (1 to 2 mg. per Kg.) generally produces dilatation by a direct local action (Gibbons, 1917).
Temperature.—In rabbits, this is raised by 3 to 4.5°C through the intravenous injection of 2 mg. per Kg. Some rise occurs even after curare, so that it is not muscular. There is no rise in decapitated animals. The action must therefore be central, and probably involves both increased heat production and diminished heat loss. Cats also respond by a rise of temperature; whereas rats, mice and pigs exhibit a fall (Githens, 1917).

Sugar.—Ergotoxin arrests the epinephrin and theobromin glycosurias, diminishing the hyperglycemia, and rendering the kidneys less permeable to sugar; the permeability to chlorids is not affected. The epinephrin diuresis is somewhat decreased by it, but not the theobromin diuresis (Miczulicz, 1912).

HISTAMIN

(Betaaminazolyethylamin; Ergamin; Ergotidin)

General Statement.—Histamin is largely responsible for the actions of aqueous extracts of ergots. It occurs also, mostly in combined form, in all tissues, and is liberated in putrefaction.

It is destroyed in the digestive tract and therefore gives but little effect when administered by mouth; but when injected subcutaneously or intravenously, it produces intense direct stimulation of the tone or rhythm of smooth muscle, similarly to pituitary extract; and lowers blood-pressure, similarly to peptone or anaphylactic shock; apparently by dilating the capillaries.

Structure.—Histamin is derived from histidin as follows:

\[
\begin{align*}
\text{HC} & \quad \text{NH} \\
\text{C} & \quad \text{N} \\
\text{CH}_2\text{CH}_3\text{NH}_2 \quad \text{COOH} \\
\text{CH}_2\text{CH}_2\text{NH}_2
\end{align*}
\]

Occurrence in Tissues.—Histamin occurs in extracts of all tissues, animal and vegetable. Some is perhaps free, but the greater part is liberated by protein digestion, whether this be effected by acids, by ferments, or by bacteria. The histamin or closely related substitution products are probably the active agents in pituitary extract, peristaltic hormones or "motilenes" (secretin) of the intestinal mucosa, vasodilator, peptone, etc., (Abel and Kubota, 1919; Bibliography).

Significance in Digestive Tract.—Considerable quantities of histamin are liberated from the food by digestion. These may be important as stimulants of the gastric and intestinal musculature, and also by dilating the intestinal capillaries during digestion (Abel and Kubota). Theories of "intestinal autoinfection" have also been built on the production of histamin by intestinal bacteria. These, however, are not justified, since the histamin is broken down so rapidly by other bacteria that very little is absorbed (Mellanby, 1916). Considerable quantities are tolerated when given by mouth (Abel and Kubota).

"Shock-poison."—It has been suggested that the liberation of histamin in injured tissue is the possible cause of traumatic shock; (Abel and Kubota).

Rise in Ergot Effects.—Histamin is concerned in the uterine stimulation, in the cyanosis of fowl; and the fall of blood pressure that is observed with some ergot preparations.

Susceptibility of Different Muscles and Glands.—The stimulation of smooth muscle is most marked in the uterus; the bronchioles are also highly sensitive; the intestine, arteries and spleen are less susceptible; the bladder and iris do not respond. The action is directly on the muscle (Quagliariello, 1914). Cardiac muscle is slightly stimulated; skeletal muscle is not affected. It has a weak picrocarpin action on guinea pigs (Barger and Dale, 1910; Dale and Laidlaw, 1910; Kutchar, 1910; Ackermann, 1910).

Uterus.—This is contracted in all in virgins guinea pigs and non-gravid cats. It increases especially the tonus of the excited uterus of cats, rabbits and guinea pigs.
HISTAMIN

(faiger and Dale, 1910) but relaxes that of rats (Fuehner, 1913). The experiments of kehrer, 1910, and guggenheim, 1914, indicate that the tone of the human uterus is also increased; but it would have to be used cautiously on account of its toxic effects (respiratory disturbances and convulsions). C. Koch, 1924, reports successful results in uterine inertia from the intramuscular injection of 1 mg; faiger, 1913, found 8 mg.

Histochemistry. Even 1 mg. produces some unpleasant side actions; with effective doses there may be headache and violent vomiting. Its use is therefore not advisable. It has little effect on mouth.

Circulation. The effects of histamin are complex and puzzling. It raises the blood pressure in a few species (rabbits and guinea pigs), but in most species (dogs, cats, monkeys, fowl) it produces extensive fall of blood pressure, which may be short or prolonged, according to the dose. With large injections, the condition appears identical with "shock" (Mellanby).

The fall is not cardiac; and attempts to explain it by the behavior of the arteries and veins meet with irreconcilable contradictions. This leaves only the capillaries. The evidence is, however, indirect.

Analogous conditions apply to the phenomena of traumatic shock, peptone shock and to epinephrin dilatation. The dilator action of cholín, on the other hand, appear to be different (Dale and Richards, 1918). The data on histamin are as follows:

Heart.—The isolated frog's heart is slowed; the perfused mammalian heart shows a short and slight slowing, followed by considerable quickening with increased excursions (lines, 1914).

Vasomotor Centers.—This is not affected directly, but the fall of blood pressure, and the respiratory disturbances usually produce moderate stimulation (Fischer and billmann, 1915).

Observation.—Dale and Richards, 1918, confirm that the depressor response to histamin as well as to epinephrin and acetyl cholín are peripheral, and are indeed generally increased when the nerve-supply has completely degenerated.

Excised Arteries.—These are constricted by histamin, in all species, and in all situations (Dale and laird, 1910, 1911), including the coronary (barbour, 1913) and the pulmonary arteries (Berenin, 1914; Anderei and Cheets, 1915); but not the liver arteries (Dale and Richards, 1914).

Prefused Organs.—These respond by vasconstriction if the histamin is perfused in saline; but in the presence of blood and epinephrin, histamin dilates, and therefore appears to be a depressor effect of intact animals (Dale and Richd, 1914).

Relation to Arterial Tone.—Whilst the dilator effect of acetyl cholín shows a definite relation to the tone and reactivity of the arteries, this parallelism does not hold for the dilator effects of histamin (Dale and Richards).

Pulmonary Vessels.—These are apparently constricted even in intact animals, for the pressure in the pulmonary artery rises and the volume of the lungs diminishes, even when the pressure in the systemic arteries is unchanged (Anderei, 1915). Berenin, 1914, states that the constrictor effect in the excised vessels is removed by atropin.

Theory of Deficient Blood Return.—Marstner and Pick, 1915, suggested that the fall of pressure after histamin, peptone, etc., could be explained by obstruction to the return of the blood to the heart; for instance, by spasmodic constriction of the intestinal arteries, and of the lung vessels; or by choking of the liver capillaries. There is, in fact, congestion of the liver and of the splanchic vessels in peptone shock or anaesthesia; but not, according to Dale and Richards, in the evanescent histamin fall. It is therefore more probably a secondary result. With histamin, at least, portal obstruction is not the essential factor, for a fall occurs in eviscerated animals. The latest period of the fall is also suggestive. It is shortest when the injection is made into an artery, longer with a vein; and longest with the portal vein. This indicates that the action is on a structure between the arteries and veins, that is, on the capillaries.

Hemostatic Effect.—This is uncertain, with local application (Hanlik, 1918).

Capillarity of the Blood.—This is not affected, in distinction to peptone (Dale and laird).

Cerebrospinal Fluid.—This is under higher tension, due simply to the asphyxial effect of the beehive contraction (Dixon and Halliburton, 1914).

Bronchitis.—These are strongly constricted by peripheral stimulation (D. E. Nelson, 1914), so that the lungs boast as in asphyxia (Faiger and Pick, 1913).

Urinary Bladder.—This is not stimulated in living animals (Abehain, 1920).

Intestines.—Histamin produces intense stimulation. This is intensified by calcium salts (Vanysek, 1914).

Digestive Secretions.—The intramuscular injection of histamin stimulates the creation of gastric and pancreatic juice and of saliva (Keehn et al., 1920). It is weakly closely related to gastrin and secretin.
436 MANUAL OF PHARMACOLOGY

Skin.—Applied to the scarified skin, a few drops of 1:1,000 histamin produce a local pallor, then a spreading urticaria and erythema (Eppinger, 1913). The erythema of the entire skin is also obtained by the hypodermic injection of 0.5 to 1 c.c. of 1:1,000 solution. A very similar reaction is produced by morphin; tyramin is ineffective (Sollmann and Pülicher, 1916).

Experimental Urticaria.—Temporary localized edemas of the skin are produced by insect stings and by the endermic application of a variety of substances; especially by histamin, peptone, morphin and its derivatives; to a smaller degree by atropin, cocaine, formaldehyde, calcium and a number of amino compounds; in susceptible individuals also by quinin, etc. and by certain proteins and anaphylactic poisons.

Now a definite relation of the urticaria to other actions, on the chemical constitution, has been recognized. The urticaria is a particular light or limited type of dermatitis (Sollmann, 1917; literature).

Tolerance.—As with muscarin, histamin produces its effects only when a given concentration is applied suddenly; if it is added very slowly (i.e., to the excited uterus), it is inactive. Again, a given concentration soon loses its effect, but raising the concentration again induces contractions. Similarly, rapid intravenous injections are much more toxic than slow injections (Oehme, 1913).

TYRAMIN
(para-hydroxyphenyl-ethylamin; Ergotamin; Uteramin)

This is concerned in the vasoconstriction but probably not much in the other effects of ergot. It stimulates the sympathetic system (Quagliarello, 1914) very similarly to epinephrin, except that its effects are more prolonged (Dale and Dixon, 1909).

Chemistry.—Its relation to tyrosin and epinephrin are shown by the formulas:

\[
\begin{align*}
\text{OH} & \quad \text{OH} & \quad \text{OH} \\
\text{CH}_3\text{CH}2\text{NH}_2 & \quad \text{CH}_3\text{CH}2\text{NH}_2 & \quad \text{CH(OH)}\text{CH}_2\text{NH}_2\text{Cl} \\
\text{COOH} & \quad \text{COOH} & \quad \text{COOH}
\end{align*}
\]

= Tyrosin  = Tyramin  = Epinephrin

It occurs commonly in the products of putrefaction, autoysis, and fermentation; and must therefore be present in the alimentary tract. It was isolated from ergot (which contains 0.03 to 0.1 per cent.) and was prepared synthetically from hordenin (its dimethyl derivative) by Barger, 1909. Further syntheses were made by Barger and Wampole, 1910.

It occurs also in the common American and European meadows (Phoradendron flavescens and Viscum album). It has not been demonstrated in other species of Phoradendron (Crawford, 1914; Ostenberg, 1914). It constitutes the "salivary" poison of certain cephalopods (Henge, 1913). In the body a part is converted into para-hydroxy-phenylactic acid. This change is also effected by surviving liver and uterus. It is completely destroyed by the isolated heart (Ewins and Laidlaw, 1910).

Circulation.—Intravenous injection of tyramin produces considerable rise in blood pressure, lasting 2 or 3 minutes. The heart is slowed reflexly.

The rise appears to be purely vascular, judging by the diminished volume of the kidneys and intestines, and by the decreased vein flow (Bickel and Pawlow, 1912).

The constrictor action is generally considered peripheral, since it occurs also on excited arteries, even on the coronaries (Barlow, 1913).

However, Baehr and Pick, 1916, claim that the pressure rise of tyramin and related bases does not occur after nicotine. If this is confirmed, it indicates that the main vasomotor stimulation is more central than the arterial muscle; presumably in the ganglia.

Tyramin does not blue the comb of the rooster acutely (Crawford, 1913); nor produce gangrene on repeated injection (Bickel and Pawlow). Harvey, 1917, asserts that long-continued administration to rabbits produces arterial sclerosis and chronic nephritis.

Cerebro spinal Pressure.—This varies with the circulatory changes (Dixon and Halliburton, 1913, 1914).
Effect on Human Circulation.—Hewlett, 1918, observed the response of 60 to injured in hypodermically into the loose tissue below the clavicle. (The local injection may prevent absorption in other situations.)

dosage usually results in slowing of the pulse and in marked rise of the blood pressure and much smaller rise of the diastolic pressure. The pulse and volume-pulse are therefore markedly increased. The T wave of the dirogram is also increased. These changes point to increased output of the heart within a few minutes, and last for about half an hour.

Termplifiable and prolonged rise of blood pressure was also described by A. Clark, Hoyt, 1915, after 20 to 40 mg. hypodermically. Oral administration is ineffective (Sharp, 1917).

collapse.—Injections of 5 to 20 mg. (15 to 15 gr.) have been tried without effect. Even with 60 mg. Hewlett, 1918, obtained only transient response to injections. After operations, there was generally permanent improvement, difficult to exclude spontaneous recovery.

D. Efficiency.—Tyramin is fairly effective in arresting superficial capillary hemorrhage, both by local and systemic application; but its efficiency is far below epinephrine, 1920).

E. Effect on Uterus.—Tyramin tends to increase the uterine contractions, but the effect of the experiments reported (Dale and Dixon, 1909; Guggenheim, 1914, 1915). It has been found clinically as a substitute for barbituric acid, 1917, and it was shown by Guggenheim, 1912; Sharp, 1911; Kehrer, 1913) does the use of in the experiments reported. With larger doses (10 mg. of morphine, hypodermically), 1917, Barbour, 1917, reports distinct increase of the strength and rate of labor pains; without undesirable side-effects. Contrary, the tyramin counteracts the respiratory depression of morphine; the respiration is slightly quickened by the above combined dosage. The effects of this on other functions are not antagonized (Barbour, Mauz and Bauer, 1920).

Actions. Respiratation.—The effects have been studied by Bry, 1914, and found to be contracted. (This is constricted (frog).

i. Intestinal.—These are stimulated in rabbits; relaxed in dogs; first stimulated when relaxed in cats (Manysk, 1914).

Volume in Man.—The injection of tyramin is followed, in man, by marked increase of the red and leukocyte counts (J. G. Brown, 1920).

—Long-continued hypodermic injections into guinea pigs (2 to 8 mg. daily for two weeks) produce severe anemia with the characteristics and course of anemia (Iwao, 1914). The result with hemochromatosis of the spleen, mesenteric lymph glands, cecum marrow is produced in rabbits by intravenous injection of 0.1 Gr. of tyramine (5).

Secretion.—Tyramin sometimes stimulates this, but not in other cases. (Kakeyama, 1915).

Stomach.—Secretion after pilocarpin or secretin is inhibited by large doses of tyramine (Kakeyama, 1915).

Stomach.—Continuous slow intravenous injection of 0.05 per cent. tyramin may raise the blood-sugar to 2.17 to 2.17 per cent., and the urine sugar to 2.17 to 2.17 per cent.

HORDENIN

Amines and Related Drugs.—This is an alkaloidal amine derivative (p-hydroxy-3-piperidin) obtained by Legers, 1906, from germinated barley. Its action is studied especially by Camus, 1906. Small doses stimulate the vagus, paralyze the vagus center, quickening the heart and raising the blood pressure. The kidney is dilated by stimulation of the sympathetic endings, sufficient to antagonize most constrictor drugs (D. E. Jackson, 1914). Fatal fibrillation. The substance is not very toxic, it has been used (0.5 mg.) in heart disease and digestive derangements (Sarbanes and Guerine, 1906); diarrhea in dogs (10 to 40 mg. per kg., hypodermically; Charmoy, 1912).
PHENYLETHYLAMIN

This occurs in putrid meat. Its formula, C₆H₅C₂H₄NH₃, is related to epinephrin. Small doses stimulate the cardiac muscle, large doses depress. All doses contract the coronary vessels; this is followed by relaxation with large doses (Barbour and Frankeil, 1915).

When phenylethylamine or tyramine are fed to rats or injected, they increase catabolism and lower the glycogen content of the liver (Abelin and Jaffe, 1920).

INDOLETHYLAMIN

This stimulates plain muscles, especially the arteries, iris and uterus. It also has stimulant central effects (Laidlaw, 1911). Perfusion through excised liver converts it into indolacetic acid. Dogs excrete 30 per cent. as indolacetic acid (Ewins and Laidlaw, 1913).

PARAPHENYLENDIAMIN

This is extensively used for dyeing brown and black furs. The wearing of these suits causes dermatitis, probably by the formation of an irritant intermediate oxidizes product, such as chinon-dichlor-dilim (Glancl, 1916). Hypodermic injection of 75 mg. per kilogram body weight produces chemosis, conjunctival irritation, increased ocular pressure and exophalmitis. The effects occur when the cervical sympathetic has been divided, and are probably caused by circulatory disturbances (Troell, 1916).

The general systemic effects were studied on frogs and rabbits by Meissner, 1918.

EDEMA BY AROMATIC AMINES

The hypodermic injection of phenylendiamin, metolotolylendiamin, acetylphenylhydrazine (pyrozin) and toluiyl-hydrazine produces effusions into the serous cavities. These are not due to hydremia, the blood being rather thickened. Probably the permeability of the capillaries is increased (L. Hess and Mueller, 1915).

Urticaria.—Many amines produce urticaria when applied to the scarified skin; for instance, phenylethylamine, phenylendiamin, hydroxydiamin, etc. (Sollmann, 1917).

ETHYLENDIAMIN. NH₂-CH₂-C₂H₂-NH₂

This has been investigated especially by Barbour and Hjort, 1920. It is comparatively innocuous, the minimum fatal dose for mice being 0.73 Gm. per Kg. hypodermically.

Symptoms.—With frogs its effects resemble those of the aliphatic narcotics.

With rabbits, nearly fatal doses (0.4 Gm. per Kg. by vein or hypodermically) produce temporary respiratory stimulation; lowering of the temperature; slight general depen- sion and transient diarrhea. The blood pressure falls (often with 1 mg., hypodermi- cally) by a central action.

Smaller doses (0.1 mg. per Kg.) produce only a fall of temperature. Daily injec- tions decrease the susceptibility to this effect.

Excited Intestine.—The drug depresses the tone and activity.

HYDRAZIN. NH₂-NH₂-H₂SO₃

When injected into dogs, hydrazin lowers the percentage of sugar in the blood, and the hepatic glycogen, without any glycosuria. The hepatic cells degenerate, but recover if the injection was not fatal.

The hypoglycemia appears to be due to increased sugar combustion, as indicated by the respiratory quotient. Injected dextrose is also oxidised more rapidly. There is no specific influence on heat production (Underhill and Murlin, 1915).
PROTEOSES

PTOMAIN POISONING

The cases of poisoning observed as a result of partaking of more or less tainted articles of food—sausages (botulinus and allantiasis), meat, milk, ice-cream, cheese, canned beef, etc., and with some specimens of mussels and oysters—a distinct development of ptomain products. In the former cases these are developed by putrefaction; in the latter, probably by disease.

Many of these ptomains have been isolated in crystalline form, and are well-defined compounds belonging to the amine series (Barger and Walpole, 1909; Barger and Dale, 1909; Dixon, 1913; Hanflik, 1916). Their pharmacologic actions are on the autonomic system (Blankenshore, Harmon and Hanflik, 1916).

Uremic Bases.—Foster, 1915, reports that the methods of isolating organic bases, when applied to uremic blood, yield toxic substances that are not present in normal blood.

REACTIONS RESEMBLING HISTAMIN

General Statement.—Phenomena resembling closely those of histamin are produced by the injection of many tissue extracts, by peptones, secretin, and other products of partial protein cleavage, by blood serum, by bacterial products; by the injection of many colloids; and in the course of anaphylaxis and of traumatic shock.

In some cases the phenomena agree closely with those of histamin, and may be due to the presence of this substance or a near derivative. In most cases, however, the correspondence of the effects is not complete (Loewit, 1913); and in some it is only superficial.

PROTEOSES ("PEPTONE")

Effects of Albumoses.—Intravenous injections of "Witte's Peptone" (0.5 gm. per kilogram) produce typical anaphylactoid phenomena (Biedl and Kraus); temporary but considerable fall of blood pressure (Thompson, 1896 and 1899) by peripheral action in dogs (but not in rabbits, Piesmksy, 1915); stimulation of the isolated uterus (Dale and Lidlaw, 1910); bronchial constriction, peripheral (Baer and Pick, 1913; no effect, Trendelenburg); increased flow of lymph and secretions (Pupelski, 1906 and 1910; Hillyard and Scott, 1912); discharge of the gall-bladder (Klee and Knappe, 1914); diuresis independently of the blood pressure (Thompson, Giszell, 1908; Frohlich and Pick, 1912); fever on hypodermic injection, etc. In most animals (but not in rabbits) appropriate doses render the blood non-coagulable, and produce hyperglycemia and glycosuria (Y. Henderson and Underhill, 1911). McGuan and Ross, 1913 and 1917, however, state that the usual result is hypoglycemia, which they attribute to circulatory changes in the liver. The secretion of bile is increased (O'Kada, 1911). Application of peptone to the scarified skin produces a wheal (Seidmann and Fliker, 1916).

Intravenous injection of small doses of pure proteoses increases the urinary nitrogen very greatly for several days (Whipple, 1910).

Resemblance to Histamin.—Dale and Lidlaw, 1911 called attention to the striking similarity of the anaphylactic and peptone effects to those of histamin; and suggested that the active principle may be similar. Certain minor differences exist: f.i., epinephrin removes the bronchial spasm of peptone and not of histamin (Januscheke and Pollak, 1911); histamin does not affect the coagulation of the blood (Modrakiewski, 1912), etc.

Active Constituents.—"Peptone" preparations consist mainly of proteoses, with some peptone and other protein cleavage products, and among these, histamin (Naga- ma, 1910). It is suggestive that histamin and similar amines are among the products of the more complete digestion of peptones. The histamin would doubtless contribute to the effect; but typical peptone effects are produced by preparations free from histamin (Hanke and Koeppers, 1910) or other foreign toxic admixtures (Underhill, 1917). The actions therefore seem to be due to the proteose.

Circulation.—The mechanism of the fall of blood pressure is identical with that of anaphylaxis (Thompson, 1896 and 1897; Pearse and Eisenbery, 1910; Frohlich and Pick, 1912).

With rabbits, the vessels of the legs and ears are constricted, whilst the splanchic vessels are dilated (Kondo, 1910). The excited mammalian heart is weakened by concentrations of 1:4,000 to 1:10,000, stimulated by 1:200 (Piesmksy). Exceded
vesels are generally constricted (Dale and Lairdaw, 1912); the ear vessels are constricted by all concentrations; those of the perfused lung are somewhat dilated (Flahav and Pick, 1913; also the liver-veins (Berezin, 1914); the intestinal, renal and coronary vessels are unaffected by dilute solutions, constricted by strong solutions (Pissemsky, 1915; Mansfer and Pick, 1915). The effects on blood pressure and respiration have also been investigated by Zamtz, 1917.

Notwithstanding these similarities, there are sufficient differences to indicate that anaphylaxis is not due to the formation of ordinary albumoses (Manwaring, 1912; Loewit, 1913 and 1917).

Blood Coagulation.—The direct addition of peptone to blood does not affect coagulation; but intravenous injection generally renders the blood non-coagulable. This is due to an antithrombin; the blood containing all the necessary elements for coagulation, so that it clots, e.g., on simple dilution with water. This antithrombin seems to be a nucleoprotein formed in the liver (Doyon, Morel and Polliard, 1913; Denny and Minot, 1914; its production is not increased by bile, bile salts, secretin or electric stimulation). R. J. Lee and Vincent, 1915, attribute the non-coagulability of the anaphylactic blood mainly to an anomalous behavior of the blood-plaques.

Effect on Hemorrhage.—Bleeding from superficial vessels is rather increased by the local application of peptone. Intravenous injection may diminish hemorrhages, parallel to the fall of blood pressure (Hamilck, 1915). Peptone does not agglutinate red corpuscles in vitro (Karsner and Hansflck, 1920).

Injections of Witte's peptone have been proposed for the treatment of hemophilia, but have caused fatal hemorrhage (Leebouillet and Vaucher, 1914).

Toxemia.—Whipple, 1916, attributes to a primary protease the toxic effects of intestinal obstruction, peritonitis, and acute pancreatitis.

Lesions.—Broughton, 1916, after intraperitoneal injections of Witte's peptone into guinea pigs, describes inflammatory lesions in the liver, heart and kidneys, similar to those produced by other foreign proteins.

Fibrille Reaction and Leucocytes.—The intravenous injection of vaccines or foreign proteins is followed by a chill, fever, muscular and joint pains, sweating, and a diminution of the leucocytosis (abst in the period 1½ hour to several days), sometimes of very marked degree (De Arc, 1913; Gow, 1910).

The leucopenia is probably associated with the pyrogenic reaction, but is not proportional to it; it is chiefly polymorphonuclear; but there are also atypical lymph cells, nucleated reds, and myelocytes. In distinction from anaphylaxis, there is no eosinophilia.

Covic and Calhous, 1919 (Arch. Int. Med., 25:96) believe that the leucopenia is due to the emigration of the leucocytes from the blood into the tissue; and that the leucopenia is due to increased production of these cells.

Peptone Injections against Infective Fevers.—Intravenous injection of peptone, in proper dosage, tends to bring on a prompt crisis in various infective fevers, and may thus shorten their natural duration. The same result is secured by the intravenous injection of other agents that produce similar reactions—non-specific bacterial vaccines (for instance, typhoid) or filtered cultures; collodial metals, etc. This treatment has been employed most extensively in acute rheumatic fever. The clinical relief is generally prompt and considerable. Occasionally, however, the reaction is dangerous. The method is not sufficiently safe for general use.

Reaction for Therapeutic Dosage.—By proper dosage and slow injection, it should be aimed to produce only a slight degree of reaction: slight transitory tachycardia; some deep breathing or dyspnea; transitory headache. These symptoms pass off in 5 minutes; but are followed after 5 to 7 hours by more or less prolonged rigor; and deep by defervescence with profuse sweating. The fall of temperature lasts till next day, and is accompanied by subjective and objective amelioration.

The injections are repeated on alternate days, until the cure is completed. Heff, 1910, has used this therapy in typhoid, septiemies, rheumatic fever, and other arthrits. Further details are given under Typhoid Vaccine.

SPLIT PROTEIN POISON

V. C. Vaughan, 1907, 1913, 1916, found that the alkaline cleavage of protein results in toxic products that appear to be identical for all proteins, at least so far as the effects are concerned (Edmunds, 1913; Vaughan, 1916). These agree very closely with the
allemesos, although they differ in detail. Rabbits, e.g., are refractory to poisons, but sensitive to the split proteins (Underhill and Hendrix, 1915). The chemical identity of these poisons has not been established.

Pancreatic Extracts.—Their hypodermic injection is toxic. The effects and lesions are described by Wag, 1919.

HIRUDIN

The cervical glands of the common leech (Hirudo) secrete a substance (hirudin, hemophilin) which delays or hinders the coagulation of blood inside and outside of the body. This substance is not destroyed by boiling or by alcohol. It appears to be a deuterobasumose.

Therapeutic Use.—Leeches were at one time used extensively for the abstraction of blood in local inflammations. Dry or wet cupping is now usually substituted, but they are still employed occasionally; two to four of the animals are applied. The skin should be well cleansed, and, if necessary, a little milk should be rubbed on to tempt the animals to bite. They should not be removed, but allowed to fall off. They cannot, of course, be used again. Each leech draws from 5 to 7 c.c. of blood. The quantity may be somewhat increased by applying hot fomentations after removing the animals. It is sometimes difficult to stop the bleeding.

For experimental use, an extract may be prepared, when needed, by crushing the head with sand, macerating with saline for two hours, and centrifugalizing. Each gram of animal requires the heads of three leeches, extracted with 3 c.c. of normal saline. The solution loses activity on standing, more slowly in the cold.

Immunization.—Daily intravenous injection of hirudin into mice creates an anti-coagulant substance, effective in vivo and in vitro, destroyed at 65°C. It also activates fibrin, but not the calcium-precipitants. The mechanism of its action has not yet been explained (Vera and Leo Loeb, 1914).

Field.—Hirudin dilutes these, in frogs, and renders them less sensitive to epi-

TISSE UExtracts With Histamin-Like Actions

Extracts of practically all tissues, but especially of glands and smooth muscle, produce histamin or peptone-like effects: stimulation of smooth muscle and glands, and sensation of blanket pressure. Intravenous injection or direct contact are usually required to produce a response.

The pressor principles predominate in saline extracts made at ordinary temperature, but are often destroyed by boiling. The depressor substances are soluble in saline solutions and in alcohol or ether. They are not identical with cholin (Swale, Vincent and Sheen, 1903; Pawlett, Beebe, et al., 1917; Vincent, 1918) and are probably more closely allied to the "peptone" and similar effects. Inorganic constituents may also play a part: expressed heart juice, f, depresses cardiac activity, simply by its potas-

SECRETIN

Pawlow showed that the presence of acid chyme in the duodenum is the normal stimulus to the secretion of pancreatic juice. It was later shown that this is not due to a nervous reflex, but to the production of a peculiar substance "secretin," which may be prepared artificially by macerating the duodenal or jejunal mucosa with dilute acids, soaps, etc. (Bayliss and Starling, 1902); or by contact of these or of irritants with the
living mucosa. Secretin does not exist as such in the mucosa, but is formed from an
insoluble "prosecretin." Secretin is identified by causing a marked flow of normal pan-
creatic juice, when the neutralized and boiled filtrate is injected intravenously. (An
extensive review of secretin is given by Carlson, Lebensonan and Pearlman, 1916.)

Nature and Properties.—Secretin is soluble in water and dilute alcohol (70 per cent.)
insoluble in absolute alcohol, ether, etc. It is fairly readily destroyed by acids, alkali,
or oxidation; and by the digestive ferments (Carlson et al., 1916). It has not been
isolated pure; none of the known constituents of the extracts produce the characteristic
effect. Barger believes that it is probably an organic base.

Actions.—Intravenous injection of secretin stimulates the flow of pancreatic juice
 bile (Downs and Eddy, 1919) and succus entericus, but not of the other digestive sec-
tions; nor do extracts of other portions than the small intestines produce the secretin
effect. The secretion is accompanied by, but not caused by, vasodilation. The
secretin is not rapidly fatigued, the flow being undiminished after a few hours of con-
tinuous injection. Similarly, repeated injections of equal doses give an identi-
fiably more flow. The flow is not affected by anesthesia.

Clinical Ineffectiveness.—Moore, Edie and Abram, 1906, suggested the administrat-
ion of secretin against diabetes. Subsequent workers have shown that it has no
effect (Bainbridge and Beddard, 1906; O. Loeb and Stadler, 1912). It was also tried aga
against digestive disorders, with equally inconclusive results. This agrees with the scient-
ific data: In the first place, it has not been shown that prosecretin is deficient in any clinic
condition; secondly, the oral administration, even of enormous doses, is quite ineffective;
since secretin is rapidly destroyed by the digestive juices (Carlson). Even the hypo-
ergic administration is inactive (Matsum, 1913; Hallon, 1912). Finally, the commercial
preparations do not contain secretin, presumably because it is too unstable (Cartes-

GASTRIN

Extracts of the gastric mucosa also contain a substance that stimulates gastric and
other secretion. The chemical behavior of purified extracts resembles histamine,
although there are differences that indicate that they contain some other basic imidazol
derivative (Reeves et al., 1920; F. C. Wood et al., 1920).

SPLNE EXTRACT

Hormonal.—Zuelzer, 1920, believed that various organs, removed at the height of
digestion, contain a hormone, which stimulates peristalsis. The commercial "Hor-
monal-Zuelzer" is extracted with dilute hydrochloric acid from the spleen, removed during
digestion. It is injected intravenously and intramuscularly, in intestinal paresis and
post-operative ileus. Its injection has often caused serious and even fatal collapse (Reeves, 1924; Seifert, Nehemvirkung, 1915, p. 136). Mahn, 1912; Sabatowski,
1912, and others, believe that the active principle is albumose or a similar amphy-
lactoed substance, which would explain the fall of blood pressure, and by this the peristaltic effect. Zuelzer, 1912, attributes the accidents to contamination, and
preparates what he believes to be a purer product, by removing the proteins through bolling
lead acetate. However, fatal accidents are still reported, whilst the therapeutic
results are very inconsistent (Burienek, 1913). It seems an uncertain and dangerous
remedy (Hesse, 1913).

An experimental investigation of Hormonal is published by Schlaginwehel, 1916.
Wieland, 1917, states that extracts of the intestinal mucosa or muscularis stimulate the
intestine, excised or intravenously, much more than other organ extracts; that the effect
is located in Ausbeych's plexus and is antagonized by weak atropin; and he believes that
this hypotonic substance is the cause of the automatic movements of the excised
intestine.

L. Stern and Rotblin, 1920, obtained a spleen preparation producing direct stimula-
tion of the smooth muscle, similar to histamine.

LUNG EXTRACT

Saline extract of beef lung is a very active thompholytic agent (Fischl, 1912; Mills,
1919). Intravenous injection produces dangerous symptoms resembling his-
tamin: splanchic vasodialition (Goto, 1910); dyspnea; often convulsions. F. Mees,
1920, attributes the effects to intravascular coagulation, produced by a xanthoprotein,
probably a phospholipin. Kakinuma, 1919, claims that the toxicity is destroyed
by the addition of glucose. Handslik, 1918, found lung extract unreliable as a hemostatic
Choroid Extract.—This produced a specific increase in the flow of cerebro spinal
fluid (Dixon and Halliburton, 1914).
HEMOSTATIC TISSUE EXTRACTS; KEPHALIN

Extracts of various tissues hasten the coagulation of shed blood. The same effect is produced by the lipoid kephalin, and this may be the main active ingredient of the tissue extracts (Howell, 1912); but this is not established.

Kephalin and tissue extracts ("thromboplastins," especially from the brain and lungs) have been tried as hemostatics and in hemophlia, purpura, etc. With normal individuals they are ineffective (Hanzlik, 1919), since wounds furnish plenty of thromboplastic substance. Their efficacy in hemorrhagic diseases is under judgment.

Toxic Phenomena.—The injection into guinea pigs of hemostatic tissue, extracts and serum produces phenomena resembling anaphylactic shock. Kephalin does not evoke this reaction (Hanzlik et al., 1919).

Kephalin.—This is closely related to lecithin, differing only by a methyl group (Koch and Woods, 1905). It is probably widely distributed in the body, but is especially abundant in the brain. Lecithin does not hasten coagulation.

Mechanism of Coagulant Action.—Howell attributes this to the neutralization of a substance (antithrombin) which is assumed to exist in freshly shed blood, and to inhibit its activation by prothrombin by calcium.

Hemostatic Action.—Brain extract agglutinates red corpuscles in vitro; kephalin does not (Krasner and Hanzlik, 1920).

Testing of Coagulant Action.—The current methods and the results with various products are described by Hanzlik et al., 1919.

Brain Extract.—The preparation is described by Hess, 1915; and Hirschfelder, 1916.

NORMAL SERUM

This contains substances stimulating smooth muscle, which are formed during clotting.

Blood-serum also contains the elements required in the clotting of blood. Its injection sometimes appears to be effective in controlling persistent bleeding, for instance, in hemophlia, severe anemias, purpura, etc. (Bienwald, 1897; Well, 1907). The results, however, are inconsistent. There are the same after-effects and dangers as with antitoxic sera; and these dangers must be taken more seriously, since the benefits are more problematical.

Smooth Muscle.—This is stimulated (Schultz, 1912), similar to peptone or histamin, but there are specific differences (Dale, 1913).

A specific constrictor substance is formed in shed blood, probably by changes in the formed elements rather than by clotting (G. N. Stewart and Zucker, 1913). Janeway, Richardson and Park, 1915, find that the vasoconstrictor principle is derived from the leaching up of the blood-platelets. It is not a protein, but a water-soluble crystallloid. This liberation is favored by heat or standing of the blood (Baraden, 1916). The vasoconstriction may play a part in hemostasis.

The principle which stimulates the intestine and uterus precipitates.

With perfused hearts (rabbits), Cashen and Gunw, 1913, find that the addition of serum produces a preliminary stimulation, with stronger and usually faster contractions; and subsequent depression with weakened and slowed contractions, sometimes heart-block, and eventually arrest. The coronary vessels are constricted. Similar effects are produced by the plasma of the operated animal, by starch solution, etc. The authors attribute them to an alteration in the heart produced by excision, and not to the formation of any poison.

The coronary vasoconstriction has been confirmed by Yamagawa, 1916. Of a considerable series of colloids tried, this effect was produced only by serum and by egg-white. It resides in the proteins.

Manwaring, Meinhard and Denhart, 1916, find that the addition of 7 to 10 per cent. of goat serum in perfusion of rabbit's heart produces tachycardia, followed by depres-
sion and irregularity. The tachycardia is due exclusively to diffusible substances in the serum; the depression to non-diffusible.

The fatal effects of intravenous injections of foreign blood serum are often connected with hemolysis and thrombosis (L. Loeb, Strickler and Tuttle, 1910). Organ extracts intravenously also often produce thrombosis (L. Loeb, 1912).

Anaphylactoid Disturbances.—Intravenous injection of sera into guinea pigs induces acute circulatory or respiratory distress or collapse. Rabbit's serum affects mainly the circulation; human serum, the respiration; and dog's serum, both (Hanakil and Karmann, 1920).

Hemagglutination.—The red corpuscles of man, cats and guinea pigs are agglutinated by beef serum, but not by other sera (Karrer and Hanakil, 1920).

Administration as Hemostatic.—Normal horse serum is injected hypodermically, 10 to 20 c.c.; the results are said to appear in twelve to twentyfour hours and last one to three months (Richardson, 1908). The intravenous injection of human serum or still, better, of human blood, is often more effective. In hemophilia, it increases the prothrombin (Add, 1916). Trember, 1910, attributes the effects to leucocytosis.

ANAPHYLACTIC SHOCK

Parenteral injection of native proteins sensitizes animals specifically, after an incubation period, so that they react violently to a further injection of the same protein.

The phenomena of this "anaphylactic shock" resemble closely those produced by histamin or peptone injection; i.e., acute fall of blood pressure, presumably by relaxation of the capillaries; and stimulation of smooth muscle, manifested especially by bronchial constriction, which leads to acute pulmonary emphysema and asphyxia; and local urticarial reactions. The relative predominance of the individual effects in different species may complicate the picture. The immediate response to the provocative injection indicates analogy with ordinary poisons.

Historical.—Anaphylactic phenomena were described by Mengelde as early as 1839, and rediscovered by Behring, 1892; Kicket (who coined the name), Theobald Smith, 1903; and Piquet, 1904 ("allergy"). Their modern investigation dates from Otto, 1905; and Rosenau and Anderson, 1906. Anderson and Rosenau, 1908, give an extensive summary of the earlier literature. More recent compilations are those of Hektoen, 1912; Dixon, 1913; and Zinser, 1915.

Production of Anaphylaxis.—This results from the parenteral introduction of all "antigens"; i.e., all true proteins; but not from their cleavage products, proteoses, leucin, etc. (Gay, 1913); nor from gelatin; nor from lipoids, etc. (The native so-called "proteoses" of seeds are antigens and therefore not true proteoses; Wells and Osborne, 1915.)

Artificial polypeptides (to heptaglycylcynin) do not produce anaphylaxis (Aberholden and Well, 1920).

It is necessary to distinguish between the first or "sensitizing" and the later or "provocative" injections. Sensitization occurs with very small doses (as little as 0.000,000,005 mg. of egg-white) intravenously or hypodermically, and exceptionally even by stomach or large intestine; or through the nose (Sewall, 1914). A minimum interval of six to ten days elapses before the sensitiveness is acquired; but then it persists for a long time, weeks or years. Repeated injections during the incubation period may produce immunity.

The maximum degree of sensitization is practically independent of the dose of the sensitizing injection; but curiously, the maximum is reached more rapidly with small than with large injections; for instance, for guinea pigs with 0.004 c.c. than with 0.1 c.c. of horse serum (O. Thomsen, 1917). Injection of the serum of sensitized animals confers passive sensitization on the recipient (Otto); immediately, with proper dosage (Doerr and Russ).

There is the same specificity as with other antigens. Specific sensitization may thus be secured simultaneously to several proteins. Wells and Osborne, 1911 and 1913.
ANAPHYLACTIC SHOCK

studied particularly the specificity for pure proteins. They believe that the specificity is due to certain constituent groups within the protein molecule; but that the whole molecule is involved in the reaction.

Chemically similar proteins from the seeds of different genera react anaphylactically with other, while chemically dissimilar proteins from the same seed often fail to do so (B. G. Wells, and Osborne, 1916).

The provocative injection must be considerably larger than the sensitizing injection. It is much more effective by vein. The response is immediate. If an animal recovers from the toxic effects, it becomes immediately refractory or immune to further injection, because the anaphylactic antibodies are saturated or exhausted (Weil and Coca, 1913).

This anaphylaxis (anergy) persists for a time, but is eventually lost.

Symptoms of Anaphylactic Reaction.—These are mainly as follows: Great restlessness, severe fall of blood pressure and consequent shock; fall of temperature (Pfleiffer and Mita, 1910), etc.; rigidity of the lungs by violent contraction of the bronchial muscles, resulting in respiratory distress and asphyxial convulsions; stimulation of other smooth muscle (uterus, stomach and intestines); diminished coagulability of the blood (Weil, 1917; Bulger, 1918); increased concentration of the blood, appearance of nucleated reds, and changes in the leucocyte ratio (Richet et al., 1910); hypocoagulability; anemia; loss of complement; increased lymph flow (Calvary, 1911); local inflammatory reaction.

Repeated anaphylactic shock results in cell destruction in several organs, with subsequent chronic inflammatory changes. In the liver, the results resemble portal cirrhosis (Longcope, 1913).

Analogous but less severe parenchymatous degenerations of the myocardium, liver and kidneys may occur in rabbits after a single injection of a large dose of horse serum or egg-albumen. They develop in ten to twenty-one days, about the time when the antibodies are produced (Longcope, 1915).

Susceptibility.—Guinea pigs are especially susceptible, and in them the lung rigidity is most prominent, arresting respiration and producing asphyxial death in a few minutes (Auer and Lewis, 1909). In dogs and rabbits this phenomenon is much less marked, the severe and prolonged fall of blood pressure being the most prominent feature. However, death may occur by bronchial constriction (Pelz and Jackson, 1918). Cats are intermediate (Edmunds, 1914).

Man seems to be relatively insusceptible. The rare acute accidents in the injection of antitoxic sera, serum disease, and some varieties of asthma and hay fever (Meltzer, 1920) are probably anaphylactic manifestations.

Lung Rigidity.—Auer and Lewis, 1909, showed that in guinea pigs dying acutely of anaphylaxis the lungs are rigidly distended and incollapsible even after death, by total contraction of the bronchial muscles. The effect occurs after destruction of the central nervous system and even after degeneration of the vagi, so that it must be exerted directly on the muscle fiber or myoneural junction (Auer, 1910). It is abolished by atropin (Auer). Chloral is uncertain (Rosenau and Anderson, 1909). Schultz and Jordan, 1917, showed that the severity of the bronchial phenomena in guinea pigs explained by their relatively thick mucosa; so that the contraction occludes absolutely over the larger bronchi.

In dogs, the fatal broncho-constriction is not prevented by atropin. Epinephrin is effective and may save the animal if it has time to act before the asphyxia has gone too far (Pelz and Jackson, 1918).

The isolated perfused lung of guinea pigs may react to anaphylaxis by bronchial spasm, or sometimes by vascular spasm. The condition may also be simulated by plugging of the pulmonary vessels by thrombi or agglutinated corpuscles (Mainwaring and Crowe, 1917).

Coca, 1910, finds the pulmonary circulation unobstructed in guinea pigs; but with rabbits dying acutely from anaphylaxis, the pulmonary circulation is almost impermeable to saline, even under pressure several times greater than exists in the pulmonary artery during life. The arrest of the pulmonary circulation would be the immediate cause of death.

Coca considers that the obstruction is due to vascular spasm, more probably than to thrombosis; but the evidence is not conclusive.
Blood Pressure.—In guinea pigs, the circulatory changes are mainly asphyxiial (Auer and Levels, 1913). In other animals there is a characteristic fall in blood pressure, often to 20 to 30 mm. Hg. The mechanism of this “anaphylactic shock” has not been conclusively demonstrated. Presumably it is the same as with the analogous histaminic fall, i.e., direct relaxation of the capillaries. The blood accumulates mainly in the large veins, especially of the liver and portal system; so that the smaller vessels of the kidneys, intestines, and other parts of the body are mechanically drained (Pearce and Eisenbery, 1910 and 1912; Edmunds, 1913): indeed, the fall does not occur if the liver has been excluded from the circulation. The liver therefore has a predominant share, directly or indirectly, in the fall, the blood pressure being lowered because a greater part of the blood stagnates in the portal system.

The vasomotor center is not directly involved in the fall; nor is there any good evidence of a peripheral action on the arterioles or veins. These continue to contract to epinephrin or barium; they do not contract to splanchic stimulation, but this could be explained simply by the altered distribution of the blood.

Recent views as to the mechanism of the fall are unsatisfactory. Biedl and Kraus, 1909, assumed vasomotor paralysis; Mautner and Pick, 1915, suggested contraction of the smaller portal vessels, interfering with the return of blood to the heart. R. Weil, 1916, attributed the fall to portal obstruction by acute injury to the hepatic cells similar to phosphorus poisoning. Airila, 1914, attributed the fall in rabbits to increased resistance of the pulmonary vessels; but Edmunds, 1914, found no evidence of deficient blood supply of the left heart in cats; to the contrary, the pressure in the pulmonary veins often rose. v. Behring, 1914, attributes the shock to clumping of the platelets and thrombosis of the cerebral vessels.

Cardiac Disturbances.—The heart suffers by the low blood pressure, and is also affected directly, although this usually plays a minor part in the “shock.” The changes are peripheral. As shown by electrocardiograms, on rabbits and dogs, they consist in disturbances of conduction and abnormalities of ventricular contraction, affecting especially the right heart. These may progress to fatal rigor (Robinson and Auer, 1913; Auer and Robinson, 1912). The heart-muscle and diaphragm show histologic changes similar to anaphylactic shock (Kundratitz, 1913). The isolated heart of sensitized animals is directly poisoned by the antigen (Ceartis-Demel, 1910-1912). Acute heart failure is also sometimes seen in intact cats (Edmunds, 1914).

Anaphylactic Shock.—The continued low blood pressure furnishes an opportunity for investigating the treatment; this is of practical importance because the phenomena are very similar to those of surgical shock. The indications are evidently to relieve the splanchic congestion and to increase the volume of blood to the heart and medulla. Pearce and Eisenbery, 1910, found that venous transfusion with blood or saline only increases the splanchic congestion without aiding the heart or medulla. Arterial transfusion is more successful; but the best results are obtained by combining transfusion into an artery with bleeding from a vein. Cardiac or vascular stimulants alone did not produce permanent improvement; but the combination of slow epinephrin infusion with digitoxin gave good results.

Local Hypersensitivity.—The anaphylactic state appears to increase the susceptibility to non-specific irritants. When xylene (r c.c.) is rubbed on the ear of normal rabbits, it is merely rubeicent; but when the animals have been injected with sub-symptomatic doses of an antigen (sensitizing and provocative), xylene produces vesication and eschar (Auer, 1900). Auer suggests that the xylene produces an exudation that contains free antigen from the provocative injection; and that this reacts with the tissues sensitized by the first injection.

Relation of Anaphylaxis and Immunity Reactions.—The relation of anaphylaxis to other “immunity” reactions indicates identity of the underlying process; anaphylaxis being merely a special manifestation of the defensive mechanism against foreign proteins. It refers simply to those phenomena of the “immunity reactions” which happen to be injurious to the animal. As with the other immunity reactions, it involves the reaction of the antigen with its antibody, under proper conditions; so that the antigen is rendered amenable to the action of the complement (alexin), leucocytes, etc.
ANAPHYLACTIC SHOCK

447

In the case of anaphylaxis, the product of this reaction is poisonous, and is therefore called "anaphylatoxin." An "antigen" is any substance that induces the formation of a specific antibody. "Antibodies" are the specific substances produced by the organisms under the influence of antigens. They are supposed to act as ambuscapes; i.e., as linking the antigen to the complement. The "complement" is an unknown substance (or substances), normally present in the blood, and which acts on the antigen-antibody combination.

E. Well, 1916, proposes the term "sensitizin" in place of "anaphylactic antibody." Ordinarily, the serum is identical with the sensitizin; but it may deprive it of part of its precipitating power without loss of sensitizing value.

Production of Anaphylatoxin.—Since a sensitizing injection and a following incubation period are necessary to anaphylaxis, it is evident that a definite change must occur in the body before the anaphylatoxin is formed or can become effective. Several possible explanations of this are tenable.

Nature of Anaphylatoxin.—The similarity of the anaphylactic phenomena indicates that whatever the nature of the antigen, the resulting poison (the "anaphylatoxin") of Friedberger, 1910; "proteotoxin" of Zinsser; "serotoxin" of Jodling and Peterson, 1917, is probably identical or closely related. The process has been conceived as a production of toxic protein cleavage products, through "defensive ferments." No such products, however, have been isolated. It is equally conceivable that the phenomena depend on altered physical properties (surface tension) of the ordinary plasma protein; and it is also conceivable that the change is in the reactivity of the tissues themselves to the antigen. The actual data are confusing and indefinite.

Protein Cleavage Theory.—This is based partly on the "similar" symptomatology of anaphylactic and peptone shock (Bielid and Kraus); partly on the presence of specific proteolytic "defensive ferments" in the blood (Zunt, 1912). Neither evidence is conclusive. General stimulation of smooth muscle is produced by many dissimilar poisons, so that the symptomatology is not a safe criterion of identity. The defensive ferments do not seem to be concerned, for they are present in the blood on the second and third day after the sensitizing injection, when the provocative injection is still quite ineffective (Abderhalden, 1912).

Irritation of Serum Proteins.—It has been observed that serum protein may be rendered toxic in vitro, either by antigen (Friedberger, 1910); or by non-specific means, specially by contact with certain colloids, especially agar (Keysser and Wersemann, 1917; Bobert, 1914; Novy and De Krull, 1917). Novy assumes that the plasma contains a thermolabile protein matrix ("Taraxigen") which is liable to be modified by a variety of agents, non-specific as well as specific, into a toxic phase "Taraxin," probably without cleavage. He assumes that this change occurs; is an individual by-product of the interaction of antigen and antibody, but that it can also be produced by direct action of other colloids on the "Taraxigen." All these assumptions are hypothetical; indeed, it is still an open question whether non-specific "anaphylaxis" has more than a superficial resemblance to specific anaphylaxis.

Site of Production of Anaphylatoxin.—Further considerations show that the direct formation of anaphylatoxin in the blood has really a minor share. In passive anaphylaxis, namely, the degree of reaction is usually quite small or even absent if the antigen and antibody are injected simultaneously, and when they would therefore seem to have the best chance of interacting in the blood; and that the severest reactions occur if the antigen is injected twelve to twenty-four hours after the antibodies—when, in fact, the antibodies have largely disappeared from the blood, and are presumably fixed in the tissues. It is therefore probable that the reaction occurs more effectively in the tissues than in the blood. This is further supported by the observation, to be described presently, that blood-free organs of sensitized animals react with the specific antigen. It leads to the view that both in active and passive anaphylaxis, the antibodies are localized mainly in the cells (as "seasie receptors"); and that it is here that the interaction of antibody and antigen, and the formulation of anaphylatoxin mainly occurs (Riedeberger, 1917). A part of the antibody, however, is given off to the blood, and some anaphylatoxin may therefore be liberated in the blood stream (Priedemann, 1909; Lind and Kraus, 1910). Manvaring, 1910, and Voegtlin and Bernheim, 1911, and Well, 1917, believe that the anaphylatoxin is produced mainly in the liver.

There is also direct evidence that the union of antibody and antigen is relatively slow in the blood stream; for they may exist there simultaneously and assuited, for days, combining slowly in vitro if the blood is removed. This suggests the presence in the blood stream of some inhibiting substance or conditions, such as are common in colloid reactions. For instance, it is known that antireactions are inhibited by excess of either antibody or antigen.

It will be seen that, whilst there is direct evidence that antibody, complement and
antigen are somehow connected with anaphylaxis, the evidence for the production of anaphylatoxin by proteolytic cleavage is mainly indirect. Against it may be placed the observation that no increase of cleavage products has been actually demonstrated, f.d.a. in the anaphylactic lung (Baer and Ansky). Further, that the reaction of excised tissues of sensitized animals to antigen are more rapid than is customary in ferment processes (Dale, 1913). Neither of these facts actually disproves the cleavage theory; for the increase of the products might be too small to be demonstrable; and the conditions for ferment action in the tissues are probably much more favorable than in the test-tube (Dixon, 1913). However, they suggest the possibility of other explications. It is quite conceivable that anaphylaxis consists in a special sensitiveness of the tissues to the antigen itself, rather than in the production of cleavage products; or that the toxicity is developed by some physical change of the serum colloids—perhaps in their surface tension—rather than by their cleavage.

Share of Tissues in Anaphylaxis.—Anaphylactic sensitization is manifested mainly in the tissues, rather than in the circulating blood. It need not be further discussed whether this is because the cleavage occurs in the tissues, or because the tissues have acquired a hypersensitivity to the antigen itself. The fact is shown conclusively by the transfusion experiments of Pearce and Eisenbrey, 1910. They found that a sensitized dog transfused with normal blood exhibits immediate anaphylactic shock when the antigen is injected; whereas a non-sensitized dog transfused with sensitized blood shows no immediate effect when the antigen is injected. It is also proven by the fact that excised and blood-free organs of sensitized animals exhibit a high specific response to the sensitizing protein.

Response of Excised Sensitized Tissue.—Schulte, 1910, first showed that washed smooth muscle of sensitized animals reacts specifically to the sensitizing protein. Foreign sera generally stimulate the smooth muscle of normal (non-sensitized) animals, but produce no reaction in sensitized animals. The production of the specific antigens in the production of the hypothetical toxic substance must therefore occur directly in the sensitized tissue. The response is almost immediate, so that the hypothetical cleavage, if such occur, must be immediate, and not by ordinary ferment action.

In guinea pigs, which have been rendered immune (desensitized) by repeated injections, the excised uterus is still sensitive to the antigen. This form of antianaphylactic must therefore be due to an inhibiting substance in the blood of the immune animal.

However, in the excised uterus, one dose of the antigen desensitizes the uterus to further doses (but not to normal serum). The antigen therefore destroys the hyper-sensitivity of the sensitized muscle (perhaps by saturating the receptors). The persistence of the normal reaction to normal serum is a further proof that this is quite distinct from the anaphylactic response.

Prolonged contact with serum of a sensitive animal again renders the uterus sensitive (passive sensitization); but a normal uterus can not be passively sensitized.

Weil, 1914 and 1916 confirmed the results of Schulte and Dale. W. H. Moore, 1915, found that the susceptibility of the sensitized uterus is increased if all blood has been removed by transfusion with Locke’s solution; indicating that the blood has an inhibiting influence.

If the muscle is further freed from tissue lymph and other diffusible elements by repeated centrifugation in Locke’s solution, the sensitiveness is greatly decreased; the sensitiveness being quantitatively restored if these muscles are treated with normal guinea-pig serum. This indicates that some constituent of normal serum is essential to anaphylactic stimulation.

Mainwaring, Meinhard and Denhart, 1916, observed that the isolated rabbit heart is poisoned by goat serum. If the rabbit had previously been sensitized to the serum, the heart is more resistant. On the other hand, the addition of the serum of a sensitized rabbit to the goat serum increases the toxicity.

Direct reactions of the tissue with the antigen have also been observed in the liver (Weil, 1917) and lungs (Mainwaring and Crowe, 1917).
UTERINE STIMULANTS AND SEDATIVES

DIRECT TOXICITY OF AGAR

The intravenous injection of agar solutions, or gels, into guinea pigs also produces symptoms resembling anaphylaxis; especially the acute pulmonary emphysema (also in perfused lungs). Hanelk and Kasner, 1920, however, showed that this is not due to stimulation of the bronchial muscle, but to hyaline emboli (presumably agar). These result in mechanical compression of the bronchi. Agar also agglutinates red blood corpuscles in vitro.

OTHER CARBOHYDRATE COLLOIDS

Bennettization.—This occurs in vitro with acacia, soluble starch, tragacanth; not with dextrin or glycogen (Kasner and Hanelk, 1920).

Perfusion of Lungs.—Neither broncho-constriction nor pulmonary distention occurs with acacia, dextrin, glycogen, or soluble starch.

RECAPITULATION OF ECBOICLES (OXYTOCICS) AND EMMENAGOGUES

Ecboiles are remedies which stimulate the gravid uterus to the expulsion of the fetus. When used in the non-gravid condition, they often increase the menstrual flow, and are then called Emmenagogues.

They may be grouped into the following classes:

1. Direct Stimulation of the Uterine Muscle or Invagination.—Pituitary, ergot, histamin are the only reliable oxytocics for therapeutic use. Other members of this class are quinin, hydastins, pilocarpin, physostigmn, nicotin, muscarin; and parasympathetic stimulants in general.

2. Intestinal Irritants.—These include:
   All Debatable Purgatives: Aloes, Myrrh, etc.
   Irritant Volatile Oils: especially Savin, Thyme, Pennyroyal, and Turpentine.
   All other Intestinal Irritants: Carbanides, Digitalis, Metals, etc. A similar action is also claimed for Borax, but may be considered doubtful.

It must be remembered that these irritants produce their ecobic effect only secondarily to a gastroenteritis. The latter may be so violent as to be fatal without accomplishing the desired result. They should not be employed for ecboiles, but the volatile oil may be useful as emmenagogues.

Application of heat or counterirritants to the pelvic region or feet: hot foot- or hip-baths, mustard plasters, hot irrigations of the vagina, etc. These milder measures are only emmenagogues. When nutrition is low, they may be greatly aided by tonics.

OXYTOCICS OF MINOR IMPORTANCE

Geosyphi radix Coetox, B.P.; Cotton Root-bark.—The dried root-bark of Gossypium herbaceum and other species. This also was used as abortificient by the negroes. It contains resins, but no alkaloids nor tannin (Power and Browning, 1914; Later, 1910). Clinical and experimental reports are not favorable; the perfused uterus, however, is stimulated (Scott, 1911).

Dose: Geosyph, Rad. Cont., B.P.—20 per cent. Dose, 15 to 30 c.c., 1/2 to 2 ounces, B.P.

Ex. Geosyph. Rad. Cont. Liqu., B.P.—Dose, 2 to 4 c.c., 1/4 to 1 dram, B.P.

Penny Root.—Holste, 1756, claims that this contains an alkaloid that stimulates uterine contractions, constricts blood-vessels, and increases blood coagulation. This needs confirmation.

UTERINE SEDATIVES AND HEMOSTATICS

A number of drugs of ill-defined actions are popularly credited with quieting the excitability of the uterus, especially the pains of premature labor; with contracting the os uteri; with arresting uterine hemorrhage; with regulating dysmenorrhea, particularly at puberty and the climacteric; and even with correcting uterine malpositions.
It is difficult to conceive a mechanism by which a drug could produce all of these actions, except through the imagination. Many of these complaints are so uncertain in their course, and indeed so largely nervous, that it is easy to imagine any results that are desired. The use of these remedies was mostly taken from uncritical folk medicine and promulgated by obscure and ill-trained practitioners during the most uncritical period of therapeutics. They owe their continuance in the pharmacopoeias mainly to their extensive use in proprietary "female weakness" remedies. These in turn rely for their sale on the liberal use of alcohol and exaggerated suggestive advertising.

Under these circumstances, there is practically no serious evidence for the clinical usefulness of these drugs. Excepting hydrastis and cotarnin, which belong to a somewhat different class, there is no record of any competent clinical investigation by experienced critical observers under hospital conditions. The clinical cases that are published are generally very superficially recorded; they generally show evidence of prejudice and exaggeration; and are often vitiated by the simultaneous use of other measures of more evident value.

Experimental Investigations.—Pharmacologically, most of the drugs of this class are practically inert, especially as concerns the uterus. Since the excised uterus reacts essentially like the uterus in situ, it may be fairly taken as an index of uterine activity. Pilcher, 1916, has investigated in this way the drugs which are used most commonly in these female remedies, employing the relatively very high concentrations of 12,000 to 1,000.

He obtained no definite effects with: Chamomilla lactuca (Helonias dioica); Loechurus cardia; Passiflora dentata; Mitchellia repens, Chestnut bark.

The following gave more or less pronounced effects (but not sufficient to confirm any therapeutic value):

- Slight Depression.—Valerian; Dioscorea villosa; Aletris farinosa; Ichthyomenis piscipula; Pulsatilla pratensis; Cypripedium pubescens; Scutellaria laterifolia; Scrophularia marylandica; Senecio aureus; Viburnum opulus.

- Insufficient Stimulation.—Acer spicatum; Cnicus benedictus; Viburnum prunifolium—Constant Marked Increase of Tone.—Caulophyllum thalictroides.

These were obtained chiefly on the excised uterus of guinea pigs. The excised human uterus required higher concentrations, but gave the same reaction.

(Pilcher, 1917).

Uteri in Situ in Living Animals.—None of the above drugs produced any effect in anything like normal doses (Pilcher and Mauer, 1918).

Excised Intestines.—These are also affected, similarly to the uterus. Caulophyllum, however, is much less active in comparison with the tone. Valerian (col.) depresses the contractions. Viburnum opulus and prunifolium are inactive (Dezelle, Burman and Pilcher, 1916).

VIBURNUMS

Viburnum prunifolium and Viburnum opulus had the widest reputation amongst these uterine sedatives, and for that reason deserve more detailed discussion, although their usefulness is no more demonstrated. Illustrative of this is the fact that the drug sold as Viburnum opulus has, for the last twenty years, consisted of the bark of a maple—Acer spicatum (Farwell, 1913, and others).

Viburnum prunifolium or Black Haw, a rather common shrub, was used somewhat in domestic medicine (Lloyd). It was introduced into medical practice mainly by the clinical papers of Phares, 1866, and Jenks, 1876. Both praise it with extravagant enthusiasm. The next ten years were the high tide of its popularity, as judged by an output of 75 articles on the subject. The interest then abated equally suddenly, for the next thirty years have produced only some 15 papers.

The whole early literature is highly typical of the least class of clinical "evidence," and does not merit serious discussion. The mechanism of its reputed action is at most a matter of speculation. The only attempts at investigation date from R. L. Payne, 1888, and Sherman, 1896, and these did not include the uterus. They showed at most that very large doses may produce depression of the whole nervous system, without practical significance.

La Torre, 1912, interprets the histologic picture as contraction of the uterus, compressing the uterine vessels.

The first real search for uterine action was made by Lieb, 1914. He believed that he observed stimulation of the excited uterus. However, more extensive investigative
by Pilcher, 1916; by A. P. Matthews and Hager; by Hager and Becht, 1910, and by
Hale, gave generally negative results under all conditions (uterus pregnant and non-
pregnant; in situ or excised). Neither viburnum has any effect on excised intestine.

PREPARATIONS—VIBURNUM

Viburnum Prunifolium, U.S.P.; Viburnum, B.P. (Black Haw).—The dried bark of
Viburnum prunifolium contains resins (viburnin), valeric and tannic acids, etc. Dose,
1 Gm., 30 gr., U.S.P.;
Est. Viburn. Prunifol., U.S.P.—A powdered extract, 1 Gm. representing 4 Gm. of
drug. Dose, 0.5 Gm., 8 gr., U.S.P.;
Flos Viburn. Prunif., U.S.P.; Est. Viburn. Liqueur, B.P.—Dose, 2 c.c., 30 minims,
U.S.P.; 4 to 8 c.c., 1 to 2 drams, B.P.

SEXUAL GLANDS

Specific internal secretions of these glands are concerned in the production of the
“secondary” sexual characters; and in the cycles of menstruation, pregnancy and
lactation. For many of these phenomena, however, the continuous functioning of the
glands in situ is necessary; the therapeutic administration of the glands in sub-
stance or extracts has therefore been only of limited value.

OVARY

This has been given for the relief of the symptoms which follow the
natural or artificial menopause. It is difficult to say how far the rather
inconstant benefits are psychic. The most favorable results have been
reported in postoperative menopause in young women.

The so-called “endometritis glandularis” is really a menstrual exaggeration, prob-
ably of ovarian origin, due to an atypical course of the luteum production; most likely
to occur at puberty and the climacteric (Wagner, 1915).

Beneficial results are also claimed in some cases of amenorrhea with chlorosis. Ex-
perimentally, it has little effect on normal animals; but when oxidation has been de-
pressed by castration, in bitches and somewhat in dogs, it is restored to the normal
level or above by the administration of ovarian extract.

The average daily dose of the dried ovary (hog) is 0.5 gm., 7.5 gr.

CORPUS LUTEUM (LUTEIN)

This is similarly to Ovarian Extract (Fraenkel 1903; McDonald, 1916;
Burnam, 1912). Clinical opinions differ as to its relative efficiency.

The specific effects of the corpus luteum on the sexual cycle are not secured by
its administration (L. Loch, 1910 and 1911; and Corner and Hurni, 1918).
Injections are slightly galactopoietic in goats (Ott and Scott, 1910; Schaeder and Mackenzie,
1918). They start hypertrophy of the mammary gland and lactation even in virgin
nibbit (Ott and Scott, 1914). Intravenous injection lowers the blood pressure (Villenin,
1913).

Graves, 1913, claims that the whole substance of the ovary is therapeutically more
effective than corpus luteum. He believes that the interstitial cells are important.
However, there is no real evidence either way.

Action on Excised Smooth Muscle.—Extracts of corpus luteum or ovary have but
little effect on the excised bladder and ureters; they stimulate excised uterus about like
other gland extracts; and they produce especially strong stimulation of the vas deferens.
This has been suggested as hio-assay; i.e., that concentrations corresponding to 0.2
per cent of the fresh gland should stimulate the vas deferens of rats. This reaction is
This name is peculiarly unfortunate, since it had previously been applied to the yellow coloring
mantine of eggs.
stronger with the corpus luteum than with the ovarian extracts (Matsumoto and Mach, 1910).

**Administration.**—The average daily dose of the dried substance is 0.1 gm., 1/4 gr.

Danreuther, 1914, uses the blood pressure as a guide: this should fall, not to exceed 15 mm. This usually requires 0.5 gm. of the dried substance, the urine often showing albumin. He believes that the corpora of pregnant ovaries are much more effective; but McCord, 1914, claims that under slaughter-house conditions, at least 90 per cent. of the weight of indiscriminately collected material would be from pregnant animals.

---

**MAMMARY GLAND**

This has been used against excessive menstruation (daily dose, 1 gm., 1/2 gr. of the dried gland). Extracts increase the movements and the tone of the excised uterus (Ott and Scott, 1909) and are somewhat galactagogue, but not in human (Schafer and Mackenzie, 1910).

---

**EXTRACT OF PROSTATE**

**Tadpoles.**—Feeding with prostate hastens the metamorphosis of tadpoles; but unlike thyroid, it does not check growth. The effect is not due to iodin, for this is not present. It seems to be specific to this tissue (Mach, 1910).

**Excised Smooth Muscle.**—This is stimulated, the uterus being especially sensitive (Ott and Scott, 1909; Mach and Matsumoto, 1909).

**Metabolism.**—This is increased, but not as much as by ovarian extract.

---

**ORCHITIC EXTRACTS**

Brown-Sequard, 1889, announced that hypodermic injections had remarkable stimulant qualities. Sensational exploitation brought his claims into rapid discredit, and the extract is now scarcely employed. The most marked effect is said to be an increase of 15 to 20 per cent. in the capacity for voluntary muscular work (ergograph).

This action has been attributed by Poehl to the base spermin (CH14N2). While this is especially abundant in this extract, it also exists in many other tissues. Its actions on the heart and circulation resemble those of cholin, which is also present in the orchitic extract. Its phosphate forms the "Charcot-Levy" crystals found in sputum, etc. The action of these substances is supported by a nucloprotein, which causes a slowed heart and fall of blood pressure through stimulation of the vagus center, and dilatation of the splanchic vessels, also through the center. The orchitic extract applied to the isolated heart (Porter and Langendorff method) shows increase in force and frequency. The excised uterus shows slight stimulation.

---

**NITRITES, NITROGLYCERIN, AND OTHER ALKYL NITRATES**

**General Statement.**—The nitrites, the nitrous esters and the organic nitrates, which are reduced to nitrites in the body, lessen the tone of arterial muscle, thus producing a prompt fall of blood pressure. Their other effects are unimportant. They are used for the relief of arterial spasm and other conditions of high blood pressure.

**Members.**—This group comprises the inorganic nitrites (NaNO2); the nitrous esters (amyl nitrate, ethyl nitrite, "Sweet Spirits of Niter"); and substances which liberate the nitrite ion within the body. Most important amongst the latter is glycerin tri-nitrate (nitroglycerin or glonoin), which is easily broken up by alkalies into a mixture of nitrates and nitrates; a similar change occurs in the body. Erythrol tetranitrate and mannitol hexanitrate undergo analogous decompositions, but much more slowly. Even inorganic nitrites are reduced to a slight extent
NITRITE GROUP

H. H. Bunsen, 1901), specially by the putrefactive bacteria of the colon, and may thus give rise to the phenomena of nitrite poisoning; but this requires very large doses such as the quantities of Bismuth Subnitrare used in Röntgen treatment.

Hydroxylamine, (NH₂OH), is decomposed in the body into nitrite and ammonium. It produces the effects of both these substances (methemoglobin formation, convulsions, mental paralysis, Lewin, 1886).

Differences in Activity.—It is generally assumed that the organic nitrates act only after being reduced to nitrites; but this is not proven. The fact that excised vessels react promptly to these nitrates suggests that they may perhaps act directly. It is also remarkable that the effective dose of nitroglycerin is but a hundredth of that of sodium nitrite. Presumably the organic esters penetrate more readily into the cells, and perhaps the reduction occurs only after their penetration or there may be certain peculiarities in the reduction. These may also explain individual differences of susceptibility. C. R. Marshall, 1912, finds that the introduction of OH and CO₂H groups into organic nitrates diminishes their vasodilator action.

The nitrates of monohydric alcohols are less effective than the polyhydric, probably because of slower decomposition. Nitroglycerin and erythrol-tetranitrate act quantitatively alike when equimolecular doses are injected into a vein; by mouth the action of the erythrol ester is weaker and more prolonged, because it is much less soluble, and therefore more slowly absorbed (Marshall, 1912).

Reducing Properties of Tissue.—Many other substances are reduced in the tissues; such are methylene blue, arsenic acid, the oxides of tellurium and selenium; nitrobenzal anilin; sulphur into hydrogen sulphide, etc. The change is not due to fermentations (Hofff, 1907, 1908). The reducing power of different organs varies greatly. Many other substances are, of course, oxidized in the tissues, the processes of oxidation and reduction going hand in hand.

Actions on the Circulation.—The most important effect of the nitrates is a prompt fall of blood pressure, due to vasodilatation by direct action on the blood vessels.

Course of the Vasodilatation.—This is first noticed in the skin of the face, in an area similar to that involved in blushing, but which may extend over the entire trunk to the illum. The meningal vessels undergo dilatation at the same time. There is consequently redness of the face, heat and throbbing in the head, and headache. The flushing of the skin is brief, but headache is apt to persist, especially with erythrol tetranitrate. The retinal vessels are also dilated.

When amyl nitrite is inhaled, there is generally at first some reflex (vagal) slowing of the heart. Very soon, however, the heart is greatly quickened, so much so that a rise of blood pressure is frequently observed at the start (Hewlett, 1906), the dilatation being more than overcome by the quickened beat.

The dilatation does not, however, remain confined to the skin, but spreads to other vessels, and relaxation of the splanchic area in particular causes a speedy fall of blood pressure (Fig. 16) and a dicrotic pulse (Fig. 17). The fall of blood pressure is due entirely to the extensive vasodilatation, produced by the direct action of the nitrite on the arterioles. The vasomotor center is not inhibited, but rather stimulated by the cerebral anemia (Pflüger and Sollmann, 1914). It is possible, however, that the preliminary blushing is a central effect.

Evidences of Vasodilatation.—The fall of pressure occurs equally well when the cardiac changes are excluded by atropin. The vasodilatation can be demonstrated directly by inspection (the blushing); by plethysmographic measurements (Dossin, 1911) and by the increased rate of vein flow.
Effects on Vein Flow and Vein Pressure.—Burton-Opitz and Wolf, 1910, on injecting nitrite into the femoral artery, found the vein flow and vein pressure increased in the corresponding leg, whilst the general arterial pressure was practically unchanged. If amyl nitrite was inhaled, the vein flow in the leg decreased with the blood pressure, because of the withdrawal of the blood into the more powerfully dilated splanchnic vessels. Capps, 1911–1913, also found a fall of vein pressure.

In man, Hewlett, 1913, found increase of the volume, but scarcely of the blood flow, of the arm. Stewart, 1915, showed a quite definite increase of the blood flow of the hand.

![Graph](https://example.com/graph.png)

**Fig. 16.—Amyl Nitrite on Carotid Pressure. Dog.** The nitrite is inhaled between the two vertical lines. The upper tracing is taken from a normal dog, the lower after atropin. The heart was quickened by the nitrite in the upper tracing, but not in the lower.

There are also definite changes in the "pulse-flow" (the flow during the cardiac cycle). These occur when therapeutic doses are given in arterial tension, even when the blood-pressure readings are not reduced (Hewlett, 1917).

Systolic and Diastolic Blood Pressure.—The relative preponderance of these indicates the mechanism of blood-pressure changes: If the greater change is in the **systolic pressure**, the cause is in the vasomotor-tone or heart-rate. If the change is greater in the **diastolic pressure**, the cause is in the cardiac force or blood-volume (Pichler). With nitrite, therefore, the diastolic fall should be greater than the systolic, unless there is a very marked increase of the heart-rate.

![Graph](https://example.com/graph.png)

**Fig. 17.—Amyl nitrite on sphygmogram: a. Normal; b. after inhalation of four drops.**

The Dilator Action is Peripheral.—It occurs after ligation of the blood vessels of the brain (Mayer and Friedrich, 1875); after destruction of the spinal cord (Laddie Brunton, 1860); in excised organs (Atkinson, 1888; Marshall, 1898, etc.); and even in excised arterial segments (Cow, 1911). It is therefore due to depression of the tone of the vascular musculature. There are as yet no convincing data as to the precise site of the action. Strong stimulation of the vasomotor nerves raises the blood pressure even during the nitrite fall (Bernheim; Mayer and Friedrich). The nitrites are said to act after degeneration of the cervical ganglia. It seems probable therefore that they affect the myoneural junction or muscle substance.

**Antagonisms.**—Nitrites are mutually antagonistic with most vascular constrictors; thus, splanchnic stimulation (Bernheim, 1874), epinephrin, strophanthin, etc., raise the blood pressure during the nitrite fall; and conversely, nitrites lessen the rise of these constrictor agencies.
The antagonism is quantitative; J.A., sciatic stimulation gives the same millimeter rise during as before the nitrites; and nitrites give the same millimeter fall during as before atropin, hydrastin, pithuitar, strychnin or ergot. This suggests that the point of attack of the nitrites is different from that of the pressor agencies (Fiehler and Sollmann, 1912).

Cameron, 1906, proposed to utilize the antagonism for the bio-assay of epinephrin. He states that 0.0 mg. of nitroglycerin exactly neutralizes the pressor effect of 0.0075 mg. of epinephrin.

The Vasomotor Center.—This is not depressed, but rather stimulated by its anemia; the stimulation, however, can not overcome the peripheral depression. This is shown by the perfusion experiments of Fiehler and Sollmann, 1912. Similarly the blood pressure does not fall if a nitrite is introduced into the cerebral circulation, but prevented from reaching the systemic vessels. (Filehne, 1874, had concluded that the vasomotor center is depressed.)

The Pulmonary Circulation.—The pulmonary vessels are not so markedly dilated; indeed, Macht, pressure found constriction in excited pulmonary arteries. The pressure in the pulmonary artery is generally slightly increased (Brandford and Dean, 1894; recent literature in Wiggers, 1917). The rise is probably due partly to the engorgement of the large veins.

Brain-volume.—In man (trephined), this is dilated by the inhalation of anhyd nitrite (Raphael and Stanton, 1919).

The Coronary Vessels.—The outflow from the coronary veins is increased in intact animals (F. Meyer, 1912; Schloss, 1913) and in excised mammalian hearts (O. Loeb, 1923). The coronary vessels are therefore dilated (also excited arterial rings; Voeglin and Macht, 1913); and the coronary circulation is improved. This explains the beneficial action in angina pectoris.

Intraocular Tension.—This is raised by anhyd nitrite, even when the general blood pressure is lowered (Wessely, 1915). This enjoins caution when using nitrites in glaucoma. The retinal vessels are also dilated (Hartlieb, 1915).

The Tachyadria.—This is due mainly to depression of the vagus center, for after section of the vagi, or after atropin, nitrites cause but little further acceleration (Mayer and Friedrich, 1873). The slight remaining quickening is abolished by dividing the accelerators (Dossin, 1911). The rate of the excited heart is not changed by nitrites (Plageur, 1905). The excitability of the vagus trunk to direct electric stimulation persists.

The depression of the vagus center is due to the fall of blood pressure, and not to a direct action of the nitrite, for no quickening occurs if the pressure is kept level by partial compression of the aorta (Filehne, 1879; Sollmann). The vagus center may still respond to strong reflex stimulation (Mayer and Friedrich).

Is man, the acceleration on inhaling anhyd nitrite is considerable, often to double. No acceleration occurs in complete heart-block. This has a diagnostic value, similar to atropin (belledir and Dubois, 1913).

In experimental partial heart-block, the rate is still quickened by anhyd nitrite (Friedrich, 1916).

Ectocardiograms.—When anhyd nitrite is inhaled by intact dogs, there is first a marked reflex increase of vagus tone, shown by slowing of the sinus-rate, exaggerated sinus arrhythmia, lengthened A-V time or A-V block, and a negative tendency of the P and T waves.

At the blood pressure falls, these changes are reversed. The vagus tone becomes depressed, the sinus-rate is quickened, the arrhythmia and block disappear, and A-V time is shortened; the P and T waves become more positive. These phenomena are not affected by previous digitalization; however, large doses of nitrite abolish the ectopic beats due to digitalis (Halsey, 1917).

Character of Pulse.—As the result of the quickening, the excursions of the heart are smaller. The blood-pressure waves appear particularly low, because the P wave is more readily dissipated, on account of the dilatation. The pulse, on the other hand, may be bounding and dicrotic, because the arteries are emptied more completely during diastole.
The heart-muscle shows no important direct change; however, the better coronary circulation and the lowered peripheral resistance may improve and relieve a weakened heart (MacNider, 1908).

The excited mammalian heart is scarcely affected by moderate doses, perhaps slightly stimulated, then depressed (Lohr, 1901; Plumier, 1905; Dossin, 1911). The excited frog’s heart may be quickened by low concentrations (2:10,000), higher concentrations weaken (1:5,000), or stop (1:1,000) the contraction.

Methemoglobinemia.—Excessive doses of nitrates form methemoglobin (Gamgee, 1868) and this causes cyanosis and asphyxia. However, since the blood corpuscles are not destroyed, the animals generally recover.

The methemoglobin formation by sodium nitrate, in vitro, is proportional to the hydrogen-ion concentration (C. R. Marshall).

Penetration of Red Blood Corpuscles.—These absorb nitrate ions, with removal of chloride ions. The entrance of the nitrate ions is retarded by certain anions (Roberty, 1916).

Respiration.—This is accelerated (Mayer and Friedrich), probably by the changes in the blood and circulation.

The Bronchial Muscles.—These are relaxed by nitrates (Doyon, 1906; excited. Titec, 1921;3 surviving lungs, Buchr and Pick, 1911). This may explain their use in asthma. The smoke of the “Charta Potassii Nitritiis” (paper impregnated with saltpeter) probably owes a part of its effect to nitrate compounds.

Gall-bladder.—This is elaxed by nitrates (Lieb and Mchorter, 1916).

Intestinal Muscle.—Hirschfelder, 1915, finds that the systemic administration of nitrates relaxes the intestinal constriction produced by lead salts. It has been used clinically in lead colic, but with limited success.

Excised Ureter.—This is rapidly paralyzed (Macht, 1917).

Digestion.—Nitrates cause some slight interference with the digestive ferments (Hale, 1912); but probably not enough to be important. Sodium nitrate is supposed to produce some gastric irritation, by the liberation of nitrous acid—this is not sufficient to interfere with its therapeutic use.

Urination.—The urinations produced in the secretion of urine appear to be purely secondary, and will depend upon whether the renal arterioles or those of the general circulation are relatively more dilated, the former causing an increase, the latter a diminution of urine.

In patients with excessively high blood pressure, the nitrates generally increase, sometimes quite considerably, the excretion of urine, nitrogen, total solids and phenolsulphonphthalain (Lawrence, 1922).

Pressure of the Cerebrospinal Fluid.—This is increased by amyl nitrates, presumably through the methemoglobin asphyxia (Dixon and Halliburton, 1913, 1914).

Metabolism.—The effects have been studied by Surveyor, 1906.

Temperature.—Small doses have no effect on normal temperature, but are antipyretic in fever, by dilating the skin vessels (Jacob, 1913; Krauss, 1913). Ethyl Nitrite, as “Sweet Spirits of Niter,” has been used popularly as a diaphoretic and diuretic. Its action is not very energetic. Large doses of nitrates also lower the normal temperature by depressing the circulation.

Fats.—Some 60 to 70 per cent. of the nitrates disappear in the body, their fate being unknown.

Rapidity and Duration of Action.—This constitutes the principal difference between the members of the group. Amyl nitrite; when inhaled, acts in ten to fifteen seconds, the action disappearing again within seven minutes. Glyceryl trinitrate, ethyl nitrate, and sodium nitrite act in two to ten minutes, the action persisting a half to two hours. With erythrol nitrate, the effects appear only after half an hour, and last five hours (Wallace and Ringer, 1909; E. Matthew, 1909; Rzenkowski, 1909; J. L. Miller, 1910).
The following table from Matthew shows in detail the average relation for oral administration in man. (The fall in diastolic pressure is about half of that in the systolic pressure; Lawrence, 1912.)

A systolic blood pressure.

Influence of Dosage.—The extent of the fall increases with the dosage, the increase becoming progressively smaller. The duration of the action is not so much influenced by the dosage.

Influence of Pathologic Conditions.—The average effect is about the same in disease as in health. In cases of abnormally high blood pressure, the absolute fall is greater, but the percentile fall and the duration are the same (Wallace and Ringer).

Idiosyncrasy.—Different patients vary considerably in their reaction, and some fall entirely to respond to the nitrates; especially those with chronic Bright's disease and edema, but also in other conditions. Sometimes one member of the group will succeed when another fails. No result need be expected if the arterial fibrosis has destroyed most of the muscular fibers. The tolerance is often very marked. In other patients, even small doses caused alarming syncope and cardiac slowing. The severity of the headache is also variable.

Habituation.—This usually occurs more or less if the administration of nitroglycerin is continued, often in two or three days. The dosage must then be increased or the response disappears. Suspension of the administration for a few days may restore the susceptibility. Matthew claims that the tolerance is not acquired with sodium nitrite or erythrol tetranitrate.

Therapeutic Use in Arterial Hypertonus.—The nitrates are employed mainly for reducing the blood pressure in conditions of arterial hypertension. The effect is not curative, but the symptomatic relief of the headache, etc., is usually marked, outlasting the blood-pressure effect of the single doses. However, they usually lose their efficiency after a short time. Increasing the dose generally produces unpleasant symptoms—headache, restlessness, sometimes dyspnea. They must therefore generally be alternated with venesection, sweating, nauseants, etc. The effect of these is usually less marked but more lasting (J. L. Miller, 1910; C. H. Lawrence, 1912). Nitroglycerin and sodium nitrite appear to be the most useful; the action of amyl nitrite being too brief, whilst erythrol tetranitrate often causes intense headache. Sodium nitrite is said to give least headache (Hewlett, 1912).

Administration and Dosage.—The dosage of the nitrates should be kept as low as possible, to prevent the rapid development of tolerance. It best to give just enough to cause a slight quickening of the pulse, and
feeling of fulness in the head; or a fall of systolic pressure of about 30 mm. This dose may be given four times a day. The initial dose may be 0.5 mg. (1/40 gr.) of nitroglycerin, increasing gradually. The equivalent doses of the other nitrites are shown on page 457. The treatment may be intermitted for a few days in every two or three weeks, starting again with a smaller dose. Hypodermic injections are rarely needed, the drug being readily absorbed.

Cardiac Insufficiency.—The relief of the heart from excessive resistance may render nitrites useful in these conditions. Nitroglycerin (1 mg.) is used, generally in combination with Digitalis.

Angina Pectoris.—The inhalation of amyl nitrate was introduced by Lauder Brunton in 1867. In some cases (presumably with spasm of the coronary arteries) the relief is complete; in others, probably of different pathology, it is ineffective. One to 3 drops of the promptly acting amyl nitrate are inhaled. It may be carried in thin glass capsules, “pearls,” one of which is crushed in a handkerchief, as needed.

Ingalls and Meeker, 1918, prefer a nitroglycerin tablet of 1/400 gr. dissolved under the tongue. This generally acts in 1 to 3 minutes. If it fails, they repeat the dose every few minutes until relieved.

They found that sodium nitrite often disturbs the stomach after a few doses. They believe that death in angina is generally due to vagus arrest of the heart; and that the nitrite fall of pressure saves life by inhibiting the vagus center. Thus, no definite evidence for this suggestion.

Migraine sometimes yields to nitrites, presumably in those cases attributed to spasm of the cerebral arteries. Epilepsy is also said to be sometimes benefited. Relief of lead colic (Krieg, 1858) has been claimed, but the efficiency is at best unreliable.

Hemorrhage.—The lowered blood pressure would tend to arrest hemorrhage, but the bleeding would be favored by the direct dilator action. The result of the opposite tendencies is difficult to foresee, and probably varies with different conditions. Nitrites would therefore be unreliable remedies. Experimentally, Frey, 1909, found slight increase of pulmonary hemorrhage; Lüscher, 1907, claims diminution of intestinal hemorrhage.

Capillary hemorrhage from superficial wounds is increased by the systemic administration of nitrites, notwithstanding the fall of pressure (Hanakin, 1918).

Untoward Effects.—Occasionally, therapeutic doses may cause fainting. Other side actions which may occur are localized edema, excessive sweating, and visual disturbances (Cornwall, 1913).

Toxic Effects.—Nitroglycerin has a toxicologic importance from its use as an explosive. Overdoses produce nausea, vomiting, colic, and sometimes bloody diarrhea. The skin is flushed and perspiring. There is vertigo and persistent throbbing headache, rarely blindness and delirium. The respiration is first hyperpneic, then dyspneic and slowed. The surface becomes cold and cyanotic; the pulse is gradually slowed, dilated and intermittent. Paralysis sets in, and is followed by clonic convulsions. The reflexes are lost. Death occurs by failure of respiration, after four to seven hours. The fatal dose varies greatly. D. D. Stewart, 1905, reports a patient in whom 20 gr. of absolute nitroglycerin produced only slight effects.

Nitrate poisoning may be caused by large doses of bismuth sulfamate (see Indol). Absorption.—Nitroglycerin is readily absorbed. Even the application of it to the skin causes some effect, and persons engaged in its manufacture suffer severely from headache during the first few days. After this, however, they appear to be quite unaffected, unless they leave work for several weeks and then resume the occupation. The work is said to be not unhealthful. The local action on the hands may result in skin eruptions and ulcerations.

Smokeless gunpowders (nitroglycerin, nitrocellulose, etc.), when exploded, liberate gases which produce the combined effects of nitrites and asphyxia. The principal products are nitrogen pentoxide and CO (Kiefer, 1907). The vasoconstriction and tachycardia are followed by persistent headache (“powder-headache”), which does not
Sodium nitrite produces, in animals, symptoms similar to those of nitroglycerin (Doeblein, 1912).

Amyl nitrite also has similar effects (Rosen, 1888).

PREPARATIONS—NITRITE-GROUPS

*Amyl Nitrис (Amyl. Nitrіs), U.S.P.; Amyl Nitrіs, B.P.; Amyl Nitrіte.—A liquid containing not less than 80 per cent. of C₃H₇NO₂ (chiefly iso-amyl nitrite). A clear, yellowish liquid; peculiar, ethereal fruity odor; pungent aromatic taste. Almost insol. in water, miscible with alc. or eth. Amyl Nitrite is very volatile even at a low temperature, and is inflammable. Dose, by inhalation, 0.2 c.c., 3 minims, U.S.P.; 0.12 to 0.15 c.c., 2 to 5 minims, B.P. It may be carried in thin glass capsules, ‘‘pearls,’’ one of which is crushed in the handkerchief as needed.

Ethylene Tetranitrate, N.N.R. (Tetranitrol), C₄H₄(NO₂)₄.—Colorless and tasteless crystalline sol. in alc., misc. in water. Dangerously explosive. Dose, 0.05 to 0.06 Gm., ½ to 1 gr. N.N.R., in tablets of 0.03 Gm.

**Ethylen Nitrіl**, B.P.—2 to 3 per cent. of C₄H₄NO₂ in alc. Dose, 1 to 4 c.c., ½ to 6 minims, B.P.

*spirіrus Ethylіne Nitrіlіs* (Spir. Ath. Nitr.), U.S.P., B.P.; Spirit of Nitrous Ether (Great Spirit of Ether).—An alcoholic solution of ethyl nitrite, C₃H₇NO₂, containing about 4 per cent. U.S.P.; 2 per cent., B.P. (It also contains aldehydes, paraldehyds and ethyl nitrate; but these do not contribute materially to its action; Marshall and Gilchrist, 1915). A pale yellowish liquid, of ethereal odor and sharp taste. Miscible with water and alcohol. Deteriorates readily. Incompatible with antipyrin, morphin and iodide. Brownish color with salicylates; slight effervescence with uva ursi, buckthorn, and senna. The addition of water throws ethyl nitrite out of solution, which then evaporates rapidly, lowering the strength. Dilution should therefore be made shortly before administration (Marshall and Gilchrist, 1915). Dose, 2 c.c., 30 minims, U.S.P.; 0.5 c.c., 15 to 60 minims, B.P.

*spirіrus Glyцerіnіs Nitratіs* (Sp. Glycerіn. Nitr.), U.S.P.; Lis. Trinitrіnіs, B.P.; Spirit of Glycerin Trinitrate; Solution of Trinitrin (Spirit or Solution of Nitroglycerin of Glycerin).—An alcoholic solution of 1 per cent. of C₃H₇(NO₂)₄. A clear colorless liquid, with odor and taste of alcohol. Miscible with water and alcohol. Dose, 0.05 c.c., 1 minim, U.S.P.; 0.05 to 0.1 c.c., ½ to 2 minims, B.P.

*Tabлеті Trinitrіnіs* (Tab. Trinitrin.), B.P.—0.5 mg., ½ to 1 gr. Dose 1 or 2 tablets. The commercial tablets are fairly, although not quite uniformly, active. They do not deteriorate very rapidly (Edmunds and Koch, 1906; Rippeteo and Smith, 1914).

**Sodium Nitrate**, U.S.P.; Sodium Nitrate, NaNO₂.—Freyer sol. in water (1:12). Dose, 0.06 Gm., 1 gr., U.S.P.; 0.05 to 0.12 Gm., ½ to 2 gr., B.P. Maximum dose, 0.3 Gm., 5 gr.

THE DIGITALIS GROUP

General Statement.—Digitalis, Strophanthus, Squill, Apocynum, Barium, and a number of other drugs increase the tone, excitability and contractility of cardiac and arterial muscle. The vagus center is also stimulated. With therapeutic doses, these actions result in slower but more powerful beats of the heart, which bring about compensation in valvular cardiac lesions and thus relieve the symptoms—the irregularities, edema, congestions, dyspnea, etc. Under these conditions, there is often marked diuresis. The blood pressure is generally unchanged in man, usually increased in animals.

The effects set in slowly on oral administration; almost immediately on intravenous injection. They tend to be cumulative, and to outlast the administration for a considerable time.

Toxic doses produce vomiting, cardiac irregularity, and sudden heart failure. The recognition of these toxic effects is important since they often arise from the cumulative action.
The members of the group are local irritants. Their hypodermic injection is painful. Their absorption from the gastro-intestinal canal is slow and often uncertain.

The active principles are generally neutral glucosides, and therefore rather unstable, especially in acid, aqueous solutions. Digitalis contains several distinct glucosides with similar actions, of which the crystalline Digitoxin is the most definite. The various "strophanthins" are derived from several plants. They are chemically related, but differ in activity and toxicity according to their origin.

All the characteristic digitalis effects are produced by all the members of the group, so that a single description will suffice. The differences between them are only quantitative. So far as they are known, they will be pointed out as occasion arises.

Drugs Producing Digitalis Effects.—A considerable number of drugs containing glucosides with "digitalis" action are used in medical practice; such as Digitalis, Strophanthus, Squill, and Apocynum. Of less practical importance are Helleborus, Adonis, Convallaria, Oleander, Cephalanthus, etc. Digitalis glucosides are important constituents of arrow-poison; viz., strophanthin, ouabain, astartin, acocacanthin, etc. (Trendelenburg, 1909). The toxic principles found in the skin and blood of the common toad (Bufo vulgaris and Bufo calamita) produce typical digitalis effects. They appear to be non-nitrogenous derivatives of cholesterin (review, Faust, 1910). A very similar principle (Bafagin) is contained in the so-called "parotid" glands of the tropical toad, Baja aqua (Abel and Macht, 1917). Frogs' skin also has a similar but much weaker action (Frieder, 1910).

Handovsky, 1920, describes an alkaloid "Bufotenin," from the skin of the common toad. It stimulates the vagus center, but paralyzes the respiration, brain and cord. Peripherally it produces direct stimulation of all smooth muscle.

Erythroplecin, a glucosidial alkaloid, can be counted in the group. Other alkaloids—veratrin, caffeine, curin, epinephrin—remind somewhat of digitalis, but are not typical. Barium salts, alkaline hydrates, and even normal saline solutions produce cardiac actions which resemble digitalis, but the resemblance may only be superficial.

Active Constituents of Digitalis.—These comprise a number of glucosidal principles, of which digitoxin and its congeners are the most important.

Well-defined chemic principles were first isolated by Schmiedeberg, 1875; his results were generally confirmed and extended by Kiliian, 1890 to 1892; but our knowledge is still incomplete and the nomenclature confusing. Some if not all of the amorphous products are probably mixtures. The different glucosides yield characteristic decomposition products. Merck, 1912, in his "Reports," vol. 25, Kraft, 1912, and Kiliian 1913, 1914, give a summary of our present knowledge.

Pure Principles.—These can be conveniently divided into four classes:

1. Crystalline; alcohol-soluble: Digitoxin, Schm., Kil.* Ca₂H₄O₁₄. This is the best defined, most abundant, most active, and therefore the most important of the constituents of the leaves (0.22 to 0.4 per cent.) but does not occur in the seeds. It forms crystals, readily soluble in alcohol or chloroform, difficultly soluble in water or ether. It can be split into a hexose (digitoxose) and the crystalline digitoxygenin Kil. It is easily destroyed by fermentations. It produces all the characteristic digitalis effects, but some of the undesirable side actions are too prominent.

2. Amorphous; alcohol-soluble: Digitalin Verum, Schm., Kil., Ca₃H₄O₁₄. Occurs in the leaves and seed. Slightly soluble in water, chlor-

DIGITALIS GROUP

form and ether. Splits into dextrose, digitalein and digitalose Kil.
Produces typical digitalis effects, being about half as active as digitoxin.
The name "digitalin" is often misapplied to other products and mixtures.

3. Amorphous; water-soluble: Digitalin, Schm., Kil.; Gitalin, Kraft,
1911, 1912; and Digalen, Cloetta, are probably mixtures (Kiliari, 1913,
1914) of related substances. They occur in the leaves and seed. Insoluble
in chloroform. They produce digitalis effects. (The name "digitalin"
was formerly also applied to other products.)

4. Water-soluble saponins: Digitonin (Digitapsinon); this occurs in
a crystalline and amorphous form. The crystalline is less readily soluble
in water. Both are only slightly soluble in alcohol and lipid solvents.
The crystalline Digitonin Kil. was considered a definite substance, which
can be split into a hexose and digitoegenin; but Windaus and Schenken-
berger, 1913, consider it a mixture, from which they have isolated Gitonin.
The amorphous Digitonin Schm.(Digitapsinon, Kraft) is probably a mixture
of the crystalline with several amorphous saponins (Kraft). The
digitonins are precipitated by tannin; they combine with many
alcohols and phenols to crystalline compounds. Digitonin does not pro-
duce the digitalis effects but has the irritant and hemolytic properties of
the saponin group. The digitapsinons of the leaves are not hemolytic
(Robert, 1912).

Chloroform Separation.—Hot water extracts all the active constitu-
ents from digitalis leaf. When the infusion in turn is extracted by
chloroform, a part of the active principle passes into the chloroform, and
part remains in the water. The chloroform-soluble fraction is much
more absorbable, and therefore more uniformly active, than the water-
soluble, and is therefore promising therapeutically. It has the properties
of digitonin, presumably in some combination (Hatcher, 1919, 1920;
Eggleston, 1920).

Githens, 1920, states that the chloroform soluble principles, for instance digitoxin
of digitophyllin, represent about 1/3 of the active principle of the leaf; the remainder
being alcohol and water soluble, i.e., digitalein.

Inactive Principles.—A number of these have been isolated, such as the crystalline
glucosid giton and digle, Kraft, 1912, from the leaves.

Commercial Digitalins.—These are impure, often variable, mixtures
of digitalis principles. The following are the most important varieties:

Digitin "Amorphous;" generally means French or Belgian digitalin (digitaline
chlordormique); uncertain composition; insoluble in water (perhaps mainly Digitalin,
Schm.).

Digitin "Crystallized;" objectionable synonym for Digitonin; for Nativelle
French; and for Digitoxin.

Digitin "Humoltry;" mixture of glucosids; mainly true Digitalin; practically
insoluble in water.

Digitin "Nativelle;" crystalline, probably mainly Digitoxin or Digitophyllin.

Digitin "German;" amorphous mixture from seed; contains principally Digitonin
(30 to 60 per cent.) and some Digitalin verum (5 to 6 per cent.), and Digitalin.
Soluble in water or alcohol.

Galenic Digitalis Preparations.—The marked differences in the
solubility of the pure principles is much less important in the galenic
preparations. Even digitoxin is largely extracted from the leaves by
water, presumably by the solvent action of the digitoxin; so that a 1:10
fusion contains at least two-thirds of the digitoxin of the leaf. The
sects of the infusion and tincture are therefore nearly equivalent. The
fusion is practically inferior because of its more rapid deterioration.
Variations in the alcoholic strength of the menstruum between 35 and 95 per cent make little difference. The fluidextract is unreliable, being sometimes only the times as active as the tincture, instead of ten times, as it should be theoretically (Hale, 1911). Glycerin extracts are inferior (Kippeto, 1920). Acidified extracts are weak and unreliable (Pearson, 1913).

Powdered digitalis is often used, but is rather more irritant. A things considered, a good standardized Tincture is still the best and most reliable preparation.

Deterioration of Digitalis.—The principles are stable when dry or in alcoholic solutions; but like all glucosides, they are subject to decomposition in the presence of water, especially by bacteria, moulds or acids. This results in loss of activity; there is little evidence for the statement that the toxicity is increased. J. Loewry, 1906, claimed that an infusion lost nearly 25 per cent. of its activity by standing twenty-four hours in room temperature, but Hatcher and Eggleton, 1915, found it practically unchanged a week or longer under ordinary conditions. The addition of alcohol is not necessary. Acids are incompatible with the digitaloid glucosides, although they have been employed in some of the preparations, f.d., of Squills.

W. Straff, 1916, finds that the splitting of the sugar from the digitaloid glucosides lowers their toxicity (for frogs) relatively little; but this does not necessarily prove that they retain the cardiac actions unimpaired.

Tinctures and other preparations containing at least 30 per cent. of alcohol generally keep satisfactorily, their deterioration averaging perhaps 20 per cent. per year (Hampton, 1918). However, there are marked discrepancies. (Sharp and Lankaster, 1917; Hale, 1917; Sykes, 1917; Pittenger and Mallool, 1918; Hamilton, 1918). The lowest temperature is a material factor (Newcomb, 1918).

The dry leaves, so long as they are not mouldy, keep indefinitely (Sharp and Lankaster, 1917), without the necessity of the elaborate precautions advocated by Fock, 1920. They are not injured by heat of 120°C. but suffer above 140 (Hale, 1917).

Chemistry of Strophanthins.—The strophanthins are glucosides, differing quantitatively in their actions (even the similarly named commerch specimens, Heffer, 1900). Confusion exists as to the identity and relations of the several kinds found on the market and isolated by different investigators. This is due partly to incomplete knowledge of the plant, partly to ignorance of the constitution of the substances; and largely also to careless nomenclature. They are sometimes denoted by prefixing the first letter of the species from which they are obtained, f.d., g-strophanthin from S. gratus, etc.

The numerous species of Strophanthus (Apocynaceae) and other plants were used by the natives of Africa for the manufacture of arrow-poisons. The official varieties are the seeds of Strophanthus Kombé (U.S.P., R.P.), and S. hispidus (U.S.P.). The strophanthin originally isolated by Fraser, 1870, was the amorphous Kombé variety (Gibson, 1904). The following outline is based mainly on the paper by Heffer and Sachs, 1911.

Strophanthin amorphous (Strophanthin-Roehrigg) is the only strophanthin. It occurs in the Kombé and hispidus. The two are very similar, probably identical. Kombé further yields a crystalline strophanthin (Houghton, 1911; Brauns and Choate, 1912, 1914) which is very similar. The amorphous is slightly more toxic for rabbits than the crystalline Kombé. All three are hydrolyzed by acids with the production of the crystalline Strophanthinin, C₁₀H₁₄O₁₂. This is several times more toxic the strophanthin, and produces similar cardiac action, but with greater tendency to regurgitory paralysis (Groebber, 1912). The crude drugs Kombé and hispidus are about equal active.

Oxaline, gratus Strophanthin-Thoms; Crystallized Strophanthin-Merck CH₅H₁₂O₃ + OH₂O.—This is the only “Crystalline strophanthin” on the market. It is the best characterized of the principles. It does not yield strophanthin. It was first isolated by Arnaud, 1888, from the wood of Accoanthera Oxaaline; and by the same investigator, 1898, from S. glaber. Later, 1920, Thoms obtained it from S. gratus which was found to be identical with glaber. This is more readily obtained greenish than the other Strophanthus species. Strophanthin has been described as methyl...
DIGITALIS ACTIONS ON THE CIRCULATION

The effects of digitalis may be divided, especially in mammals, into two well-defined stages, the therapeutic and toxic. The typical phenomena of the two stages are shown in Fig. 18.

Preliminary Fall on Intravenous Injection.—During the intravenous injection of digitalis, the pressure falls sharply (a), probably on account of the local irritant action on the heart. This does not occur in the other methods of administration. The fall is not at all lasting (Blake, 1839).

The therapeutic stage (Fig. 18, b and c) is characterized by a slower, fuller pulse, due to the stimulation of the vagus mechanism (central and peripheral), and of the cardiac muscle. The cardiac efficiency, the output per beat and per minute, are increased. This tends to raise the blood pressure; in animals this tendency is supported by a more or less powerful vasoconstriction, involving particularly the intestines and liver. In man, the blood pressure is not much altered, presumably because of the more efficient vasomotor regulation; nor is the normal human heart usually slowed by ordinary doses, although the conduction of auricular impulses is delayed.

The modifications of these actions in disease will be considered under the therapeutic use. Before taking this up, the important phenomena require a more detailed presentation.

The Digitalis Slowing.—In normal mammals, this is practically entirely vagal, and involves almost exclusively the vagus center; for it is almost completely eliminated by section of the vagi (Ackermann, 1873; Kochmann, 1906, 1909; Etienne, 1909), and atropinized animals show...
practically no slowing. The slowing produced by digitalis in auricular fibrillation is a different phenomenon. It occurs even after atropin, is therefore quite peripheral (Cushny and Mackenzie; Gottlieb, 19)

The different digitalis drugs probably differ quantitatively, in the degree of stimulation (Kochmann; Etienne, 1909; Haynes, 1906). This might be of great importance to our information more complete.

The slowing is due mainly to direct stimulation of the vagus center, and not merely the rise of blood pressure (as was supposed by A. B. Meyer); for the slowing occurs in the clinical cases in which the blood pressure is unchanged or even diminished (Franz and Schwartz, 1906). Greene and Peeler, 1913, found the turtle heart slowed or stopped when digitalis was perfused through the brain only; the slowing being abolished when the vago-dividing the vagi. In animals the rise of pressure undoubtedly contributes to slowing, for the slowing is about twice as great if the pressure rises than if the pressure is kept just level by hemorrhage (Kochmann, 1906).

Vagus Stimulation from Rise of Blood Pressure.—It is well known that the tone of the vago-center is governed largely by the blood pressure, the heart being slowed as the pressure rises and quickened when the pressure falls (Bernstein, 1857; Verworn. 1925). The slowing on rise of pressure is entirely vagal, in the heart it is due in the later toxic stage (Liague, 1906); but that this is not due to paralysis of vagus may be judged by the fact that vagus stimulation still weakens the beats.

Other Phenomena of Vagal Stimulation.—The heart under the influence of digitalis exhibits also the other phenomena of vagus stimulation greater dilation in diastole and lengthened diastolic pause; tendency to exaggerate the respiratory pulse variations; lessened diastolic tone, increased conductivity, lengthened interval between auricular and ventricular contractions, tendency to heart-block, etc. Some of these tender become important in pathologic conditions and with toxic doses; clinically the vagus stimulation seems to inhibit most strongly what function of the heart is already partly depressed (Mackenzie).

Effect on the Amplitude and Output of the Heart.—In virtue of vagus stimulation produced by therapeutic doses of digitalis, the diastolic excursions of the normal heart are more nearly maximal, and the diastolic pause is prolonged, thus facilitating the influx of blood. With vagus stimulation, the systolic contraction is less complete so that output per beat is often reduced, and the output per minute is also diminished (unless the rate has been extremely rapid; Y. Hender, 1909). With digitalis, however, the muscular stimulation makes systolic excursions also more complete, so that the heart is both filled and better emptied (Cushny, 1897). The output per beat is therefore greatly increased; the “pulse pressure” or “pulse volume” is proved. This increase more than offset the slowing, so that the minute output is also increased (Cohn and Levy, 1920).

The increased output per beat amounted to 50 per cent, in the cardiometer experiments of Cushny, 1897. If the slowing is excluded by atropin, the time-output would be increased proportionately. If the slowing occurs, the increase would be proportionately less; but in the therapeutic stage it is still considerable—to 50 per cent. In Cushny experiments, Tierceron, 1907, also showed with the stethoscope that the output is greatly increased. Heinz, 1900, found the flow of blood from the carotid, at a constant pressure, to be increased by 50 to 250 per cent. The effect would be the greater, weaker the heart was before the digitalis; that is, the more removed the excursions from the physiologic optimum.
Heart Rate in Man.—Patients with auricular fibrillation, or with dynamic or unstable hearts, respond constantly by slowed pulse to the therapy. A fairly normal heart, however, may be slow by large doses or by the auricular impulses; the auricular contractions occurring with unrefined or quickened rate. The origination of the sinu rhythm is therefore not slowed by digitalis, except in adynamic hearts (Cohn, 1915).

Auriculo-ventricular Conduction in Man.—This is constantly impaired, being within forty-eight hours, and increases with the administration, from simple lengthening to heart-block. After withdrawal, it persists generally about two days, but sometimes two weeks.

Systolic or Muscular Action of Digitalis.—The increased systolic excursion of the heart due to a direct action on the cardiac muscle. The study of its fully developed features, as they occur in the toxic stage, shows that digitalis increases the contractibility, the systolic tone and the excitability of the cardiac muscle.

Digitalis is produced by smaller stimuli in hearts under the influence of the therapeutic and the smaller toxic doses of digitalis (Plenew). Relative Duration of Systole and Diastole.—In the digitalis heart, the duration of the actual contraction and relaxation is practically unchanged. The speed of the systolic contraction is somewhat increased (deFeer, 1912). The slowing occurs mainly in the diastolic pause; the systolic pause is also lengthened a trifle. Atropin removes the systolic as well as the diastolic slowing; so that the effect is entirely vagal (Casby, 1897). The two phases behave similarly in the excited and perfused mammalian heart (Haynes).

The excited mammalian heart, in the therapeutic stage, shows practically the same phenomena, except that there is much more slowing, since the vagal center is excised. The slowing is diastolic and can be removed by atropin (Haynes, 1906). The excursions of both ventricles are increased especially in systole, so that the energy of each beat may be more than doubled. The time required to produce maximal slowing is an hour for digitalis, one-fourth hour for strophanthin (Haynes). Existing irregularities are removed, and a fibrillating heart may resume regular contractions (Heldmon, 1898; Brown and Mager, 1899; Lottile and Magnus, 1903).

Cardiograms.—These show slowing of the phases and pauses, and changes to the peaks; the latter are increased by small, lowered by large doses (Bickel and Pawlow, 1911). Reversal of the P- and T-wave often occurs early during digitalis treatment, being probably a sign of the muscular action. This effect is also produced by digitalis in feline patients (Cohn, 1915; H. W. Stevens, 1916; Halsey, 1917; Wilson, 1818), and after section of the vagi (Robinson and Wilson, 1915). These electrocardiographic changes can be produced typically and immediately in dogs by the intravenous injection of 30 per cent. of the minimal fatal dose of the digitalis substances; this being supposed to correspond to the therapeutic dose. They do not affect the response of the heart to atropin (Halsey, 1917; Cohn and Levy, 1918).

Relation of Therapeutic to Fatal Dose.—In cats also the characteristic change of T-wave appears generally on the intravenous injection of 30 per cent. of the fatal dose; however, the ratio varies for different cats between 25 and 60 per cent.; it is constant in the same animal (Levine, 1909).

General Metabolism of the Heart.—This is increased in mammals in proportion to the activity (Robhde and Ogawa, 1912). In excised frog's hearts, the oxygen consumption is decreased according to the diminished rate and excursions (Gottschalk, 1913).

The Phenomena of the Therapeutic Stage in the Frog's Heart.—If a digitalis drug is injected into a frog, the exposed heart shows actions which resemble those seen in mammals. The inhibitory effects are more important, whilst the contractility is but little affected in the therapeutic stage. The rate becomes progressively slowed, and the diastolic relaxation is more complete. The slowing occurs even after atropin (Buch, 1872) but otherwise it resembles vagus stimulation. Direct vagus stimulation produces additional slowing. By using the perfused excised heart (F. Williams, 1896), it can be shown that the diastolic tone is considerably decreased, so that a given pressure diastends the heart more than normal; and since it contracts completely in systole, the output per beat is increased. The time-output and the blood pressure may
be increased or diminished; but the heart is not more capable of overcoming an excessive aortic resistance. The toxic effects will be described later.

*Adrenalinum with Pilocarpin.*—A perfused frog heart that has been slowed and weakened by the vagus action of pilocarpin is strengthened but not quickened by digitalis (Ransom, 1917).

*Ventricular Strips of Turtle.*—Large doses produce acceleration (even after atropin or ergotostin), and increase of amplitude and tone (Greene, Burtwell and Fecedor, 1915).

**Behavior of the Different Chambers of the Heart.**—The two sides of the heart behave very much alike to Digitalis; but the auricles tend to show relatively greater inhibitory effects (since they are more subject to vagus control), whilst the ventricles are more disposed to the muscular action. In the therapeutic stage, the rhythm of the auricles and ventricles is synchronous.

The relaxation of the auricles is but little changed; their contraction is more complete; but with slightly larger doses the inhibition predominates so much that the contractions are less complete. The inhibitory effects disappear if the vagi are divided (Cushny, 1897).

**Influence of the Cardiac Action on the Blood Pressure.**—The increased output of the heart should result in a rise of pressure. Accordingly, the pressure rises even when changes in the peripheral vessels are definitely excluded (i.e., in Bock's method, where the aorta is tied, the circulation being shunted through the carotid directly to the jugular vein—Bock, 1898; C. W. Greene, 1910).

**No Effect on the Maximal Pressure.**—Whilst the digitalis heart can discharge a larger volume of blood against a normal pressure, the maximal pressure—i.e., the totality of pressure on clamping the aorta—is not increased (Bode; Heins, 1900).

**The Vasoconstrictor Action.**—The cardiac actions of digitalis would of themselves tend to raise the blood pressure. The most important element in the rise which is observed in animals, however, is a vasoconstriction, involving mainly the intestinal vessels. This is shown most conclusively by the observation that the volume of the important splanchic organs decreases as the blood pressure rises (Gottlieb and Magnus, 1901). Further evidence is that the venous outflow is also decreased; and that the rise is not always accompanied by increased output of the heart (Tigerstedt, 1907, stromuhr).

These experiments, however, were made with doses far larger than are used in therapeutics. Small therapeutically effective doses may produce intestinal constriction even when the blood pressure does not rise. The vascular effects are more lasting than the cardiac (Joseph, 1915).

The vasoconstrictor effect is peripheral because it occurs in excised organs (Donaldson and Steffens, 1885; Kobert 1886; Branton and Tunncliffe, 1896, etc.). It occurs also after the nerve-endings are paralyzed by apocodine (Dixon, 1903). The action is therefore presumably exerted directly on the arterial muscle. The vasomotor center is but little affected.

**Vasomotor Center.**—Strophanthus produces a moderate stimulation; digitalis much less or none. In no case is the central action sufficient to make itself felt through the other actions of the drugs. Fatal doses result in sudden cardiac arrest and asphyxia, thereby producing intense stimulation of the vasomotor center (Fliecher and Solmann, 1915).

**Vasodilator Action.**—Very dilute solutions of digitalis produce an opposite effect; i.e., the perfused vessels are dilated (Kasztan, 1910).
DIGITALIS GROUP

Fahrenheit, 1912). The vascular effects are therefore analogous to the cardiac effects; the smaller doses decrease, and the larger doses increase the tone.

Difference in the Vascular Areas.—The constrictor tendency varies according to the drug and the vessel. It is generally said to be greatest for digitoxin, and relatively weak for strophanthidin; but an exact series has not been established.

F. t., de Heer, 1912, and Joseph, 1913, found that ouabain had a strong constrictor effect in mammals; while Moog, 1912, claims that its constrictor action is but one-tenth that of digitoxin. Stroemmann, 1914, finds strophanthidin the weakest constrictor in frogs. Caffeine is antagonistic. Vogt, 1909, claims that strophanthidin does not produce constriction in man, but Straub, 1900, finds evidence of constriction with the string galvanometer.

The constrictor is strongest in the intestinal and splenic vessels, less in the renal, and weak in the vessels of the skin, brain, etc. The dilator and constrictor effects vary in degree in different animals; but with therapeutic doses, in animals, the most constant and predominant effect is the slow constriction of the intestinal vessels. The dilator effect occurs earlier, but the constriction lasts longer (Joseph, 1913). In man, the volume of the arm is not changed by intravenous digitalis or strophanthidin (Hewlett, 1913).

Altered Distribution of Blood.—The different susceptibility of the vessels leads to alterations in the distribution of the blood in living animals. The intestinal vessels will tend to be constricted; those of the skin, extremities and brain will tend to be dilated (Gottlieb and Magnus, 1903). The renal vessels occupy an intermediate position; with therapeutic doses they tend to dilate (Loewi and Jonescu, 1908); with toxic doses, they will be constricted. The dilations may be due to the direct dilator action; or to mechanical displacement of blood from the more powerfully constricted areas; or to nervous reflexes.

In the experiments of Gottlieb and Magnus, 1903, the dilatation of the vessels of the extremities was shown to be mainly mechanical; for it did not occur (or rather, the leg vessels constricted), if the displacement of blood was prevented by ligating the iliac veins.

The direct dilator effect has been rendered very probable for the kidneys; for it has been shown on the excised organs that certain concentrations dilate the renal vessels, while they constrict the intestinal vessels.

Pulmonary Vessels.—These are somewhat constricted in perfusion experiments (Takagawaich). Excised arterial rings are also constricted by all digitaloids, except digitoxin, which dilates (Macht, 1914). In life this action is unimportant; for the slight rise in pressure in the pulmonary artery is mainly cardiac (Plumier, 1905; Wiggers, 1911). The circulation time is shortened in the pulmonary and in the general circulation (Langlois and Desbouis, 1915).

Mesenteric Vessels.—The filling of the vessels of the pia mater and retina follows the general blood pressure (Hirschfelder, 1915).

Coronary vessels may be constricted, especially by digitoxin, less by strophanthidin (Loeb, 1903; Haynes, 1906; Rabe, 1912). Excised arterial rings are also constricted (Vogt and Macht, 1913). In any case, the constriction would be overcome by the improved conduction; so that, with therapeutic doses, the coronary flow in life was found unaltered (Bond, 1911), or even increased (F. Meyer; Sakai and Saneyoshi, 1915; H. Miller, 1908), found that digitoxine enabled the heart to tolerate a greater degree of coronary obstruction. Large toxic doses contract the coronary vessels even in life, with rising blood pressure; this is sometimes followed by increased flow with falling pressure (Sakai and Saneyoshi, 1915).

Venous Pressure.—This is not materially altered, even when the arterial pressure rises (Capps and Matthews, 1913; it has also been studied by Ackermann and by Peiper).
Blood Pressure in Man.—The rise of pressure which is so characteristic for most animals is not often seen in man, either in health or disease (Ceytin, 1905; Schwartz, 1906; Cushing, 1911; Mackenzie, 1911; Price, 1913; Cohn, 1915; Eggleston, 1917). In heart disease, the improvement under digitalis may even be accompanied by a fall of pressure, if this has been abnormally high (Fraenkel, 1905; Price, 1914; Martinet, 1917). A rise is very exceptional, occurring only if the pressure has been below the normal level. The diastolic pressure is always lowered when digitalis relieves in compensated lesions, no matter what the changes in the systolic pressure. The pulse pressure is therefore generally increased (Martinet, 1914).

The difference can not be explained by dosage; for in animals the rise occurs with the smallest doses which have a noticeable effect on the heart. The explanation must be sought in the more perfect blood pressure regulation of man, which compensates the pressor tendency by inhibition of the vasomotor center and by stimulation of the vagus center. If the digitalis slowing is prevented by atropin, the pressure rises also in the human subject (Fraenkel, 1905).

The compensatory vasomotor regulation has not been investigated in man. From what is known of it in animals, it would be expected that the vessels of the extremities and of the kidneys would probably be dilated whilst the intestinal and portal vessels would tend toward constriction. The altered distribution of the blood may contribute to the therapeutic result.

Blood Pressure in Rabbits.—These do not show as great or constant a rise as do other animals. This is probably explained by the lesser resistance of their blood vessels which therefore dilate if the pressure tends to rise above the normal. If the pressure has been lowered by hemorrhage, digitalis produces an effective rise toward the normal level (Hernando, 1911). Digitalis did not produce much rise after chloral, presuming because the heart was too greatly injured. The effects of small therapeutic doses were studied by Joseph, 1911.

Diuretic Action.—The digitalis drugs are powerful diuretics in cardiac dropsies; the diuretic effect being proportional to the improvement in the circulation and to the absorption of the edema. In all other conditions they have little or no effect on the urine. Practically negative results are obtained in normal individuals (Schwartz, 1906); in heart disease without effusion (Cushing, 1911; Cohn, 1915) and in purely nephritic edemas (J. Miller, 1912). The diuretic effect can not therefore be due to any renal action, but must be ascribed to the improved circulation. There is no diuresis in normal individuals, and in the absence of edema because the renal circulation is already adequate for the secretion of the fluid at the disposal of the body. It fails in nephritis, because here the anuria is not due to defective circulation.

The factors involved in the improvement of the renal circulation are several: The dilatation of the renal vessels (Jonescu and Loewi, 1908) the relief of the venous pressure; the increased output of the heart; the increased "pulse pressure;" and the hydremia resulting from the absorption. These mechanical conditions cause corresponding increase of urine filtration even in dead kidneys (Sollmann, 1915).

Gsell, 1913, found that artificial changes in the pulse pressure produced parallel changes in the excretion of urine, chlorides, urea and nitrogen.
Influence of Hydremia.—Martinet, 1914, found that the viscosity of the blood and the protein content of the serum remain unchanged so long as the absorption of edema is in progress. When the edema has disappeared, but the diuresis still persists, the viscosity increases. This indicates that the hydremia is not the primary cause of the diuresis. Loria, 1912, also states that strophanthin or calomel increase the viscosity of the blood even when there is no diuresis.

Excessive doses of digitalis constrict the renal vessels and irritate the kidneys, so that the urine becomes scanty, and often blood-tinged. This may conceivably happen if cumulation occurs in the therapeutic use; especially with digitoxin.

Toxic Effect on the Circulation in Mammals.—These are characterized by irregularities of the rhythm and strength of the cardiac pulsations (Fig. 19).

They are exaggerated manifestations of the vagus and cardiac stimulations which were initiated in the therapeutic stage. The vagus effects (slowed rhythm, diastolic tendency, lessened conductivity) reach their acme most rapidly; so that the first indications of overdosage are commonly those of marked inhibition. This inhibition is in turn overcome as
the muscular excitability becomes greater and greater; so that the final effects are mainly muscular (increased tone, heightened irritability, spontaneous ventricular rhythm, extrasytoles). The irregularities which result from these interactions weaken the circulation and interfere with the nutrition of the heart, until this becomes arrested.

Cushny's Stages.—The successive effects have been studied most carefully by Cushny, 1897, who divides them into the inhibitory stage and the stage of muscular irregularity.

Traube's Stages.—The effects may also be divided into three stages, according to Traube, 1865: (1) slowed pulse with rise of blood pressure (therapeutic stage); (2) sudden change to rapid pulse, with further rise of blood pressure; and (3) fall of blood pressure with continued rapid but irregular pulse. The inhibitory stage would be inserted between 1 and 2.

In the typical course, the effects pass successively through the therapeutic, vagus and muscular stages; but the vagus stage is often omitted in animals. The "toxic effects" in man are generally of the inhibitory type.

The Inhibitory Stage (Fig. 19, A).—This corresponds to strong vagus stimulation. The rhythm becomes very much slowed—to 40 or 50 beats per minute. It is often irregular; there are scattered diastolic pauses which become more frequent and lasting, particularly in the auricles. These irregularities are partly exaggerations of the normal respiratory variations; but they are often independent. The two sides of the heart contract at the same rate, but the ventricles are apt to assume a spontaneous rhythm, which may be faster or slower than that of the auricles. This independent rhythm is probably due in part to the blocking of the auricular impulses by the lessened conductivity; the increased excitability of the ventricular muscle also plays a part, for the ventricles may continue to beat during the auricular standstill. The excessive slowing and the irregularity diminish the time-output of the heart in this stage, although the amplitude is increased. The blood pressure falls.

Occurrence and Duration of the Inhibitory Stage.—This stage occurred in about 90 per cent. of Cushny's animals. After lasting a few minutes, it passes quite suddenly into the muscular irregularity. It is more frequent and more persistent in man. The difference may be due to different dosage and administration.

The Stage of Muscular Irregularity.—The rate, rather suddenly, becomes more and more accelerated, as if the heart escaped from the vagus influence. Electric vagus stimulation has less and less effect on the rate; but since it still increases the diastole the vagus can not be paralyzed. The escape is due to the excitability of the heart becoming so greatly increased that the vagus is unable to restrain it. The auricles and ventricles may at first keep the same rate; but the ventricles soon assume a rapid rhythm independent of that of the auricles; for the conduction of the auricular impulses is more and more blocked, whilst the spontaneous excitability of the myocardium is more and more increased. The accelerators usually do not respond to stimulation (Fredericq, 1913).

Periodic Grouped Beats.—This independence of the auricular and ventricular contractions results in curious periodic variations in the volume of the pulse, the rhythm at this time being fairly regular.

One or more enormously strong beats are followed by very much weaker beats, sometimes quite imperceptible in the pulse, which is therefore intermittent (see Fig. 19, B, e and g). These phenomenon occur in groups, which remain fairly regular for a short time, but soon change to some other type, as may be seen in Fig. 19, B and C. These
effects are sometimes due to respiration. In other cases, however, they are cardiac. These are also seen in the atrophined heart, and are mainly due to the aortisms of the auricles and ventricles (Cushny, 1899). It will be recalled that the ventricular contractions are normally originated by the auricular contractions. Toxic doses of digitalis seem to interfere with the transmission of this impulse, and at the same time, they raise the excitability of the cardiac muscle to such a degree that contractions can originate in the ventricles. The auricles and ventricles therefore beat independently; either may be the more rapid. As a consequence, the contractions will sometimes alternate, sometimes coincide, forming groups (see Fig. 20). If the auricular systole occurs during the ventricular diastole, the ventricles will be filled with blood when they contract, and the result will be a large pulse-wave; if the auricular and ventricular systole coincide, no blood will be moved, and there will be no pulse (see Fig. 20, p). This is the most satisfactory explanation of the group phenomenon. A further factor may come into play; it is probable that the auricular stimulus to the ventricle is not completely blocked by the digitalis. If the auricular and independent stimuli coincide, the ventricular contraction would be strong; if they interfere, the contraction would be weak or absent. This effect would support that previously described and lead to the same kind of grouping.

The two sides of the heart continue to beat synchronously, although the periodic variations of strength have no relation.

After a time, extrasyolettes (i.e., premature contractions by which no blood is expelled) appear, and the pulse shows corresponding intermissions. These become more numerous. The rate continues to increase, becoming faster than in atropin poisoning. Various complex irregularities are superadded; and the contractions become thoroughly disorganized.

The blood pressure is very high in the earlier period, and a combination of rapid and forceful contraction and vasodilatation. When the periodic irregularities set in, the output diminishes.

Terminal Changes.—The quickening of the rate now exceeds the optimal limits. The contractions become superficial, fluttering, much less effective, and more fatiguing. The blood pressure falls and the heart is unable to keep the pace. First the auricles, then the ventricles, pass into tetany; dilatation and the circulation is arrested. The chambers stop in median position, and then gradually become greatly dilated.

Muscular Changes in Rabbits.—In acute death from large doses, all parts of the heart may be suddenly arrested. Auer, 1912, found the endocardial muscles of the right ventricle hardened. He believes that this change involves the conducting system, and that even the earlier actions of digitalis are due to slighter degrees of these chemische changes. Similar abnormalities occur in anaphylaxis.

Toxic Effects on the Excised and Perfused Mammalian Heart.—These resemble is the main the muscular irregularity of the intact heart. After the therapeutic stage, the contractions become quicker and irregular. The diastolic relaxation becomes progressively less complete, and the heart has a systolic tendency. It finally passes through lemmur cordis into systolic standstill, the tone increasing even after the heart has stopped. Stretching of the muscle (as by increasing the coronary pressure) may temporarily restore the pulsations (Hodgkin, 1891; Braun and Mager, 1899; Gottlieb and Magnus; 1903; Haynes, 1906; Etienne, 1906).

The principal difference between the intact and the excised heart is the position of arrest, the former is systolic in the intact, and systolic in the excised. The systolic standstill, which occurs also in the frog's heart—is the really characteristic effect of digitalis. In the intact mammal, the falling blood pressure impairs the coronary circulation, so that the myocardium can not remain contracted.

Toxic Effects on the Frog's Heart.—This also shows a complex of inhibition and muscular stimulation, but the manifestations differ materially from those in mammals. They vary somewhat according to the dose and method of application. They are outwardly peripheral, and are not modified by excision of the heart or by atropin; but vagus stimulation remains effective until rigor sets in.
Typical Course.—If moderate toxic doses are injected into an intact frog, and the heart is allowed to stop (Boehm, 1879), the diastolic phenomenon appears almost immediately. After a latent period of from five to fifteen minutes, the diastolic tendency becomes conspicuous. The chambers expand more, the diastole is lengthened and the rate is somewhat slowed. The A-V interval is unchanged (Clark and Mines, 1912). The systole is also more complex. With strong hearts, the effect is mainly on the aortics; but if the heart is weak, the aortics are also stimulated (Clark, 1914). This corresponds to the thoraecole state.

The toxic irregularities start soon after. The systolic phase of the ventricle becomes exaggerated, so that at times the apex, at times the base, remains firmly contracted during the diastole. These partial diastoles may alternate so that the blood is merely pumped back and forth from one part of the ventricle to the other. This has been called, rather inappropriately, "cardiac peristalsis." Again, a part of the ventricle may remain firmly contracted for a considerable time, and then may resume rhythmic contraction. The "peristalsis" was first described by Vulpin, 1852.

Eventually, the ventricular diastoles become weaker and weaker, until the ventricle finally goes into permanent systolic standstill, and appears as a small white lump, contrasting sharply with the turgid auricles. The apex is often arrested before the base.

The auricles continue to pulse for a time and eventually stop distended.

The ventricular systolic standstill is not paralytic; for if the ventricle is forcibly distended with fluid, it will again start effective beats (Schmiedeberg, 1854). The standstill is due to excess of tonus, which prevents diastolic relaxation under the ordinary venous pressure. It is not an ordinary but prolonged contraction, for the heart-muscle is not in the refractory phase (Tait and Pringle, 1916). Schmiedeberg considers it as increased "elasticity."

Other hearts may not show the "peristalsis," but instead the phenomena of partial auriculo-ventricular "block," i.e., the ventricular rate suddenly falls to one-half, then one-third, one-fourth, etc., of the auricular rate (Straub, 1901). The auriculo-ventricular interval is also lengthened (Clark and Mines, 1911). Eventually the auricular rate, and finally the sinus rate, may also be halved. The block may be explainable by prolongation of the refractory period; for Brandenburg, 1904, showed that the heart is not less sensitive to the extrasystoles than the auricles. On the other hand, the auriculo-ventricular conduction is increased, for if the sinus-auricular junction is crushed (I-Stannius experiment) the ventricles are not arrested as in the normal frog, but at once initiate a spontaneous rhythm.

In other hearts, the systolic phenomena so far described may be preceded by inhibition. The diastolic relaxation predominates, the heart remains regular and the beats become greater and slower to temporary diastolic standstill. This is witnessed but rarely in intact animals, and is then followed by the usual systolic phase (Boehm).

De Noer, 1917, has made detailed studies of the effects on existing irregularities, etc. In excited and perfused frogs' hearts, the effects of dilute solutions correspond to those of naga stimulation. The rate is slowed, the diastolic excursions increased, the systolic excursions at first unchanged, then diminished. This progresses to diastolic standstill (Jacobi, 1900; Wibrand, 1900), from impaired conduction and heart-block (Straub; Clark, 1914). The heart still responds to mechanical stimulation. Higher concentrations produce the typical systolic phenomena and systolic standstill. Very concentrated solutions paralyze the heart (Werschlin, 1910). This is a latent period of from five to fifteen minutes, even when strong solutions are used.

The diastolic standstill occurs especially on applying the digitals to the outer surface of the heart. Werschlin claimed that the given concentration produces the same effect on endocardial and pericardial application; but Holste, 1912, and Clark, 1911, attribute the diastolic standstill from intracardiac application to technical error.

The diastolic standstill is a regular feature of low concentrations of the various digitalis substances (Benedentici, 1902), including barium (Poulsson, 1910). The inhibitory phenomena bear a close resemblance to naga stimulation. Halachinsky, 1908, demonstrated the summation of submaximal digitals and vagus inhibition. However, the digitalis inhibition is not influenced by atropin (Benedentici, 1908). It must therefore be concluded that the vagus and digitals act independently on the same function of the muscle. (Schmiedeberg, 1910, suggests that they stimulate specific "diastic fibers," but the existence of these is altogether hypothetical.)

Isolated Auricle of the Frog.—The toxic dose of digitals is at least ten times as great as for the ventricle; the phenomena, however, are similar (W. Straub, 1912).

Fixation of Digitaloids in Heart.—W. Straub, 1910 to 1912, investigated the quantitative relations of digitals on excised frogs' hearts, using the response of "test hearts" as a quantitative method. He found the effects roughly proportional to the concentration of the poison, not to the absolute amount used. From this he argued that the reaction must be confined to the surface (envelope) of the muscle cells; the mechanism
being similar to that of saponin action. Further investigation, however, showed that the quantity is also important (Clark, 1912; Gruenwald, 1932; Insekutz, 1935), and that the concentration is probably important mainly in determining the rapidity of penetration.

The effects of digitalis outlast its actual application. With small doses, the heart recovers completely on washing; but when immersed anew in digitalis solution, even after a long time, its threshold is found lowered (Gottlieb, 1914; Insekutz, 1935). These facts indicate that digitalis is absorbed and stored in the heart muscle, remaining there in active form for a considerable time. The amount of drug used up, however, is very small (Straub; Gruenwald; Clark; Holste, 1932); somewhat greater with digitalin than with strophanthin (Weiszaecker, 1913). Fuchsner, 1913, finds that methyl-violet, which has a typical digitalis effect, actually accumulates in the cardiac muscle of frogs, the effects corresponding to the quantity of dye so fixed.

There is reason to believe that an actual storage of digitaloids occurs in the heart cells of mammals (Hatcher, 1912), although the evidence is not conclusive. Lhota, 1912, states that the storage occurs particularly in the heart and blood vessels, but also in the liver and other organs.

Wilbur, 1911, reports that irritants (iodin) produce effects similar to digitalis on terrapin's heart.

Concentration Coefficient.—Sollmann, Mendenhall and Stiegel, 1915, determined the ratio of concentration and activity. They found that the feebleness of the actions of ouabain, the more is its activity increased by doubling the concentration. The reasons for this are explained in their paper.

Vigor of the Heart.—Holste, 1912, and Weiszaecker, 1913, find that this influences the response quantitatively. The greater the intensity of the cardiac functions, the more the strophanthin effect.

Temperature.—The cardiac effects of the digitaloids on frogs increase with the temperature (Trendelenburg, 1909), the increase being greater for low than for high temperatures. The activity is increased by heat not only directly, but also through the more rapid heart rate (Sollmann, Mendenhall and Stiegel, 1915). In the perfused mammalian heart, the effects are also quickened by heat; in this case the more rapid coronary flow is a contributing factor (Gunn, 1914).

Hyperpyrexia (by hot baths) also increases considerably the toxicity of digitalis for intact mammals; the effects, including the reversal of the T wave, being qualitatively as in normal mammals (Hirschfelder et al., 1920).

Influence of Serum.—Werschinin found the systolic action much weaker in Ringer solution than in serum-solutions of the dog. Oppenheimer, 1913, observed that serum inhibits the action of the less soluble digitaloids, but not of strophanthin. Cholerin and egg-albumen did not have equivalent effects.

Oxygen increases the digitalis effect (Gruenwald, 1912).

Influence of Ions.—The systolic digitalis action occurs only in the presence of Ca ions in the perfused solution. Excess of alkali or absence of potassium rather increases the systolic action; excess of Ca has little effect (Clark, 1912). On the other hand, strophanthin delays the standstill of the heart when this is perfused with Ca-free solutions or with pure K solutions; but it hastens the arrest when added to a solution from which Ca and K are both absent (O. Loewi, 1912; Konschegg, 1913). Strophanthin may therefore to a certain extent replace Ca, and thereby antagonize the K ions. The effects of the ions on the vagus action are quite different (Clark, 1912).

Antagonism with Alkaloids.—Lhota, 1900, claims that cocaine diminishes the toxicity of strophanthin by lessening the cardiac excitability. Wilbur, 1911, found that strycchin often removed the ouabain heart-block in terrapin's heart.

Central Effects of Digitalis.—The peripheral effects dominate the symptom-complex so greatly that of the direct central effects only the excitatory action is important. The cardiac action is so selective that frogs whose heart have been stopped by digitalis may hop about as if normal. The medullary centers are probably stimulated directly. This is proven for the vomiting and vagus centers, probable for the vasomotor center, and perhaps also for the respiratory center; but the indirect effects from the altered circulation are much more important than any possible direct actions.

Central Symptoms.—When digitalis is injected into the ear vein of unanesthetized rabbit, or subcutaneously, the symptoms occur immediately, and appear to be largely central.
GASTRO-INTESTINAL ACTIONS OF DIGITALOIDS

Vomiting and diarrhea occur with overdoses of all digitaloids. Until recently they were erroneously attributed mainly to local action, especially of the digitonin. Hatcher and Bailey, 1911, pointed out that they occur more frequently on intravenous than on oral administration; and Hatcher and Eggleston, 1912, proved that the vomiting movements occur even when the whole alimentary tract has been excised. The action is therefore central, and it is useless to look for "non-emetic" digitalis preparations. The differences are merely quantitative. These conclusions are supported by the clinical data; for the nausea or emesis is always preceded by cardiac effects (Eggleston, 1913). The gastro-intestinal symptoms generally disappear within two or three days after withdrawal (Cohn, 1915).

Very sensitive individuals may, of course, be nauseated by the acrid taste of even small doses, but local irritation sufficient to produce emesis could only occur with doses much larger than the clinical. The digitonin must play a very insignificant part, for it is not emetic in doses very much larger than occur in the usual administration. The fat of the leaf is also non-emetic (Eggleston and Hatcher, 1913). The oil of strophanthus seed is emetic, but only in quantities 15,000 times as high as are present in a therapeutic dose of the tincture (Hatcher, 1910).

Ratio of Emetic Action.—This may be expressed as the relation of the emetic to the fatal dose, intravenously. Eggleston and Hatcher found True Digitalis the most emetic (emetic dose = 22 per cent. of the fatal); then come strophanthus, ouabain, digitalis, digipuratum, digalen and adonis (ratio = 40 to 50 per cent.); then digitoxin and amorphous strophanthin (50 to 63 per cent.); least emetic were Squill and Apocynum (75 to 88 per cent.).

Klotzmann, 1912, states that digitalis diminishes gastric secretion in fistula-dog. Squill was formerly used as nauseant expectorant; Eumynurus (wahoo) as cathartic; Gal-bladder.—This is stimulated (Lied and McWhorter, 1915).

Uterus.—Strophanthin revives the movements of the excised uterus when they have been arrested by calcium-free Ringer's solution. Short exposures to strophanthin renders the uterus hypersensitive to calcium (Ransom, 1920).

Epinephrin Output.—This is not affected by strophanthin (Stewart and Rosoff, 1919). Previous workers used inadequate methods.

LOCAL ACTIONS

Digitalis and the allied drugs, when injected hypodermically, cause fairly severe irritation, pain and albumin formation, which practically preclude their use by the channel. Intramuscular injection is feasible, although not painless. The irritant action varies in different drugs.

Digitalis (particularly digitoxin) and squill are more irritant than strophanthin and ouabain (Haysnes, 1906).

Relative Iritrant Action.—Holste, 1913, from hypodermic and conjunctival application to rabbits, establishes a series for the isolated principles as: Most irritant = digitoxin; then digitoxin, then digitelain and cymarin (from apocynum). Practically no irritant = digitalis, ouabain and strophanthin. Digalen was much more irritant the digipuratum. On the skin of young pigs, O. Loeb and Loewe, 1916, also found digalen and amorphous strophanthin the most irritant. Digipuratum, strophanthin and ouabain was about as irritant as digitalis infusion.
Strophanthin does not inhibit the emigrations of leukocytes from inflamed mesentery (Ikeda, 1916).

Aesthetic Action.—Steinach, 1888, and Pana, 1890, found that application of strophanthin to rabbit’s conjunctiva produces anesthesia lasting several hours. In man, however, there is considerable inflammation. Other digitaloids are also anesthetic.

THERAPEUTIC USES OF DIGITALIS

Historical.—The professional use of Digitalis is relatively recent. It was recognized by Wm. Withering of Birmingham (Cushny, 1933; Alpers, 1935) as an ingredient of an old woman’s secret formula. After ten years of experimentation, he published his results in 1785. He was chiefly interested in the diuretic effect, and mentions the cardiac action only incidentally. The evidence for the connection of the circulatory and diuretic effect was first emphasized by John Ferrier in 1759. The drug quickly assumed an important place, though its proper field was not recognized. The cardiac slowing particularly attracted attention, and as late as 1821 Traube referred the clinical effects entirely to this “depressant” action; hence, Digitalis was used in aneurysm, internal hemorrhage, etc., for which it would be entirely unsuitable. Ten years later, Traube accepted the rise of blood pressure, which had been discovered in animals, as the basis of the therapeutic effect. This has been disproven only quite recently.

Strophanthus was brought to Europe in the early sixties, and its cardiac actions were promptly discovered. Its introduction into medicine is due mainly to Th. R. Fraser, 1851.

The use of Scilla dates from the ancient Greeks, although its cardiac action was not recognized. Ajacium was used by the early settlers as a hydroaustic cathartic and diuretic; presumably they learned its use from the Indians. Convolvulus has also been used for several centuries in domestic medicine, against cardiac symptoms.

Field of Clinical Usefulness.—Digitalis and the allied drugs are highly useful in the course of chronic disease, when the heart contracts imperfectly and becomes dilated; either because of incoordinated or irregular contractions, as in auricular fibrillation; or because of exhaustion of the cardiac muscle by its inability to compensate for the mechanical defects of structural lesions. The indications for its employment are governed by the functional conditions of the cardiac muscle, and only indirectly and to a minor degree by the gross anatomic lesions.

The most striking results are seen in auricular fibrillation; but equally beneficial though less obvious improvement occurs in chronic dilation in the absence of fibrillation. In the latter case, the improvement tends to be self-perpetuating, so that digitalis needs to be given only at intervals. With auricular fibrillation, the effect must generally be maintained by more or less continuous administration.

Digitalis medication has not given definite clinical results in acute cardiac conditions, other than exacerbations of chronic lesions; partly perhaps because it was administered by methods in which its action is developed too slowly to meet acute conditions; but mainly because acute heart failure is generally due either to profound intoxication of the cardiac muscle, or is secondary to other conditions (for instance vascular paralysis in fever, etc.), which must be the real object of treatment.

Explanation of Clinical Effects.—The slowed conduction and the muscular stimulation are both important; the slowed conduction being most important in auricular fibrillation; the muscular action in uncomplicated dilation. The improved tone and contractility of the muscle increases the amplitude of the systolic contraction, and thus the time-output. It counteracts the dilation directly, and may narrow a leaking valvular ring.
The vagus stimulation and slowed conduction reduces the generally rapid rhythm toward the normal optimum, and tends to remove irregularities. In auricular fibrillation, it blocks the majority of the confusing impulses; and permits the ventricle to make effective contractions.

All these actions increase the efficiency of the circulation, insuring a better filling of the arteries, improving nutrition and oxygenation, and relieving the congested veins. The heart is among the first to feel the effects of this improvement. The vicious circle of weaker heart, poorer circulation is reversed into the beneficial circle of stronger heart, improved circulation; so that the effects outlast the administration of the drug, and the improvement is perpetuated. At the same time, the circulation in the kidneys is improved, by the faster blood flow, the increase of pulse pressure, and the relief of the venous pressure. The kidneys are thus placed in the best condition for filtration or secretion. The anuria is relieved. If there has been edema, the improved kidney action results in extensive diuresis and thus in the absorption of the edematous fluid. This in turn improves the heart action and the whole circulation, by relieving them of the compression of the ascites. The vasodilator action may also play some part; since it is strongest in the intestines and liver, it may help to relieve the congestion of these organs.

Rise of blood pressure, as such, has no important share in the action; for it rarely occurs clinically, even with intravenous injection, or in cases which are greatly benefited (Fraenkel and Schwartz, 1907).

Differences in Health and Disease.—The actions of digitalis are the same whether the heart is normal or abnormal; but the results of these actions are somewhat different. In health, the results of digitalis constitute departures from the normal, which are antagonized by compensatory mechanisms; in disease, the results constitute a return toward normal, and are therefore not antagonized in the same way. Consequently, the effects of digitalis are generally greater on those circulatory functions which have departed most widely from the normal. The removal of the cardiac abnormalities also entails consequences which are not witnessed in the normal individuals; such as more efficient regulation of the rate, the removal of irregularities, of dyspnea, of edema, the diuretic effect, etc. These differences could almost be predicted from a proper understanding of the pharmacologic data; but it is important that they be taken into consideration when the results of animal experiments are transferred to the clinic.

Efficiency of Digitalis in Cardiac Dilatation.—The clinical value of digitalis may be best appreciated if it is conceived as restoring the tone and contractions of an exhausted, fatigued or overdriven, but otherwise normal heart muscle, to healthy efficiency. It is most useful in those conditions in which the ventricular muscle is called upon to do an amount of work which exceeds its capacity, and which therefore induces dilatation. This occurs particularly in valvular lesions, where the incomplete emptying of the heart places the muscles under an ever-increasing strain. The response will depend upon the quantity of muscular tissue on which the digitalis can act: it is therefore generally more effective in ventricular dilatation (mitral and tricuspid insufficiency) than in auricular dilatation (mitral and tricuspid stenosis). The diastolic expansion of a normal heart is increased by the vagus action of digitalis; but the excessive dilatation of a weakened heart is reduced by the muscular effect. The difference in size may not be demonstrable by clinical methods.
DIGITALIS GROUP 477

If the cardiac muscle is degenerated, as in cardiosclerosis, digitalis will be useless or even harmful, by imposing too great a task upon the weakened muscle fibers.

In *experimental ventricular dilation*, produced by partial occlusion of the aorta, digitalis accelerates the heart to the normal volume. This occurs also after strophin (Hirschfelder, 1918).

Efficiency of Digitalis in Cardiac Irregularities.—The second important factor in the usefulness of digitalis is the regulation of arrhythmias. It is especially effective in the "absolute irregularity" of auricular fibrillation. Other irregularities are not so much improved or may even be exaggerated. Digitalis is rather dangerous in partial heart-block. It must not be forgotten that overdosage of Digitalis may provoke any of the clinical types of irregularity even in a healthy heart, and this may occur more readily when the heart is disposed to them by disease. It is therefore necessary to watch carefully for the appearance of any irregularities.

Influence of Cardiac Irregularities on Cardiac Output.—Experiments on dogs show that *extrasyostoles* have very little effect, even when they are frequent (1 in 4 to 8). Where *auricular flutter* and especially *auricular fibrillation* reduce the output considerably. This is due to the irregularity (premature beats, etc.) rather than to the rapid rate. *Heart block*, partial or complete diminishes the output greatly, proportional to the slowing (Oster and Sewardson, 1920).

*Auricular fibrillation* (formerly miscalled "nodal rhythm" by Mackenzie) is apt to occur when the auricles are excessively dilated, as in advanced myocardial and valvular lesions. The overstretched auricular muscles are unable to make concerted contractions, and instead enter into a state of continual tremulation or fibrillation. These numberless irregular impulses are transmitted to the ventricle, and thus produce a very rapid confused rhythm. The output of the heart is greatly decreased, and the results are very serious.

This is the condition in which digitalis produces the most striking and rapid improvement (Cushny, 1917; Mackenzie, 1911). The rhythm does not become normal but the rate is reduced to about normal, the irregularity becomes less and the dyspnea and other symptoms of heart failure are relieved. The improvement of the heart is better affected in the apex-beat (auscultation) than in the pulse (Christian, 1913).

Mechanism of Action in Auricular Fibrillation.—The auricular fibrillation is not changed, although it may be presumed that the distortion is lessened. The main factor in the improvement is probably the lessened conductivity, by which many of the superfluous auricular impulses are blocked from the ventricle (Cushny, 1917) for somewhat similar results may be obtained from simple vagus stimulation. (In auricular fibrillation, the usual type of stimulation of the right vagus usually shows the ventricular rhythm without affecting the auricular rate (Robinson and Draper, 1917).

However, the point of attack of the digitalis in auricular fibrillation is not through the vagus center, as in normal animals, but peripheral; for it occurs even after atro-in., Cushny, 1918, finds that a similar effect on A-V conduction is produced by digitalis in excised hearts that have been weakened by prolonged perfusion. He suggests that the peripheral action of digitalis, both in this case and in auricular fibrillation, is conditioned on malnutrition of the heart-muscle. The direct regulating action of digitalis on the cardiac muscle may play some part; for it has been found that digitalis tends to remove irregularities in excised hearts.

Effect on Blood Flow.—The improvement under digitalis in auricular fibrillation is accompanied by a prompt and decided increase in the blood flow through the heart. Since there is no evidence of purely local vasodilatation, this means improved output of the heart. In a case in which there was no clinical improvement there was also no increase of the blood flow (Stewart and Scott, 1915).

To obtain the best results in auricular fibrillation, the digitalis must be started with full doses. Smaller doses must then be continued for a long time, giving just enough to keep the rate between 60 and 70 per minute. Overdosage is often indicated by occasional reduplication of the pulse wave. This is an indication to reduce the dosage.
These "coupled beats" (pulsus bigeminus) are not produced by digitalis in any other condition (Mackenzie). Each ventricular beat originating from the auricles is followed by another arising in the ventricle (Lewis, 1911).

If the auricular fibrillation occurs in cardiothoraxosis or when the myocardium is excessively weakened, digitalis is much less effective and much more dangerous. Excessive doses of digitalis (also of barium, aconite, etc.) may of themselves produce auricular fibrillation, in man as well as in animals, by increasing the excitability of the auricles (Cashny, 1911).

Deficient Vagus Tone.—In simple quickening of the cardiac rate, by diminished vagus tone, the efficiency of digitalis depends upon the cause. In the milder grades of cardiac dilation, the vagus tone is automatically inhibited in the effort to keep the blood pressure to the normal. Digitalis, by strengthening the heart, removes the need for these rapid contractions, and they naturally return to the normal rate. The return is double–less hastened by the direct stimulant effect of digitalis on the vagus mechanism. In some cases, it fails to show a fast but regular rate; that is, the rapid heart rate of fever is not much affected.

Paroxysmal Tachycardia.—The response varies. In some cases, digitalis is practically ineffective; in others, intravenous strophanthsin reduces the rate very strikingly.

Periodic changes in sinus rhythm (such as the exaggerated respiratory variations, which occur in general nervous exhaustion, rather than in cardiac disease) are not benefited by digitalis. On the contrary, the vagus stimulation would tend to render them more marked.

Extrasystoles.—These would not be removed by digitalis since they are probably due to heightened irritability of the myocardium—a condition which could only be exaggerated by digitalis. Extrasystoles due to nervous exhaustion, indigestion, nicotine, etc., do not require medicinal treatment; they tend to disappear under suitable hygiene, and in any case, they have no serious significance. (The influence of various drugs in extrasystoles has been studied by McCord, 1912.)

Guthrie, 1917, reports that digitalis (toxic doses) decreases the irritability of frog and turtle heart to extra systoles by electric stimulation.

Partial Heart-block (diminished conductivity of the auriculo-ventricular bundle).—This is always exaggerated by digitalis; a slight retardation between the auricular and ventricular contraction may thus be converted into a partial block, so that the ventricles respond only to every second or third beat of the auricles; or a partial block of this kind may be converted into a complete block, the ventricles assuming their characteristic slow independent rhythm. In partial heart-block (even when the a–c interval in the jugular tracing is merely lengthened) digitalis should be avoided, and employed only with caution when it is otherwise urgently needed. If the need for it exists, however, it may relieve the symptoms even though it exaggerates the partial block.

Complete Heart-block.—In this, digitalis can do no further harm; for it does not slow the spontaneous ventricular rhythm. On the contrary, it would tend to quicken the heart; at all events it would tend to render it more effective. It might therefore be of some use (Bachmann).

In complete experimental heart-block (dogs) strophanthsin first increased the rate and strength of the ventricular contraction. This was followed by sudden widening of arrhythmia and tachycardia, increasing to fibrillation. The auricles were strengthened, their rate sometimes quickened or slowed. The blood pressure rose in the first, and still more in the second stage (van Egmond, 1913).

Irregularities in the Strength of the Cardiac Contractions (Pulsus alternans).—These, as contrasted with irregularities of rhythm, are currently attributed to exhaustion of the myocardium. They should therefore be improved by digitalis. It must be employed with caution, however, for similar irregularities are prominent in digitalis poisoning, and an exhausted heart is more subject to these effects.

Use of Digitalis in the Special Cardiac Lesions.—No cardiac lesion, as such, either indicates or contraindicates digitalis. Whatever the lesion, digitalis would be superfluous so long as compensation is fairly perfect.
be indications for its use arise only when compensation fails; and then possibilities for good or harm are determined by the physiologic conditions, as they have been discussed, rather than by the location of theatomic changes.

**Aortic Insufficiency not a Contraindication.**—The older clinicians, since Corrigan, considered digitalis as contraindicated in this condition, fearing that the prolonged astole would give the blood in the brain a chance to gravitate back into the heart and thus produce syncope.

The apprehension appears to be unfounded (Christian, 1910). Digitalis is now even freely, as in other lesions. It is advisable to keep the patient in bed during the digitalization.

The occurrence of syncope on changing suddenly from the prostrate to the upright position may occur under the influence of digitalis, even with other lesions; the patient would be cautioned as to this.

Gehhart, 1911, has tried the effect of digitalis on experimental aortic insufficiency in rabbits. He found that it lessened the dropy and mortality; but did not prevent cardiac hypertrophy.

**Chronic Myocarditis.**—Digitalis would generally be efficient against the dilatation and irregularity; but it must be used cautiously if the muscle is degenerated.

**Cardiac Tachycardia.**—It must be remembered that the most useful effects of digitalis are produced by stimulation of the cardiac muscle. As a result of the better nutrition produced in this manner, the muscular fibers may afterward hypertrophy, or new fibers may possibly be formed; but the primary action of digitalis itself is confined to the already existing muscle; consequently it will be of no use if there is practically no muscle left to respond to it. It is therefore useless with a heart which has undergone marked fatty or fibrous degeneration. In this condition it is often contraindicated, because the overworked muscle is more readily poisoned.

**High Blood Pressure.**—This has little bearing on the usefulness of digitalis. Its existence does not contraindicate the administration.

**Acute Myocarditis and Endocarditis.**—The use of digitalis is debatable; it can easily lead to dangerous overstrain of the hypersensitive muscle.

**Digitalis in Pneumonia and Other Fevers.**—It has been shown conclusively that fever does not modify the digitalis actions, the heart responding just as in non-febrile individuals (Cohn and Jamieson, 1917, T. S. Hart, 1919, Hirschfelder, 1920). Digitalis would therefore be indicated in pneumonia patients with cardiac lesions, and particularly with auricular fibrillation (Cohn, 1915). In the absence of these, however, its usefulness is very doubtful (Hart, 1919). The terminal collapse in fever is apparently not due primarily to cardiac failure; and digitalis is practically ineffective, just as in other forms of "shock" (G. Schwartz, 1920).

It should be remembered that fever renders the heart more susceptible to digitalis, so that the dosage should be smaller (Hirschfelder et al., 1920).

**Aneurysm.**—The sudden distention of the aneurysmal sac by a larger mass of blood, which would be the result of digitalis, is exactly contraindicated. The only reason why digitalis has not done more harm in this way is that it has not generally been used in large enough doses to have a marked effect.

**Remarque.**—This would similarly contraindicate digitalis.

**Absorption.**—The slow onset of the symptoms shows that absorption from the alimentary canal is very gradual; it is more rapid with rectal, and especially with intramuscular administration.

**Absorption** influences the rate of absorption materially. With oral administration, the rate of adsorption increases with the dose (Hatcher, 1909); but is always quantitatively uncertain. The variation is especially great with Strophanthus (Hatcher, 1909). This accounts for the unsatisfactory clinical results from the oral use of this drug. The safe dose would be so small as to be generally ineffective; a really effective
dose could be highly dangerous, according to the individual absorption. *Helleborin* is probably not absorbed at all from the alimentary canal, since it commonly produces only diarrhea, without cardiac effects (Cushny, etc., 1912). Digitoxin appears to be better absorbed than digitalis (Eggleston, 1915) or strophanthin (Hatcher and Eggleston, 1910). The tincture of digitalis is absorbed more rapidly than the infusion.

The chloroform-soluble extract is absorbed more completely and uniformly (Hatcher, 1910). Digiprutinum and digitalen are not decidedly superior (Haskell, McCants and Gardner, 1916).

**Different Portions of the Digestive Tract.**—Quantitative studies by Ogawa, 1912, indicate that digitalis is not absorbed from the stomach. From the intestines, 24 to 51 per cent. were absorbed in two hours from digitalis leaves; with digipurinum, the absorption was 52 to 61 per cent. in two hours; 65 per cent. in three hours.

**Destruction in Alimentary Canal.**—The digitoxials are practically unaffected by pepsin or trypsin (Goodall and Reid, 1914); but a small quantity of the glucosides is probably destroyed by the acidity of the gastric juice (Hale, 1911; Holste, 1912; Segond, 1912). Johannebod, 1914, found that alkaloids weakened only crystalline K-strophanthin; acids, this and amorphous K-strophanthin and strophanthhus tincture. The amorphous strophanthin is changed mostly to strophanthidin, and partly to an inactive resin. Osolain is unaffected by ether acids or alkaloids, which is an advantage in administration. However, with the usual short contact, the destruction of the other principles is probably also unimportant (Hatcher, 1909).

In the rat, with the oral administration, strophanthin is mostly destroyed in the large intestine. Of digitoxin also, variable amounts are destroyed before absorption (Hatcher and Eggleston, 1910). Lhota, 1912 and 1913, invokes gastric destruction to explain the habituation which he believes to occur in rabbits.

**Disappearance in the Body.**—The digitoxials disappear from the blood almost immediately after the injection of even much more than fatal doses (Hatcher and Eggleston, 1911; Lhota, 1912).

This rapid disappearance is due to wide distribution in probably all the tissues; for it occurs if the circulation is restricted to limited areas; not, however, if it is restricted to the heart and lungs alone. The liver plays perhaps a larger part than other organs. In rats, the greater part is fixed by the liver (Hatcher and Eggleston, 1910).

The further fate of the digitoxial substances is not definitely known. From the duration of their action Cioetta and Fischer, 1906, and Hatcher, 1912, conclude that a part must be stored in the cardiac tissue. Lhota, 1912, claims that digitoxin is found chiefly in the heart and blood vessels, less in the liver and other organs. According to Clark, 1913, there is no evidence that the digitoxials are either fixed or destroyed in the tissues, so that their distribution would be rather one of selective solution-affinity. In proportion to their slow excretion, they would gradually diffuse back into the blood.

**Excretion.**—The digitoxials are partly destroyed in the body, mainly by the bile, and partly excreted unchanged. The excretion occurs chiefly through the bile, so that the substance may be demonstrated in the feces after intravenous injection. A small fraction is excreted by the kidneys. This increases if the bile duct is tied (Hatcher and Eggleston, 1910).

**Onset of Action.**—When small therapeutic doses of the Digitalis drugs are administered by the alimentary canal, the effects develop very slowly. It may be several hours before any action can be noted. The full effect is reached much later; twenty-four to thirty-six hours for the circulatory actions; seventy-two hours for the diuresis.

This delay is due mainly to the insufficient dosage; i.e., several doses must accumulate before the effective dosage is reached. When full therapeutic doses are given at once, as in the Eggleston method, definite effects (T wave) occur within 2 to 4 hours, and reach the maximum in 6 to 24 hours (Robinson, 1910; Pardee, 1920).

Absorption, however, plays some part in the delay; for with intravenous injection of strophanthini or digitalis, the circulatory action begins at once, and the diuresis starts in a few hours (Fraenkel and Schwartz).
1907, Hatcher and Bailey, 1910). However, the reaction continues to increase for some time.

**Duration of Action.**—The digitalis effects endure for a long time after the administration has stopped, whether the drug was given by the mouth or vein. It is difficult to establish a time for the clinical reaction, because when compensation has been established, it tends to persist, independently of the drug (except in auricular fibrillation), until some extra demand causes a fresh break of compensation. This probably holds true to some degree of the other cardiac changes. The persistence of the drug effect depends also upon the total dose. One can therefore only deal in approximations. The effects of a "full" dose of digitalis or digitoxin seem to persist, with gradual decline, for one to three weeks, according to the total dosage; but for shorter periods with some of the other digitaloids, especially strophanthin and ouabain.

Clinically, the duration of the actual digitalis action can be judged by the alteration in the T-wave of the electrocardiogram. This persists from 1 to 22 days, averaging about 9 days after discontinuance of the administration (G. C. Robinson, 1919, White and Morris, 1918). The other clinical facts lead to the same conclusion (Eggleston, 1919).

Pardee, 1910, estimates the rate of disappearance in man, after full therapeutic doses, as averaging 0.42 Gm. of Digitalis per day.

The duration of the digitalis-effect can be measured accurately in animals by Hatcher's method (differential fatal dose): In cats, one-half of the original effect of an intravenous injection persists for the following number of days: digitalis, five to twelve days; digitoxin, fourteen (dogs, two days; rabbits less than one day); digitalein, three; digitalin German, three; digitoxin true, less than two; ouabain and strophanthin less (Hatcher, 1921). Klein, 1914, believes that the action of strophanthin may persist for a month in cats.

The duration is much shorter in dogs and especially in rabbits, as quoted for digitoxin. Apparently, the more resistant a species is to digitalis, the shorter is the action. Both facts perhaps depend on the rate of elimination.

**Racial Tolerance.**—Great differences exist in the susceptibility of different species to the digitalis poisons. Rodents, toads (Valpian, 1810) and the grass-snake are especially resistant but not immune. With mammals the difference is perhaps partly a matter of excretion; but the resistance seems to be mainly in the tissues.

Curiously, the resistance of the toad and snake does not extend to the related action of barium or saponin (Heuser, 1902; Clark, 1912). The toad resistance is generally attributed to habituation for its own poison; and Filippi, 1913, claims that toads deprived of their poison are very sensitive to digitalis.

The fatal dose for rats is nearly a thousand times greater (per kilogram) than that for cats, even hypodermically (Hatcher, 1906) and thirty times as much as for rabbits. Gunn, 1913, found that the concentration required to arrest the isolated heart in a given time is also forty times greater for rats than for rabbits; showing that the difference lies in the heart itself. Similar relations hold for the toad and snake (Clark).

Lbota, 1912, asserts that rabbits acquire an added tolerance by habituation; this needs confirmation. Klein, 1914, describes a similar induced tolerance in cats. Salisberg, 1907, claims that ruminants are more resistant to oral administration, but not to intravenous, indicating, that in these animals the drugs are partly destroyed in the digestive canal. Lbota, 1909, states that young animals are more resistant than adults.

**Cumulative Action.**—The effects of digitalis tend to be cumulative; that is, the same doses, continued day by day, tend to produce ever-increasing effects; or more commonly, toxic effects develop suddenly, without warning, after small doses have been continued for some time. In the therapeutic use, the dose must therefore either be diminished, or toxic
phenomena result, often quite abruptly. This cumulative action may be explained in part by the slow and uncertain absorption and excretion. The principal factor, however, is probably the slow, persistent and progressive action: Since the effects of a single dose may persist over several days or weeks, the effects of all the doses which are given in the meantime are more or less summed up; and the effects of digitalis are determined by the total dose, and not by the single or even by the daily dose.

CHRONIC DIGITALIS POISONING IN ANIMALS

von Lhota, 1910, has studied this in dogs which were poisoned for several months by slowly increasing doses of Digitalis. The phenomena correspond closely to those observed in man: The pulse after nine or ten days shows occasional short periods of slowing, but with the heart regular and strong. If the administration is continued, the slowing becomes more persistent and more marked and arrhythmic. Later, the pulse rate again increases to normal or somewhat above. The pulse changes outlast the administration for a long time; in severe acute poisoning, they may persist for several weeks; after chronic poisoning, they may last over a month. Lhota believes that the effects are at first cumulative, but that later some tolerance is acquired especially in rabbits (Lhota, 1911); but the evidence for habituation is not convincing.

Typical cumulative poisoning has also been observed in cats (Klein, 1914).

TOXIC EFFECTS IN THE CLINICAL USE OF DIGITALIS

These are not at all uncommon. The effects of the drug vary so much according to the condition of the heart, according to absorption and cumulation, etc., that the dosage is very uncertain. The drug must be given until the desired therapeutic effect is obtained; and the zone between the really efficient therapeutic action and the toxic action is so narrow, that the minor toxic manifestations are apt to occur at any time. Indeed, it is often necessary to "push" the drug intentionally to this point, for the full therapeutic effect practically coincides with the minor toxic manifestations (Eggleston, 1913). These do no permanent harm, if the dosage is reduced immediately on their occurrence; but if they are disregarded the results will be most serious.

Digestive Disturbances.—These occur early and are easily recognized, so that they are very important. They consist in nausea, great malaise, and often headache which may be very distressing. If the drug is continued, vomiting will occur. Diarrhea is not very common with digitalis, more frequent with strophanthus, squill and helleborein. When any of these digestive symptoms occur the dosage should be reduced or stopped. They will then subside in one or two days.

Cardiac Irregularities.—Digitalis may simulate any of the clinical irregularities; so that it is sometimes difficult to distinguish between them, particularly in advanced poisoning. To establish their causation by digitalis, it must be shown that they were absent before the drug was given, and that they disappear in a reasonable time after its discontinuance. The early effects, however, are fairly characteristic. The most common is excessive vagus stimulation (sinus irregularity). It is best seen when the heart is slowing after a little exercise. The rate may fall to 50 or even lower; so that syncope may occur between the contractions. The rhythm may remain regular; but ventricular extrasystoles are common. The stage would not occur in auricular fibrillation, nor in absolute heart-block.

The next stage is usually that of partial heart-block, especially if the

1 Bailey, 1911, claims that in a series of ninety cases at Bellevue Hospital, 25 per cent. showed some form of toxic action, although the administration was conducted with the greatest care.
conductivity was naturally low. It may occur with relatively small doses (Windle, 1911), and may be permanent (Tausig, 1912); Christian, 1915, records transient auriculoventricular dissociation.

The final stage is that of muscular irritability, first indicated by extra-
systoles. These are particularly common in auricular fibrillation, giving the "coupled beats." With more advanced toxic action, there occur the same effects as in animals: high blood pressure (vasoconstriction); very rapid rhythm, with periodic changes in amplitude, pulsat alternans (rarely).

Dosage.—Eggleston, 1912, finds that the toxic effects depend mainly on the total dose, modified by the weight of the patient, the activity of the preparation, absorption, individual susceptibility and the nature of the heart lesion. With the ordinary ener-
genic administration, the characteristic coupled beats occur when the total quantity of digitals has reached 2.25 to 6.25 Gm. Since the action persists partly from one to three weeks, these irregularities will recur with a smaller dosage.

Ratio of Toxic and Lethal Dose.—With intravenous injection, the lethal dose of any digitals preparation is constant for cats. The toxic dose, however, varies with different animals. According to electrocardiograms, it ranges from 25 to 60 per cent, of the lethal dose; averaging about 50 per cent. In any individual cat, however, it is fairly constant (Levine, 1910).

Duration of Irregularities.—This depends on the total dosage, and therefore on the severity of the phenomena. Eggleston, 1912, found that coupled beats generally lasted the administration by four to twelve days; heart-block, three to six; auricular fibrillation, three; muscular irritability, two; sinus irregularity, two days.

ACUTE DIGITALIS POISONING

The symptoms set in relatively late (one to twenty-four hours); and they generally have a long course, so that a weak or two may elapse before death. The symptoms are those of cumulation—gastro-intestinal disturbances, slow and arhythmic pulse, etc., lassitude, muscular and sensory derangements. Death generally occurs suddenly, with dyspneic convulsions. Consciousness persists late.

The treatment would consist in evacuation, quietness, possibly diffusible stimulants, and other symptomatic treatment. A cathartic should be given. (The claim of Krause, 1906, that diastase is an effective antidote to strophanthin is doubtful.)

The fatal dose varies greatly, on account of the variable absorption, the occurrence of vomiting, etc.; 2.5 Gm. of digitals has been fatal, whilst 4 Gm. has been followed by recovery (Levin).

The symptoms in mammals are similar. The symptoms of fatal intravenous injection of strophanthin include vomiting and diarrhea (both central), and convulsions (Bateh, 1909).

Contraindications.—Digitalis should be avoided in partial heart-block, and in advanced myocardial degeneration. Its administration requires even more than ordinary care in coronary sclerosis, in aortic insufficiency and in the presence of any irregularities, particularly auricular. Renal diseases emphasize the tendency to cumulation.

ADMINISTRATION

General Statement.—Digitalis is usually started when decompensation has occurred. It is then desirable to induce the effects as promptly as may be feasible and safe; and to maintain them as long as necessary.

 Intravenous administration would be the promptest method; but it has drawbacks that restrict it mainly to emergencies. Ordinarily, the objects are fully met by proper oral administration. In this, it is necessary to remember the long duration of the digitalis action, and the consequent cumulative action. It must be emphasized that therefore the total accumulated dosage is of more importance than the single
doses; that practically no therapeutic effect is produced until the total dosage approaches the toxic; that the dosage must be reduced when the desired action has developed; that the patient must therefore be closely watched. He should be seen at least daily, while under active medication; and the intensive methods are safest under hospital conditions. If toxic symptoms appear, the administration should be temporarily suspended; i.e., if nausea develops; if the pulse falls below 50; or if any of the characteristic digitalis irregularities arise.

In the intensive methods it is also indispensable to employ digitals preparations of known activity; tested first on animals, and then checked by cautious observation in the clinic. The dosage should be measured accurately, and not estimated by "drops." Fever is temperature renders the heart more susceptible to digitals, so that the dosage should be reduced.

Systems of Oral Administration.—These may be grouped into the intensive, the cumulative, the constant dose, and the maintenance methods. The intensive methods aim to give, the greater part of the total dosage at once, and practically the whole within a day. The cumulative methods accumulate the effective dosage by divided doses in two or three days. The constant dose methods tend to err on the side of safety, and often do not reach the effective dosage at all. The intensive methods are most effective, and under the best hospital conditions are probably the most satisfactory. The cumulative method occupies a middle ground.

Intensive Method.—Eggleston, 1915, determined the total dosage of standardized digitals necessary to produce full therapeutic or minor toxic effects, as 0.15 "cat-units" per pound of body weight. With tincture so adjusted that 1 cc. kills 1 kilogram of cat, this would mean 15 c.c. of tincture per 100 pounds of body weight. Eggleston therefor proposed to give half of this dose at once (i.e., 7.5 c.c. of standardized tincture per 200 pounds); followed in six hours by one-fourth of the total dose, then smaller fractions every 4th to 6th hour till the total dosage or full response are reached.

The advantages of this method have been confirmed by White and Morris, 1918; G. C. Robinson, 1919, and others. The response starts definitely in 2 to 6 hours after the first dose; reaching its maximum within 24 hours; and continuing without further administration for 4 to 15 days.

Relation of Therapeutic Effects to Dosage.—This has been worked out by Eggleston, 1915. In terms of "cat-units," a "cat-unit" corresponding to the quantity of the drug per kilogram of cat, that is just fatal by intravenous injection under suitable condition (Hatcher, 1900). Eggleston found that the relation of effect to dose (cat-units) is remarkably uniform, for a given drug, regardless of the presence or nature of cardiac disease. Whatever the condition, the total dose of digitalis by mouth, to the appearance of the first improvement averages 0.00 cat-units per pound of body-weight (about 0.4 Gm. of good digitalis per 100 pounds); for full therapeutic or minor toxic effects, 0.16 cat-units per pound (about 1.5 Gm. per 100 pounds). With digitoxin, the corresponding doses are: first improvement, 0.04 cat-units per pound (0.14 mg. per 100 pounds); full therapeutic effect, 0.066 cat-units per pound (2.3 mg. per 100 pounds). The other digitals give variable results, by mouth, because of uncertain absorption. They are therefore unsuited for the intensive method.

Cumulative Method.—These start with a daily dose equivalent to 1 to 6 c.c. of the Tincture of Digitalis (MacKenzie and Cushny), divided into 3 or 4 portions, and continued until the desired effect is obtained, when the dose is reduced to the maintenance dosage.

Maintenance Dosage.—When decompensation is only temporary the improvement is often lasting, and the digitals may be discontinued when
compensation has been restored. In auricular fibrillation, however, it is necessary to keep up a continuous digitalis effect. Clinical experience has shown that this should not exceed the daily dosage of 1 c.c. of Digitalis Tincture (A. Franks, 1907). This is not quite equivalent to the capacity of destroying digitalis, which Pardee, 1919, calculated to average 1.5 c.c. of Tincture (1 c.c. = 1 cat unit). There is therefore little danger of accumulation.

Continuous Methods.—The older methods of using digitalis employed a dosage approximating the maintenance dosage. This would be unsuccessful, except when employing preparations stronger than the standard.

Choice of Digitalis Preparations.—Of the various preparations of Digitalis, a good tincture, physiologically standardized, has many advantages. The infusion is uncertain and unstable. It was formerly considered as more active than the tincture, but this was generally due to the administration of larger doses. Fluidextracts are unreliable (Haskell and Eckler, 1913). The powder may be used, but has no advantage, and is apt to be more irritant. The pill of Digitalis, Squill and Cabomel ("Guy's Hospital Pill") seems needlessly complex. Digitaluparum seems to be a good preparation (Boos, Newburgh and Marks, 1918); but as has been stated, a good Tincture is as satisfactory as any.

It may often seem that the preparation, or one digitaloid drug, gives results where another has failed. This is scarcely a conclusive demonstration of its superiority, even in that particular patient, since the cardiac condition, and therefore the response to digitalis, is apt to vary from day to day. Differences in clinical results are often due to differences in the disease, rather than in the drug. The same is true of the gastric effects. Cushny, 1912, considers that 1 part of Digitalis is clinically equivalent to 1/3 part of Strophanthus, or 3 to 4 parts of Squills.

Intravenous and Intramuscular Injection of Strophantin.—Intravenous digitalis therapy was tried clinically by Kottman and by Mendel in 1905; but the preparations which they employed were not satisfactory. The method has been put on a sound basis by the introduction of strophantin (A. Fraenkel and Schwartz, 1907; Krehfeld, 1907). This is soluble in water and has the advantage of a more uniform composition—a very important matter when so potent a procedure is employed. It also acts more promptly than digitalis, and has less tendency to accumulation and vasoinstiction.

The therapeutic events correspond with those of digitalis administration, but occur much more rapidly: The first change is the increased amplitude of the pulse wave, which can be observed in three or four minutes. The pulse then becomes fuller and less irregular, and the symptoms of cardiac failure (dyspnea, cardiac distress, etc.) are improved. The slowing of the rhythm sets in somewhat later: its maximum is only reached after several hours, when the rate may become slower than that of the normal heart. The blood pressure is not altered—or rather it tends to remain or return to the normal. The diuresis also begins in a few hours. The increased amplitude outlasts the slowing.

The intravenous administration is especially indicated in the acute muscular failure of advanced heart disease—it is immaterial whether the failure is of the right or left heart. It sometimes appears to give good results in collapse, e.g., of typhoid fever (Hoepfnier; Liebermeister). It is also of advantage in starting digitalis therapy in somewhat less urgent cases, following it in twenty-four hours by oral administration of digitalis. The intravenous method is not very suitable for continuous digitalis therapy—partly on account of the inconvenience and discomfort, and partly because the smoother action secured by gradual adsorption should
be more beneficial to the heart than the daily repetition of the stormy effect of the intravenous injection.

Comparison of Intravenous Ousabain and Oral Digitalis.-A. E. Cohn and Levy, 1910, compared the effects on patients. The response to ouabain was naturally more prompt and less persistent. Ouabain led less often the alteration of the T wave, but more frequently to toxic effects.

Use after Digitalis.—The previous use of digitalis renders the intravenous injection very dangerous, since the effects of the two drugs will be immediately added. At least two or three days free from Digitalis should intervene, and the dose of Strophanthin should be divided in half and injected in three or four fractions several hours apart. In advanced cases, this fractionation should be practiced even if the patient is not under digitalis.

Intravenous dose: With the amorphous strophantin (Boehringer) this is 1 mg. or less per day. Hatcher and Bailey, 1910, have used ouabain in the same way. It is about two and one-half times as active, and its dose would therefore be ½ mg. or less, as 1,600 to 1,800 solution in normal saline. Bailey, 1909, prefers the intramuscular injection of the same dose (as 1:4000). This is almost as prompt and effective, but is slightly painful. Intravenous injection sometimes produces cyanosis, chills and slight fever (Seifert, 1906). *Digitalatum* may be used, 0.1 Gm., 1/2 gr., per dose. The Intravenous dose of other digitaloids (according to their toxicity for cats, Hatcher and Bailey, 1910) would be: digitoxin, 1.5 mg.; tincture digitalis, 4 c.c.

RECAPITULATION OF OTHER DIGITALOID DRUGS

These present quantitative differences, which might be of some therapeutic value if they were better understood. At present they possess no serious advantage over digitalis for oral, and the strophanthins for venous administration. These accomplish all that can be done by any digitaloid drug. Many of the substitutes are inferior in solubility and absorbability.

Isolated Digitalis Principles.—These have proven disappointing, since the only one which can be obtained pure, digitoxin, is undesirable.

Digitoxin.—This has the undesirable features of producing excessive irritation, and of being nearly insoluble in water. It may be dissolved in 25 per cent. of alcohol. It has been used clinically, especially by Masius, 1894, Corin, 1894, and Englestein, 1896 (cf. Intensive Oral Digitalis Medication). It is better absorbed than Digitalis. The usual daily dose by mouth is 1 to 4 mg., largely diluted; hypodermically, 0.5 mg. (1 c.c. of 0.05 per cent. in 25 per cent. alcohol; Unverricht, 1895; it produces irritation).

Digitalin “True.”—This is also insoluble and emetic, but non-irritant and not greatly cumulative. Clinically, it has proved too feeble, a variable quantity being probably decomposed in the stomach (Deucher, 1896). It has been used in doses of 1 to 3 mg. up to 8 to 16 mg. per day; even 50 mg. have been given without toxic effects (Plath, 1897). It is administered in pills or dissolved in dilute alcohol.

Commercial Digitalins.—These have no advantage over the galenic preparations. The uncertain composition of these mixtures, and the danger of confusing the similarly named but very different preparations, should precide their use. At least, “digitalin” should never be prescribed without specifying the variety (verum, German, French, etc.)

Digitain German.—This contains considerable digitoxin. Soluble in water or alcohol. Daily dose, 0 to 30 mg., ½ to ½ gr. (Beaure, 1907).
Commercial Specialties.—These are also indefinite mixtures of the same
impure principles. The most important are:

Digipuratum, N.N.R. (Gottlieb).—This is a purified solid extract, freed from digito-
xin, and standardized to the same activity as digitalis leaves. It contains all the cardiac
glycosides, is uniform, reliable and stable (Hale, 1910) and is relatively non-irritant; but
all these features are possessed by a good tincture (Dixon, 1912; Cow, 1912). It is
insoluble in cold water, but dissolves on the addition of a little alkali. Its dosage is
that of digitalis leaves.

Digalen ("Digitoxin soluble," Cloetta, 1904).—This has been widely advertised as
an amorphous and soluble isomer of digoxin. Killian, 1907, states that it consists
mainly of Digitoxin in Schm. his opinion should carry weight. It was said to be free
from the disadvantages of digitoxin; but it is of variable activity, unstable (Hale, 1910)
produces considerable irritation, is not suitable for hypodermic injection, and causes
cumulative effects (Fraenkel, 1907; Westerark, 1908). It therefore possesses no real
advantage over a good tincture (Dixon, Cow, 1912), except for venous injections,
and these cause pain and sometimes thrombosis. It is marketed as a solution (1 c.c. =
0.5 mg. of the glucoside). The intravenous dose is 1 c.c., repeated in one-half to one
hour if necessary.

Strophanthins.—These have the advantages of being less irritant and
less cumulative than digitalis; but the absorption is so uncertain that their
use by mouth is not advisable (Hatcher and Bailey, 1909). This is re-
flected in the very different doses of strophanthus used by various clin-
icians. It is also liable to produce diarrrhea. The main field of the stro-
phanthins is for intravenous injection. Ouabain has the advantage that
its identity is assured.

Apocynum (Canadain Hemp) is an effective member of the group,
but without serious advantages.

Action Constituents.—These were isolated independently by Finnemore, 1909, and
Moore, 1909. The principal constituent of Apec. cannabinum is a neutral crystalline
bitter principle, Cynotoxin, that of Apoc. androsaemifolium is Apocynamarin. They
are identical pharmacologically and perhaps chemically. They are destroyed by boiling
with acids or alkalis, although they are not glucosidal. They are believed to be diac-
tones of Killian's digitoxigenic acid. Impens, 1913, affirms that the active principle
(whick he calls "Cynarumin") is the same for both species, and that apocynamarin is
probably a decomposition product. The chemistry and cleavage products of cymarin
are described by Winandw and Hermann, 1915. Apocynin and apocynin of Schmie-
berg were impure mixtures. Commercial apocynin is acetovanilliu (Finnemore, 1908),
and is practically inactive (Wood, 1904).

Actions.—These agree with digitalis (Dale and Laidlaw, 1909, who studied the pure
principles). The cardiac action, therapeutic and toxic, of cymarin (Iroq. Kuroda, 1914;
electrocardiograph, v. Hecht, 1915) is somewhat weaker than that of strophanthin.
It produces practically no irritation, but relatively strong vasconstrictor effect. Kur-
oda claims that the cumulative and emetic effects are weak; but Taviani, 1915, finds the
serious disadvantages of uncertain absorption, and variable strength of the commercial
cymarins. Large doses are also nephritie.

Beco and Douin, 1910, with intravenous injections in dogs confirm the slowing,
by vagus stimulation (central and peripheral); but claim that the cardiac tonus was
decreased, and never raised. The blood pressure rose by general vasconstriction,
specially splanchnic (direct action on vessels). The urine flow was hindered, the renal
reaches being constricted even by minute doses.

Cymarin has been used clinically like strophanthin, by vein or muscle, o.5 to 0.5
mg. hypodermic injection is too irritant. It is difficultly soluble in water, easily in
alcohol. It has also been given by mouth, 0.5 mg. three to five times daily (von
Noorden, 1915; bibliography). Gaisböck, 1915, on the basis of his clinical and ex-
perimental studies, emphasizes the need of caution in its use.

The drug could probably be spared.

Scilla (Spuit).—This produces the same effects as digitalis, experi-
mentally and clinically (in auricular fibrillation). The dosage required
to produce the typical response of heart-block and reversal of T-wave is
from 24 to 48 c.c. of tincture per day (Viko, 1920), i.e., considerably larger than the official dose. Toxic symptoms are rare. The milder action and larger dosage are due to poor absorption, for the intravenous dose is about the same as for digitalis (Eggleston). The poor absorption renders it undesirable as a digitalis substitute (Dixon, 1906) although it was advocated by Haynes, 1906.

Scilla was formerly used as expectorant (nauseant) and general diuretic. It is not well suited to either purpose. There are much safer expectorants; and diuresis occurs only when cardiac edema is relieved (Viko).

**Active Constituents.**—The activity was attributed to two amorphous glucosides, scilliparin and scillitoxin; but Ewings, 1904, found these to be impure mixtures. Kopaczewski, 1914, claims to have isolated two active principles: Scillitin, the toxic constituent, a nitrogen-free glucosid and Scilliduretin, watersoluble, markedly diuretic but of low toxicity.

**Adonis** resembles scilla more closely than digitalis (Chevalier, 1913). Roch and Cramer, 1914, find even large doses inefficient in cardiac diseases. Tuckermann, 1913, claims that "adonin" is a mixture of an acid and neutral glucosid, both possessing digitaloid effects; the acid being also hemolytic.

**Convallaria** (Root of Lily of the Valley); active constituent, the glucosid convallamarin, is considered rather uncertain (Roch and Cramer, 1914).

**Helleborin** is a glucosid from the rhizome of Helleborus Niger (Helleborus). Its digitalis action depends on the presence of an acetyl group (Sieburg, 1913). It is not absorbed from the human intestinal tract and therefore produces only diarrhoea clinically (Cushny, etc., 1912).

**Erythrophloia** is an alkaloid with digitalis action, obtained from "Sassy Bark" (Chemistry, Power and Salway, 1912).

**Barium Salts.—** (See Index).—These have been used in veterinary medicine, but are too dangerous for man (Report, Council Pharm. Chem., 1911, p. 53).

### BIO-ASSAY OF DIGITALOID DRUGS

The potent effects of these drugs makes variations in their activity very serious. Considerable variations occur in the crude drugs, and still more in their preparations. It is therefore essential that they be standardized. Since their activity is not due to a single principle, chemic assay is out of the question; and recourse must be had to bio-assays. It has been objected to these assays that they standardize the toxic and not the therapeutic effect. The objection is not well founded, since both actions are produced by the same substances and must therefore bear a definite ratio to each other. Clinical experience has borne out the great practical value of the bio-assay (Rowntree and Macht, 1916).

The U.S.P. has adopted the frog-methods as official, but optional. Several methods are in actual use (Gottlieb, 1914; Santesson, 1915).

**Fetal-dose Methods.**—These determine the fatal dose, i.e., the smallest dose which kills a given weight of animal in a given time. The most convenient is the twelve of twenty-four-hour frog method (suggested by Cushny, and elaborated by Houghton 1898; being the first commercial bio-assay process). Guinea pigs may also be used for determining the fatal dose (Reed and Vanderkleed), but have no serious advantage. The chief objection to the lethal dose methods is that the results are not characteristic for digitalis, but might be due to any toxic constituent.

The **average of F.D. (minimum fatal dose)** of some of the drugs is as follows (expressed as milligrams of drug per gram of frog-weight; the data are taken from Houghton and others):

DIGITALIS GROUP

Houghton, 1900 and 1913; and Hamilton, suggest expressing the strength as Heart Torsion (D.T.), based on the toxicity of 10 mgm. of dry digitalis on the rabbit. For guinea pigs, the M.F.D. of digitalis is 0.00 to 0.1 Gm. per 240 Gm. pig (Reed). Pittenger and Vanderkleeen, 1912, propose the use of gold-fish.
The Frog-standstill Methods. These determine the smallest dose which produces the typical systolic arrest of the heart. They are thus theoretically superior to the tail-dose method; practically the results are fairly parallel. Various modifications are in use. The simplest of all the assay methods is the one-hour frog method of Famulener and Lyon.
The M.S.D. (minimum systolic dose) is as follows (milligram per gram; Hale and others):

<table>

Modifications. Gottlieb, 1908, 1914, allows only thirty to forty-five minutes for the systolic standstill. This was used by Lehner and Lohb, 1914. Focke, 1906, uses a fixed dose, and judges the strength by the time required to produce systolic arrest. The method is described by Fuhrner, 1911, and Heine, 1913. The short time does not suffice to secure complete absorption (Schmiedeberg). Objections have also been raised by Lateckaj, 1908, and Hartung, 1912.

Excised or perfused hearts have been used mainly in scientific investigations (Schmiedeberg, 1913; Hartung, 1913; Zunos, 1913; Straub, Santeios, 1917). Palpitations. All frog methods, and to a somewhat smaller extent the guinea-pig method, are open to certain errors, depending on the inconstant absorption and inconstant susceptibility of different animals (Vanderkleeen and Pittenger, 1913). These must be met by using a sufficient number of test-animals. In addition, there are considerable seasonal and other variations. Each lot of frogs must therefore be tested (limited by D.U.), based on the toxicity of a standard preparation. This opens another fallacy, namely, that a given change of conditions may modify the susceptibility in a different degree for each drug, as has been shown for the influence of temperature (Hast, 1913). Alcohol (25 per cent.) is not disturbing for frogs (Haskell, 1911), but is protective for guinea pigs. With guinea pigs, age, sex and weight are unimportant; but there are considerable individual and marked seasonal variations, and the food also has an influence (Vanderkleeen and Pittenger, 1911; Haskell, 1913). Vanderkleeen and Pittenger, 1914, believe that the variations of guinea pigs are not great enough to necessitate control animals.

Even with these limitations, practical experience shows that the intact-frog methods, when properly and critically performed, permit the estimation of the relative activity of similar preparations (such as a series of tinctures) with a probable error not exceeding 25 per cent.—a sufficiently close approximation for practical purposes. On the other hand, they are unreliable for comparing the relative activity of dissimilar drugs, i.e., "Digitalis and Digitalin. The greater toxicity of strophanthin could be due, at least in part, to more rapid absorption—a factor which might be very different in the human subject. This could be excluded by using the excised heat; even then, however, it would be doubtful whether the same quantitative relations hold for the human heart as for the frog's.

The intravenous cat method of Hatcher avoids most of these objections (Eggleston, 1919). Differences in absorption are excluded by the method of administration; the action is purely cardiac, and thus measures the characteristic digitalis-effect, which is not easily simulated by other toxic principles; and the cat heart must resemble the human in its reactions more closely than that of the cold-blooded animals. Indeed, experience indicates that its resemblance is closer than that of other mammals. Even unrelated digitalloid principles may therefore be compared. Another advantage is, that the response of individual cats is remarkably uniform, so that the probable error is much smaller, and the standardization of the individual cats is usually not necessary. The method is sufficient simple: it merely determines the fatal Kg-dose; the solution being injected into the femoral vein at such speed that death occurs in about one and one-half hours. This quantity, expressed as milligram of drug per kilogram of cat, constitutes a "cat-unit" (Hatcher and Brody, 1910). The intravenous therapeutic dose for man is about 5 cat-units.

With the slower acting digitalis preparations, the death-point can be hastened by using the rapidly acting ouabain to complete the reaction; about 75 per cent. of the fatal dose of the digitalis are injected in fifteen minutes, and after an interval of ten minutes
the reaction is completed with 150,000 of ouabain (Hatcher and Brody, 1910). This experiment had also been very useful in ascertaining the absorption and persistence of digitoxides.

The cat-method is probably the best for the investigation of fundamental clinical problems; but it is not necessary for the commercial standardization. The results of Eckler, 1911, enjoin caution against its use without special experience. The following table gives for a number of drugs, the milligrams that contain a cat-unit, viz. that kill 1 Kg. of cat (Hatcher, 1912).

Macht and Colson, 1917, state that the Hatcher method gives more uniform results if the vagi are divided; but the toxicity is higher.

Attempts to utilize the blood pressure and pulse reactions have been unsuccessful, since these are too variable.

PREPARATIONS—DIGITALIS GROUP

* Digitalis (Digit.) U.S.P.; Digitalis Folia (Digit. Foli.), B.P.; Digitalis (Fox Glove Leaves).—The dried leaves of Digitalis purpurea. The B.P. specifies that they must be collected when the plant is beginning to flower. Dose, 0.05 Gm., 4 gr., U.S.P. 0.01 to 0.12 Gm., 5 to 2 gr., B.P.; as pills. Maximum dose, 0.2 Gm., 3 gr.

The activity of different samples of digitalis varies considerably, so that they should be standardized by bio-assay. This applies also to the Tincture. If preserved reasonably dry, the leaves keep indefinitely. The leaves of the first-year plants are as good as the second (Sharp and Lankaster; Caesar and Loretz, 1910). Plants cultivated in America (Newcomb, 1912) are as good as the wild European (Hale, 1910; Miller and Baker, 1913; Rowstree and Macht, 1916). Those grown during a wet season are less active (Caesar and Loretz, 1907).

The petioles, ribs and hairs of the leaves are relatively inactive (Newcomb and Rogers, 1918).

Other species of digitalis, e.g. D. Thapsi, also have the actions of the group (Farwell and Hamilton, 1917).

White and Morris, 1918, claims that Digitalis latius is as effective as purpurea on the heart, and appears to be less emetic and less convulsive.

* Infusum Digitalis (Inf. Digit.), U.S.P.; Infusion of Digitalis.—1.5 per cent; flavored with cinnamon (U.S.P. VIII also contained alcohol). Must be freshly prepared from the leaves.

Dose, 4 c.c., 1 dram, U.S.P.

* Inf. Digitalis, B.P.—0.7 per cent; note that this is only half the strength of the U.S.P.

Dose, 7 to 15 c.c., 2 to 4 drams, B.P.

Tinctura Digitalis (Tr. Digit.), U.S.P.; B.P.—to per cent. of drug in 20 per cent. alcohol. Miscible with alcohol or water (with slight turbidity due to the fat; certain proprietary tinctures deprived of fat do not become turbid, but have no other advantage). Incompatible with acids or tannin. Dose, 0.5 c.c., 8 minit., U.S.P.; 0.5 to 1 c.c., 5 to 15 minit., B.P. Unstandardized tinctures generally vary in activity by 200 to 400 per cent. (Fraenkel; Edmunds, etc.).

Digitalis Principles and Proprietary Preparations.—These were discussed on page 462 and 479..

Strophanius U.S.P.; Strophani, Sem., B.P.—The dried ripe seeds of Strophanium Kome (also of Strophanium baipus, U.S.P.), obtained from central and western Asia. Dose, 0.006 Gm., 1 gr., U.S.P., 1 gr., B.P.

Ext. Strophani, B.P.—A powdered extract, representing 50 per cent. of drug. Dose, 16 to 60 mg., 1/4 to 1 gr., B.P.

* Under proper precautions, the "Maximum doses" of the drugs of this group can be temporarily exceeded.
Tinctura Strophanthi, U.S.P., B.P.—10 per cent. (This is the same strength as the B.P. VIII, but four times as strong as the old B.P.) Dose, 0.5 c.c., 8 minims, U.S.P.; 1:2 to 0.5 c.c., 2 to 8 minims, B.P. Maximum dose, 0.25 c.c., 8 minims. However, the absorption is so uncertain that no reliable dose can be stated. Unstandardized tinctures are about as variable as digitalis.

Strophantinum (Strophantin), U.S.P.; (Amorphous) Strophantin.—A glucosidic mixture of glucosides from Kombie Strophantus White or yellowish powder. Very sol. in water or dilute alc.; nearly insol. in lipid solvents. Dose, 1 mg., 1/8 gr., by mouth; stravenous (or muscular), 0.75 mg., 1/20 gr., U.S.P.; Maximum dose, 1 mg., 1/6 gr. Oubain.—Strophantin-Crystalline; sol. in water (to 1 per cent.), more sol. in wet. sol. in alc.; difficulty in lipid solvents. Dose, one-half that of the official Strophantin.

Amuls of Oubain deteriorate rapidly through the alkalinity of the glass (Levy ed Calen, 1920); but may be made stable by using a m/50 phosphate mixture of 1/7—(Cohn and Levy, 1920).

Stills, U.S.P., B.P.; Squill.—The dried fleshly scales of the bulb of Urginea maritima Urginea Scilla, B.P.). Dose, 0.1 Gm., 1/5 gr., U.S.P.; 0.06 to 0.1 Gm., 1 to 3 gr. B.P. Maximum dose, 0.5 Gm., 8 gr.

Acet. Scill., B.P.—30 per cent. (twice the strength of the old B.P.). Dose, 0.3 to 0.5 c.c., 5 to 15 minims, B.P.

Fledes. Scill., U.S.P.—Dose, 0.1 c.c., 1/25 minims, U.S.P. This formerly contained acetic acid, but Houghton, 1906, showed that the acid diminished the activity by all. For the same reason, the Vinegars of Squill are unsuitable.

Orzynel Scill., B.P.—33 per cent. of Acet. Scill. Dose, 1 to 4 c.c., 1/10 to 1 dram, B.P. Pil. Ipecac. sc. Scill., B.P.—Contains about 5 per cent. of Opii no. (Pulv. Ipecac. in Scill and Ammoniac. Dose, 0.25 to 0.5 Gm., 4 to 8 gr., B.P.

Fol. Scill., Co., U.S.P.—25 per cent. of Squill, with Ginger, Ammoniac and Soap. Dose, 0.3 to 0.5 Gm., 4 to 8 gr., B.P.

*Syrem Scill., U.S.P., B.P.—Prepared from Acet. Scill., representing about 5 per cent. of Squill. Dose, 2 c.c., 30 minims, U.S.P.; 2 to 4 c.c., 1/2 to 1 dram, B.P.

Syrem Scill. Co., U.S.P. (Cose's Hive Syrup).—An antiquated cough mixture; the usage dose, 2 c.c., 30 minims, U.S.P., representing 0.10 Gm. (1/2 gr.) each of Squill 6 Senega, and 4 mg. (1/25 gr.) of Tartar Emetic.

*Ty. Scill., B.P.—20 per cent. Dose, 0.3 to 1 c.c., 5 to 15 minims, B.P.

Urginea (Urgia), B.P.; (Indian Squill).—The dried young bulbs of Urginea indica. Preparations correspond in title, strength and dose to the B.P. preparations of Squill.

Apocynum (Canadian Herb).—The dried rhizome and roots of Apocynum cannas-

Irid. A. pinnata.—Average dose, 0.05 c.c., 12 minims. Convallaria (Lily of the Valley).—The root of Convallaria majalis. Euphorb. Cortex, B.P.; (Wahne).—The dried root-bark of Euphorbus atropurpureus. Contains an amorphous bitter principle. Used mainly as cathartic, similar to podophyllum. Dose, 0.5 Gm., 8 gr.

Est. Euph., B.P.—A powdered extract. Dose, 0.06 to 0.12 Gm., 1 to 2 gr., B.P.

CACTUS

General Statement.—Preparations from Cactus (Cereus grandiflora) have been used as substitutes for digitalis, particularly in functional cardiac neuroses. Proprietary preparations have been widely advertised. Experiments on animals and men have shown that these are devoid of digitalis and strychnin actions and are indeed absolutely inert. The clinical testimony is not conclusive. Careful observers have failed to find any clinical effects; those who describe positive results have perhaps undervalued the element of suggestion in the treatment of functional neuroses (Report, Curr. Pharm. Chem., 1910; J.A.M.A., 54:888).
**MESCAL**

This plays an important part in the ceremonial of Indian tribes. It is a preparation of the cactus Anhalonium Leumini, in which Lewis, 1888, demonstrated principles with narcotic and strychnine effects. It contains four alkaloids which agree qualitatively in their actions. The latter are quite numerous: a slowing of the heart, a curare-like action on striped muscles, a specific depression of the pulmonary system, and a stimulation of either the parasympathetic or sympathetic central nervous system. The stimulation is shown mainly in the dis- tinct special senses, most conspicuously in vision, the effect appearing as a loss of coördination. It produces hallucination of all the special senses, but particularly of sight. There are flashes and lines of ever-changing colors. Since they are the same in both eyes, they must be central (Dixon, 1890). A psychologic study of mescaline hallucina- tions has been made by Knauer and Maloney, 1913. W. Miller, 1972, failed to find the described visual and auditory effects and double personality, but observed other psychic and physical disturbances. Brear, 1905, experimented with its action on mentally affected patients. Pectolin, one of the alkaloids, has been investigated by Pincus, 1907. Mescal is not used therapeutically. 

**Aphelin** seems to be identical with hordenin (Speth, 1910).

**CAMPHOR**

**General Statement.**—Camporph, \( \text{C}_{10}\text{H}_{16}\text{O} \), is a solid derivative of terpene, \( \text{C}_{10}\text{H}_{16} \), allied to the volatile oils. It is prepared by the dilution of the wood of the camphor-tree. This natural camporph polarizes to the right. A synthetic camporph has been prepared, which is racemic. A levorotatory camporph is also known. The three isomers agree qualitatively in their actions. The L-form is somewhat more active on the nervous system. Therapeutically, they seem to be equivalent; but only the natural is official.

Camporph is a mild irritant and antiseptic, often employed as a counter-irritant in the form of camporph liniment or spirits. It is also used as a protective against moths. Systemically, the effects are very inconstant, owing perhaps to its uncertain absorption and rapid destruction. It is used intramuscularly to stimulate the circulation in collapse conditions, apparently with good results; the mechanism has not been satisfactorily explained. Toxic doses produce convulsions. In frogs it exerts a curare action.
Local Actions.—Externally camphor acts similarly to the volatile oils, reducing mild analgesia and rubefaction, with little sensory irritation. It is applied in neuralgia, inflammations, etc.

The irritant action of small doses of camphor on the digestive canal is used against dyspepsia. Large doses produce vomiting.

Antiseptic Action.—Camphor is somewhat antiseptic. A saturated solution is used as a stimulant mouthwash and gargle. A bit of camphor is a good preservative for modern solutions, proteins, etc. (Romaneli, 1917).

Camphor has been employed as intestinal antiseptic (0.5 Gm., three times daily), at its usefulness is doubtful.

Diffuse Peritonitis.—Intraperitoneal injections of the camphorated oil were advocated by Vignaud and Arnaud, 1912. Doses of 200 to 300 c.c. are said to be harmless. Pinto et al. —See— 1912, claimed that the toxemia and pyrexia are diminished, but the benefits are doubtful and the treatment has not obtained wide acceptance. Selbert advised 22 c.c. of 20 per cent. oil solution, hypodermically, every four hours. Good results were also reported by Weintraub, 1919, and Leo, 1913. Leo termed intravenous injection of the saturated watery solution (about 12,000).

E. Stein, 1915, tried camphor against experimental pneumococcus pneumonia. He used the different races of organisms differ in susceptibility.

Absorption, Fate and Excretion.—Camphor is quite readily absorbed on the mucous membranes and subcutaneous tissue. Hatcher and Gleeson, 1914, find the absorption more rapid from oral than from a muscular administration. It is rapidly oxidized to campheral, \( \text{H}_2\text{O}_2\text{O} \cdot \text{OH} \); and this excreted in combination with glycuronic acid, \( \text{H}_2\text{O}_2\text{O} \cdot \text{O} \cdot \text{C} \cdot \text{H}_2\text{O} \). (Schmiedeberg and Meyer, 1879).

This destroys the activity of the camphor; and accordingly, Happich, 1912, claims that the toxicity is higher when glycuronic acid formation is disturbed through starvation deprivation of oxygen. Similarly, he states that intraperitoneal injection are more than twice as toxic as intravenous.

Experimental Effects of Camphor on the Circulation.—These are incon-istent, different investigators reporting divergent results and conclusions. Enerally there is no definite response if the circulation is normal. When the heart muscle is depressed in various ways, camphor may, under varying conditions, improve the cardiac contractions and remove asthmatic spasms. The response is, however, uncertain; and gives only doubtful support of the claimed therapeutic action.

Perfused Rat-Heart.—This has been found an especially suitable object for demonstrating the improvement. After being injured by cooling, electric stimulation, phos- phorus, digitalis, yohimbine, or chloroform, the addition of camphor (natural or syn- etic) usually increased the rate and removed asthmatics; the toxis was generally proved; so also the coronary flow. The effects on the excursions were not consistent. Less favorable results did not always follow; indeed, the heart sometimes became worse. (Froeschlich and Pollak, 1923).

Combination with Vasodilators.—The improvement of the perfused rat heart was increased by the addition of dilators of the coronary vessels, i.e., caffeine or papaverine (Froeschlich and Pick).

Heart of Other Mammals.—These have given more confusing results:

No definite effects have been demonstrated in normal hearts, in situ or isolated. Interberg, 1903; Klempner, 1907; Plant, 1914; and Richards, 1914, obtained purely negative results. Seifertan, 1905, sometimes observed strengthening, but by no means way by the amount of camphor. However, that camphor tends to prevent or remove fibrillation, F. Gottlieb, 1905 and 1906, found that the heart of intact animals is also rendered resistant to fibrillation. This was contradicted by Winterberg. Richards found no definite effect of camphor on the isolated heart. Fibrillation or asphyxia; nor Fibrillation or chloral or phosphorus. Heard, 1915, worked with the heart in situ, but isolated on its nerves, and with the bloodpressure kept constant by a compensator; camphor did not affect heart action. Hearst, 1913, claimed a rise of blood pressure from intravenous injection of camphor, in animals with their hearts weakened by phosphorus, but no effect after
choral. During complete heart-block, in dogs, van Egmond, 1923, could generally observe no effect from camphor. The coronary blood flow increases if the pressure rises (F. Meyer, 1912). The coronary vessels (as also the ear-vessels) of rabbits are also dilated directly by perfusion with camphor (1:2,500 to 5,000); still more by boric acid and menthol. With a tenth of these concentrations, the dilation is preceded by constrictor (Likhatcheva, 1916).

Frey's Heart.—The effects of applying camphor solutions were studied by Heubner, 1870; and Oehm, 1870; those of perfusion by Plant, 1914 (bibliography). They are slight and insistent with normal hearts, but camphor restores the beat of frog hearts arrested by muscarin (Harnack and Witowski, 1876) or by chloral (Boeckel, 1901). The restoration is only transient (Plant, 1914).

It is produced by the various camphor derivatives on turtles (Lippens, 1911); camphoroid acid being somewhat more stimulating. With ventricular tachy of tortoise hearts, Plant observed slight quickening, not modified by chloral. The ultimate effects of strong solutions of camphor are depressant, weakens, and stops the hearts.

Isomers.—Joaingiu, 1917, found the dl, and i equally active on the frog heart, weak concentrations increasing the rate, higher concentrations causing arrest.

Menthol also stopped the heart, but weak concentrations did not accelerate.

Blood Pressure and Vascular System.—According to Liebmann, 1912, the most frequent result of moderate doses is a peripheral dilator effect, first on the pulmonary, then on the systemic blood vessels. The blood pressure therefore generally falls; but this may be preceded by brief central vasocstriction. Large doses occasionally produce periodic variations in the blood pressure, through the vasomotor center. Large rises of blood pressure may occur during convulsions.

The earlier investigators (Pellacani, 1885; Alexander-Lewis, 1890; Paesler, 1890) generally described a rise of blood pressure from vasomotor stimulation. Wiedemann, 1877, and Stockman, 1888, observed rhythmic rises of blood pressure, attributed to heightened reflex irritability. Stimulation of the vasomotor center, however, does not occur with therapeutic doses, but only as the convulsant effects are approached; and especially during the convulsions proper (Pilcher and Sellmann, 1912). Often the blood pressure is not changed by moderate doses. The most frequent result, according to Winterberg, 1950, and Liebmann, 1923, consists in persistent fall of blood pressure occasionally preceded by a slight and short rise. The rise is due to central vasomotor stimulation; but the fall is produced by peripheral action on the vessels. Hers and Brooks, 1913, obtained quite negative results. Liebmann finds that the pulmonary vessels dilate before the systemic. The widespread vasodilatation results in lowering the pressure in the right heart. Frey, 1909, found no effect on pulmonary hemorrhage.

The cerebral vessels are also dilated (Bertalan, 1916).

Lieb and Herrick, 1917, report that the hypodermic injection of irritants, including camphor, into decerebrated animals often produces a slight and transient rise of blood pressure, but that they fail entirely in anesthesia, shock, or hemorrhage.

Excised Vessels.—Lichatschew, 1890, reports that camphor, borneol and menthol, in 1:2,500 to 1:500 dilution, produce a strong dilation of coronary and other vessels; this being strongest with borneol and weakest with camphor. More dilute solutions (1:10,000 to 50,000) have no effect on the coronary. Other arteries are temporarily constricted.

Clinical Effects on Circulation.—Camphor is used clinically as a temporary cardiac stimulant. Opinions are divided as to its usefulness. The effects, if they occur, are inconsistent and unreliable. However, its employment is harmless.

In normal individuals and in cardiovascular disease, camphor (even up to 3 gm. hypodermically.—Heard and Brooks, 1913) does not alter the blood pressure, or the rate or quality of the pulse. In collapse conditions, especially in febrile toxemia, most clinicians believe that hypodermic injections improve the volume, tension and regularity of the pulse temporarily. G. Schwartz, 1906, generally found a rise of blood pressure of 12 to 20 mm., too slight to explain the improvement. It is possible but not certain that the weakened human heart responds better to camphor than experiments on animals would indicate. It is also conceivable that the stimulation is reflex, since the injections produce a localized reaction (Heard and Brooks). The regulating influence on delirium cordis might be beneficial in auricular fibrillation, but the action would probably be too brief.

Heard and Brooks failed to find any change in the blood flow of the human arm after hypodermic injection of 0.3 to 0.7 Gm. of camphor in oil.
CAMPHOR

495

Administration.—The camphor is employed intramuscularly, dissolved in sterile olive oil, 1 to 2 c.c. of the 10 per cent. solution being repeated in ten- to fifteen-minute intervals as needed. For babies of one year, A. Jacobi advised 1/50 to 1/4 grain every two hours. Intravenous injection (250 to 350 c.c. of 0.1 per cent. in saline) is safe, but less effective (Weintraub, 1913).

Liquid Petrolatum should not be used as solvent for intramuscular injections. It is not absorbed, becomes incapsulated, and forms sensitive tumors (Mook and Wander, 1910).

Other Uses.—Camphor Spirit is a household remedy in colds, bronchitis, etc. It is probably somewhat expectorant, diaphoretic and antipyretic (Binz, 1875 and 1877). The skin vessels are dilated. It was also advised in tuberculosi, but has not found much support. Camphor has been used as a nervous depressant in hysteria, epilepsy, chorea, and convulsions, and as an anaphrodisiac. This rests on no rational basis.

Respiration.—The effects of non-convulsant doses are very slight and inconstant, practically negative.

Eisendl and Means, 1914, and Higgins and Means, 1913, studied the effects on man, using 0.5 to 0.9 g. hypodermically. They found the center sometimes slightly stimulated by bronchodilation and slight increase of carbon metabolism. The rate was often slowed; the volume, single or minute, was unchanged.

In animals, the respiration is somewhat slowed but deepened, so that the minute volume is increased. Wieland, 1915, claims lowering of the threshold for CO2. Isaac found it especially effective after morphine.

However, Voegelin and Wiggers, 1918, obtained rather uncertain stimulation after morphine and other depressants.

Excised Ureter.—This is stimulated by the l isomer; the d being indifferent (Macht, 1918).

Skeletal Muscle.—Direct application produces a curare effect in frogs, not in mammals. Other camphors derived from various volatile oils also produce this effect (Blieherbrandt, 1902).

Invertebrates.—Newly hatched squid, placed in 1/15 saturated solution of camphor in seawater, respond by spasm of the mantle and contraction of the chromatophores. The stimulation appears to be in the ganglia. It is followed by paralysis, which may be overcome by nicotine (Moore, 1919).

TOXIC EFFECTS

These are similar in man and animals, consisting in stimulation and then depression and paralysis of the central nervous system.

The treatment would consist in evacuation and stimulation. Alcohol and oils should be avoided since they favor absorption.

Symptoms in Man.—These consist in nausea, vomiting, colic, vertigo, disturbed vision, twitchings, convulsive movements, delirium, loss of consciousness, face flushed then pale; epileptiform convulsions are a constant feature in animals, and sometimes occur in man (after 1.5 Gm.; Austragesslo, 1915); often anuria (illustrative reports, Stanley, 1903; P. Baker, 1910; Koppang, 1912). Death is rare in man, occurring by asphyxia and collapse. Convalescence may last several days or weeks; the gastric disturbance is especially persistent.

Renz, 1910, reported the poisoning of twenty children by the oral administration of 10 to 45 c.c. of camphorated oil. All were more or less convulsed, with blue-black lips, but otherwise fair color. The severe cases had locked jaw. Emesis was induced by mustard water, and all recovered promptly (20 min. to 4 hours).

Convulsions.—In mammals, these are located mainly in the hemispheres; for removal of the hemispheres with section below the optic thalami diminishes (Albertoni, 1881) or abolishes (Moritz, 1915) the convulsions.

The spinal cord also shows some stimulation, and finally paralysis, but this does not come on until late, and is not important in man.

In frogs, on the other hand, the action on the spinal cord is very pronounced, and consists in a paralysis. This entirely obscures any action which the drug may have
higher up in the nervous system in these animals. It appears that the path for reflex impulses is blocked before that for impulses coming from the higher brain (Wiedemann, 1877; Bine, 1878). The symptoms are described by Grove, 1910.

**Toxic Dose.**—This varies greatly: 0.7 to 1 Gm. has been fatal to children and toxic to adults; 2 Gm. generally produced dangerous effects; but 15 Gm. have been survived (Koppang); and in an infant of eighteen months, 1 Gm. produced little if any symptoms (Miller, 1914).

**Solvent and Place of Administration on Toxicity.**—Cairns, 1914, and Carnot and Cairns, 1914, have studied these on guinea pigs. With oral administration the toxicity of camphor is greatly decreased by oil. Hypodermically, oil solutions are also less toxic than alcoholic, ethereal or even watery solutions. Intraperitoneal are more toxic than hypodermic injection. Oral administration is more effective than intra muscular (Hatcher and Eggleston, 1914).

**CAMPHOR ISOMERS**

The synthesis of artificial camphor is described by Kebler, 1907; Houseman, 1915; Langgaard, and Maass, 1907, showed that the actions of the three isomers are qualitatively identical. Granville, 1907, claimed that the therapeutic effects, internal and external, are indistinguishable. Haemaelacinein, 1908, states that the levorotary is less effective on the heart; but its central actions are more powerful (Grove, 1920).

Jeagingma, 1917, Eusher and Pollak, 1920, found their action on the heart identical and also, that they are equally antiseptic.

Heffer, 1914, concluded that artificial camphor is probably more toxic and also contains impurities; that it could be substituted externally, but more experience would be needed to justify its internal use. The war has furnished the occasion for this experience; and Luets, 1913, concludes that its hypodermic use, clinically, has given no bad effects.

**Borneol** (Borneo-Camphor, C₉H₁₆O), is used in the orient. It acts similarly to camphor.

**CAMPHORIC ACID**

This was introduced by Fuerbing, 1888, as anhydrous against the night-sweats of phthisis. It aroused some enthusiasm at first (literature, Fujisaki, 1906); but experimental investigations have given entirely negative results (Dreesmann, 1889; Fujita; Tyrode, 1908; Roth, 1911), and the clinical effects were also disappointing (Tyrode). The drug is therefore going out of use.

**Other Actions.**—Tyrode, 1908, could discover no effects of any kind. Fujisaki and Roth described central and peripheral stimulant and depressant effects, somewhat different from camphor. It produces a rather marked stimulation of the respiratory center in mammals. Korbet, 1897, ascribes to this the alleged benefits in tuberculosis.

**Preparation—Camphor**

"Camphora (Camph.), U.S.P., R.P.; Camphor.—A ketone, C₁₀H₁₆CO, obtained from Cinnamonom Camphora. White translucent masses of crystalline structure. Its pulverisation requires the addition of a little alcohol. It has a characteristic odor and warm aromatic taste. It is slightly soluble in water, but freely in aq. fixed and volatile oils and fat-solvents. Dry camphor volatilizes readily, but its solutions are practically stable, even in open bottles (Lewall, 1909). Dose: 0.2 Gm. 3 gr. by mouth; 0.5 Gm. 1½ gr. hypodermically, U.S.P.; 0.1 to 0.5 Gm.; 2 to 3 gr. R.P.

The solubility of camphor at ordinary temperature is 15.98 of water; 12.77 of Ringer’s solution (Leo and Rimbach, 1919). Its use in the orient antedates history; but it does not seem to have been known by the Greeks and came into use in Europe in the Mediaeval period. At present, 70 per cent. of all the camphor produced is used in the manufacture of celluloid.

"Camph., U.S.P.—A saturated watery solution containing less than 0.5 per cent. Very little therapeutic action. Dose: 10 c.c., 3½ drams, U.S.P.

"Camph., B.P.—0.1 per cent.

"Linimentum Camphorae (Lin. Camph.), U.S.P., B.P.; Camphor Liniment (Camphorated Oil) 20 per cent. of camphor in Cottonseed oil, U.S.P.; in Olive oil, B.P.
MENTHOL

This is prepared from the volatile oils of various mints. It acts mildly to camphor, and is used especially locally against headache, neuralgia, itching, etc. Applied to the skin, it produces at first a cool sensation, followed by slight prickling and a burning. The cooling effect is not physical, the temperature of the skin being normal or even increased. It is explained by specific stimulation of the nerve-endings for cold (Goldscheider). Alcoholic solution are antiseptic.

PREPARATIONS—MENTHOL

Menthol, U.S.P.; B.P., C₁₇H₂₉OH.—A secondary alcohol obtained from peppermint oil. Colorless crystals of peculiar odor and warm aromatic taste. Only slightly soluble in water, freely in alc. Dose, 0.05 Gm., 1 gr., U.S.P.; 0.03 to 0.12 Gm. to 2 gr., B.P., as campharsic, etc. Externally, in alcohol, oils or ointments, 1 to 3 per cent. on mucous membranes, 10 to 25 per cent. on skin.

Emp. Menthol, B.P., Menthol Plaster.—15 per cent.

SAPONINS (SAPOTOXINS; SAPO-GLUCOSIDS)

General Statement.—These comprise a series of related compounds, usually non-nitrogenous glucosides, which occur in many plants. The actions are somewhat related to the bacterial and other toxins, and to the saps and bile salts. Like the latter, they lower surface tension, and therefore emulsify or dissolve fats, lipoids and fine powders. This emulsification is characteristic. Through the same property they form an excessive and persistent foam when even very dilute (1:10,000) watery solutions are shaken; they hemolyze blood, even in isotonic salt solutions; they decrease the permeability of other cells and are therefore general protoplasmic poisons. Fish are killed by high dilutions (1:20,000). In higher animals, they are but little absorbed, so that they act mainly locally irritants to the mucous membranes. A few, however, are absorbable and toxic. Their interest is mainly scientific. Senega is somewhat ed as a nauseant and emetic. Sarsaparilla and guaiac were formerly employed as alternatives in syphilis. Quillaja (soap bark) and saponaria (soap root) are used technically for cleansing.
Chemical Properties.—Many of the typical members of the group respond to the formula, C₆H₂₉O₄, They are glucosides and give a purple color with concentrated sulfuric acid. They are generally not attacked by animal fermentes. Physically, they possess the characters of colloids; they do not dissolve; most are soluble in water, and are not precipitated by moderate amounts of alcohol; but they do not dissolve in pure alcohol or in fat-solvents. Many are precipitated by saturation with neutral salts, especially ammonium sulphate; by basic lead acetate, etc. Some behave as acids, others are neutral. When heated with dilute mineral acids they are decomposed into sugars (differing for the individual saponins) and a sapogenin. Schiedeberg calls these decomposition products “saponins,” and all the original substances “sapotoxins.” Others apply this name to the more toxic saponins (Review, Kobert, 1914).

Occurrence.—Sapo-glucosides are very widely distributed through the vegetable kingdom, occurring in at least 400 plants, belonging to 50 different families. They are probably formed in the leaves, but are found in all parts of the plants. The foaming is so conspicuous that many of these drugs have received characteristic popular names, soap-bark, soap-root, etc. They are employed, even by non-civilized peoples, for cleaning; and on account of their high toxicity to fish, as fish-poisons. Opihotoxin, a definite principle of isolated snake-venom, is believed to be closely related to the saponin (Faust).

Crocus bulbs contain a saponin that is toxic to young animals, but not to old (Kobert, 1917).

Local Actions.—Most of the sapo-glucosides are markedly irritant to mucous membranes. They have an acrid taste and provoke a flow of saliva (dialogue action), nausea, vomiting and diarrhoea; if inhaled, they cause sneezing; if injected hypodermically, they cause subcutaneous inflammation.

Therapeutic Uses.—The local actions resemble those of ipecac and are similarly employed. Senega is used as nauseant expectorant, especially in chronic cough; and as emetic. Its non-absorption constitutes an advantage. The emulsifying action determines the use of quillaja as detergent, especially for the cleansing of articles which are injured by alkalies. The use of quillaja in medicinal emulsions, or for producing foam in soap water, etc., is not admissible.

Some of the less toxic saponins might be used for this purpose (Kobert, 1904), but they have not been sufficiently studied to be entirely safe.

A certain number of these drugs have some importance on account of stock-poisons (Vaccaria, Raw Potatoes).

Sarsaparilla, which owes its activity entirely to the sapotoxin or saponin which it contains, formerly enjoyed considerable reputation as an alterative. This is no longer accepted (H. C. Wood, Jr., 1916); if it possesses any action at all it is simply that of a very mild nauseant and cathartic.

Systemic Actions.—If sapo-glucosides are injected directly into the circulation they produce hemolysis, diuresis (B. MacCallum, 1905; Asher, 1908); and direct action, especially on the central nervous system, which may be rapidly fatal. At first there are violent convulsions; then paralysis, especially of the respiratory center. The effect on fish is also paralytic. Rapid absorption through the gills makes even small doses effective.

Smaller doses given by the blood cause especially intestinal symptoms, and death after several days by collapse. Why the symptoms are so largely intestinal is unexplained. Given subcutaneously, they produce these same symptoms, but much more slowly. If they are applied directly to skeletal or cardiac muscle or to nerve-trunks these lose their irritability at once, and if the solution is fairly strong (1 per cent), there is rigor. The addition of saponin increases the toxicity of digitoxin for the frog’s heart (Postojef, 1911). Nearly all saponins are toxic to the frog heart (I. Traube, 1910). Saponins act on amebae, but apparently not on bacteria (Bacon and Marshall, 1909).

Effects of Hemolysis.—Hemolysis liberates potassium and other toxic substances from the corpuscles (Gottlieb and Lefmann, 1907; W. H. Brown, and Loevenhaut, 1911); but these are not concerned in the systemic saponin actions: The latter occur with doses which are not hemolytic; nor are the systemic saponin effects avoided by cholera which prevents the hemolysis. Presumably the permeability of the nerve cells is directly affected by the saponin.
Poisoning.—Most sapo-glucosides are absorbed so poorly that they produce only local effects; gastro-intestinal, vomiting, persistent diarrhoea, etc. However, the violent local action may lead to corrosion and this to absorption (f.l. with quills in rabbits, the common corn-cockle (chemistry, Brandt, 1900) is absorbed fairly readily and thus produces systemic poisoning. This is important since its seed may be admixed with grain. The systemic symptoms agree with those of intravenous injection. On the other hand, certain vegetables, f.l. spinach, contain saponins which seem harmless to man. Incidentally, some saponins show a different toxicity for different species (Kobert, 1914). The toxicity is not simply proportional to the hemolytic power.

Hemolytic Action.—Saponins lake blood even in an isotonic medium. The phenomenon depends on their affinity for the lipoids of the cell envelope and stroma. It is prevented by the addition of cholesterol or other lipoids which combine or bind the saponin.

Hemolytic Concentration.—The limit concentrations f. 1:400,000 to 1:10, vary enormously but are characteristic for the different saponins (Kobert, 1914).

Phenomena of Laking.—Saponin hemolysis occurs in two stages, which are practically distinct: The liberation of hemoglobin; and increased permeability of the envelope (G. N. Stewart, 1890 to 1909, Wocciel, 1908). The latter occurs even in formalin-fixed corpuscles. The action is probably both on the stroma and on the envelope; dissociating the former from its combination with hemoglobin, and rendering the latter more permeable, thus leading to the entrance of water, swelling, and water-laking. Saponin does not cause the complete disappearance of the stroma; its salts do (Neueberg and Haenel, 1908).

Solution of Lipoids.—The integrity of the corpuscles is intimately connected with their lipoid content. The stroma and envelope consist to about one-third of lipoids, chiefly cholesterol and lecithin, and two-thirds of protein (Pascucci, 1905). Many hemolytic agents are lipoid solvents; such as the saponins, bile salts, soaps and fatty acids, lipolitic narcotics, heat, etc. Their action is generally proportional to their lipoid-solubility. Saponins also increase the permeability of artificial cholesterol-lecithin membranes (Pascucci, 1905). The hemolytic serums and toxins probably also act on these lipoids, but perhaps likewise on the protein. It is perhaps not necessary that the lipoids are actually dissolved; they need merely be altered. Hypotonic solutions probably disorganize the entire structure of the corpuscles.

The hemolytic activity of different saponins has no relation to their effect on surface tension (Woodward and Alberg, 1916).

Specific Resistance of the Corpuscles.—The blood of different animals shows specific differences. It is noteworthy that the resistance of species varies inversely for saponin and water-laking (Ryvesch, 1907 and 1911). Normal serum is somewhat protective, perhaps by its cholesterol; and this protection is slightly increased by starvation.

Acquired Resistance.—Repeated injections of saponin and other hemolytic agents lose the general resistance of the corpuscles (Kobert; R. Well, 1910; contradicted by Kapp, 1913). No true antibodies occur. Prolonged saponin feeding increases the resistance, both of the corpuscles proper and of the serum (Alberg and Smith, 1914). A similar increase of resistance occurs also in certain diseases in which hemolytic poisons are probably produced, f.l., in syphilis, advanced cancer, etc. (Well; McNell, 1910).

Mixed Hemolysis.—Fuehrer and Greb, 1911, found that the combination of various specific and chemical, alkaloidal and glucosidal, gave complex results; the summation of the effects being sometimes simple, excessive or deficient.

Protective Action of Cholesterol.—Ransom, 1907, showed that the addition of cholesterol prevents the hemolytic effect of saponins (also of blood pigments, Hildebrandt, 1911; of cobra lymph, and of some bacterial lysins, f.l., staphylococci; tetanus; of sodium oleate; of the immune-serum hemolysins); but not of some other hemolytic agents. Serum, which contains cholesterol, also exerts this protective action. The phenomenon is explained by a chemic combination between cholesterol and saponin. The protection does not extend to the central saponin actions. The OH group seems essential to all these protections. Lecithin and other lipoids, which do not form chemical compounds, afford a much weaker protection, probably by binding the saponin physically,
Their effects extend also to other lipoid-solvent hemolytic agents (Pilcher, 1915). Cholesterol also protects the heart against digitoxin, but not against the other digitaloids (Karaulow, 1913). It prevents not only the hemolytic but also the systemic toxicity of sodium oleate (Klotz and Bothwell, 1915).

Combination of Cholesterol with Saponins.—Cholesterol precipitates saponins from their solutions. Windaus, 1909, showed that definite, crystalline, non-hemolytic compounds are formed. Those with digitoxin and cyclamin have been especially studied (Vaut, 1916).

Protective Action of Serum.—Washed corpuscles are laked by saponins in one-fourth the concentrations required in dehydrated blood (Laube, 1913). This is probably due to the cholesterol content. The injection of saponin into animals lessens this protective action for two or three days, by binding the cholesterol (Wacker and Heuck, 1913).

The hemolytic action of a watery solution of saponin is rapidly destroyed by the solution of fluorescent substances, eosin, and erythrosin (Norrich, 1909).

Infusion of tea also has an inhibiting effect on saponin hemolysis; this has been proposed as a test for genuine tea (Maggiora and Ferron, 1914), but is probably merely to the tannin.

PREPARATIONS—SAPONINS

Caulophyllum: Blue Cohosh; the rhizome and roots of Caulophyllum thalictroides. (Chemistry, Power and Salway, 1915.) Used as diuretic, emmenagogue and anthelmintic. (See article under Nicotin and Ergot.) Dose, 0.2 to 2 Gm., 5 to 30 gr.

Guaiacum Lignum, B.P.; Guaiac Wood.—The heart-wood of Guaiacum officinale or sanctum. Contains 20 to 25 per cent. of the resin and some saponin (a trace of the latter is also contained in the resin). There is some reason to believe that the saponin is the bearer of the action, which is nauseous and purgative. Guaiac is an almost obsolete remedy for syphilis, gout, rheumatism, tuberculosis, etc. It was introduced soon after the discovery of America.

Guaiacum, U.S.P.; Guaiac, Res., B.P.; Guaiac Resin (Guaiac).—The resin obtained from Guaiac Wood. It contains a number of resinous acids, especially guaiasic acid, which is colored blue by oxidation. Dose, 1 Gm., 15 gr., U.S.P.; 63 to 1 Gm., 5 to 15 gr., B.P.

Guaiac resin is commonly used as a reagent for oxidative ferment. Schar, 1917, finds the best results with resin extracted from the wood by chloroform; then the natural resin; then alcoholic extract of the wood. Solutions lose their sensitiveness with age.

Mist. Guaiac., B.P.; Guaiacum Mixture.—2.5 per cent. suspension of the resin. Dose, 15 to 30 c.c., ¼ to 1 ounce, B.P.

Tr. Guaiac., U.S.P.—10 per cent. of the resin. Dose, 4 c.c., 1 dram, U.S.P.

Tr. Guaiac. Ammon., U.S.P., B.P.; Ammoniated Tincture of Guaiac. 20 per cent. with aromatics and ammonia. Dose, 2 c.c., 30 minims, U.S.P.; 2 to 4 c.c., ½ to 1 dram, B.P.

Tr. Guaiac. Res., B.P.—0.3 Gm., 3 gr.

Hemidesmos Rad.—The root of the Hemidesmus indicus.

Quillaja Cortes, B.P.; Quillaja (Soap Bark).—The dried inner bark of Quillaja Saponaria.

Tr. Quill., B.P.—5 per cent. Dose, 2 to 4 c.c., ¼ to 1 dram, B.P.

Saponaire; Soap-root.—The root or leaves of Saponaria officinalis.

Sarsaparilla, U.S.P.—The dried root of Smilax species. Dose, 2 Gm., 30 gr., U.S.P.

The Jamaican variety contains a single saponin glucoside, "sarsasaponin" (Power and Salway, 1914).

Fistas. Serras., U.S.P.—Dose, 2 c.c., 30 minims, U.S.P.

Fistas. Serras. Co., U.S.P.—100 c.c. represents 15 Gm. of Sarsaparilla and 4 Gm. of Mecereum, flavored with Glycyrrhiza and Sassafras; ½ Gm. alcohol; ¼ Gm. glycerin. Dose, 2 c.c., 30 minims, U.S.P.

*Syr. Serras., U.S.P.—20 per cent. Sarsaparilla; 1.5 per cent. Senna; flavored with licorice, sassafras, anise and wintergreen. Dose, 1 c.c., 4 drams, U.S.P.

Senega, U.S.P.; Senega. Rad., B.P. (Seneca Snakeroot).—The dried roots of Polygala Senega. Dose, 1 Gm., 15 gr., U.S.P.

Inf. Seneg., B.P.—5 per cent. Dose, 15 to 30 c.c., ¼ to 1 ounce, B.P.

Syr. Seneg., U.S.P.—10 per cent. Dose, 4 c.c., 1 dram, B.P.

Tr. Seneg., B.P.—20 per cent. Dose, 2 to 4 c.c., ½ to 1 dram, B.P.
SAPONOSIDES

SOLANIN

The glucosidal alkaloids, solanin, solanene, and solanidin, which occur in plants of the potato genus (Solanum nigrum, dulcamara, tuberosum (Potato), Carolinense, and nato), possess a typical sapotoxin action. In certain species, particularly in S. camara, they are associated with a small quantity of atropin-like alkaloid and with saponins (dulcamarin). The latter plant is sometimes used as a nauseant. Solanin, the formula, C_{15}H_{22}NO_{7}, it splits into sugar and solanidin, C_{14}H_{23}NO_{6}. The main literature is reviewed by Meyer and Schmiedeberg, 1895. Tulip bulbs contain an alkaloid, tulipin, that is closely related to solanin and colchicin (ibert, 1917).

Solanum Dulcamara.—Bittersweet.—The young branches are used. Dose, 4 c.c. of the fluidextract.

Potato (Solanum tuberosum).—The toxic principles are distributed throughout the plant, but only very small quantities are found in the pulp of the tuber—too small to elicit any action. The quantity is larger in the peel, and especially in very young 1 sprouting potatoes, but it is not increased by storage. The amount in potato is linearly too small to be harmful (less than 0.01 per cent.) and it was doubted whether it could be due to solanin (Droste, 1917). However, under conditions it is not understood the solanin may occasionally rise to 4 or 5 times this quantity. See 0.4 Gm. of isolated solanin provoke untoward symptoms in man, potatoes con- taining this high quantity of solanin are poisonous, as shown in the outbreaks of Leipzig (the, 1919) and Glasgow (Harris and Cockburn, 1918). In both, the suspected potatoes contained over 0.4 Gm. of solanin per kilogram.

The symptoms pointed to gastrointestinal irritation: vomiting, diarrhea, colic, edema, depression, etc.

Solanum Carolinense.—The berries have been recommended in epilepsy. They are said given with bromides, and the therapeutic effects of the mixture are probably due in part to the latter. Dose, 4 to 5 c.c. of the fluidextract.

SNAKE VENOM

Actions.—The effects of snake venom are partly local, partly central. The local effects are especially in an intense cellullitis at the site of the bite. This is accompanied by swelling and progresses to gangrene. The blood is also deeply affected. Its coagu- lation is altered, as with albumoses. The red blood corpuscles are dissolved. There is considerable tendency to extravasation and thrombosis. The leucocytes sink to 25 cent. of their normal number.

Snake venoms have no effect on infusoria, bacteria, or on plants, but they are toxic to all animals above the hydra.

The systemic actions are nervous, and mainly central. The most conspicuous is a great paralyzation. There is a period of incubation (in man, of about four hours' dura- tion); the patient then becomes drowsy, and then presents an ascending paralysis of the end, i.e., in the order of legs, arms, larynx, and tongue. This may be preceded by convulsive movements. There is also salivation and vomiting. The respiration becomes dyspneic, giving rise to asphyxial convulsions and causing the cause of death, the heart beats for some time after the respiration stops. A paralysis of the vasomotor center is frequent with these poisons, leading to a fall of blood pressure. The lat- ter in part due to peripheral effects on the heart and on the endings of the splanchnnics, the heart the paralysis involves both ganglia and muscle. There is also some curare like action.

These actions are common to all snake venoms; with certain snakes, however, the exact actions predominate, with others the systemic.

The danger depends on many conditions. For rattlesnake venom, the fatal hypo- rthermic dose would perhaps be 0.15 to 0.3 Gm. The actual mortality in America is probably about 10-5 per cent. for all snake bites, 17.7 per cent. for rattlesnakes (Wiflson, 1910).

Cobra Venom.—This has been reexamined by Cushny and Yagi, 1916. Frogs behaved mainly a slow curare likeaction. This was also the cause of death in mammals. pro- lyl-amic doses also act directly on all forms of muscle, producing first stimulation, then depression.

Autonomic nerves, ganglia and myoneural junctions were not affected; nor was there any direct action on the central nervous system.
Hemolytic Principle.—This is probably a toxalbumin (Kyes and Sachs). Cobra venom lakes washed human and guinea-pig corporcles directly, in the absence of serum whereas washed sheep and ox corporcles are highly resistant, but are rendered susceptible by the addition of serum or lecithin. Kyes, 1910, therefore considered the venom as anacrobe and lecithin as complement. The existence of this toxic “cobralecithin” was discredited by Manwaring, 1916, and others. Von Dungern and Coca showed that venom contains a lipoid-splitting ferment, which liberates hemolytic cleavage products. Noguchi believes that soaps of unsaturated fatty acids may act as “complement.”

Ophiotoxin and Crotalotoxin.—These, according to Faust, 1910 and 1911, are the chief toxic constituents of cobra and rattlesnake venom respectively, being responsible for the central actions. They are definite, non-nitrogenous principles, not glucosidal, but otherwise very closely related in their physical, chemical and pharmacological characters to the saponins; and probably related to the toad poison, and hence to cholesterol. They produce practically all the effects of the whole snake venom, except agglutination.

Rattlesnake venom is not toxic to rattlesnakes. The serum of these snakes, however, is not antitoxic. It, as also the bile, has only a low toxicity (Walker and Marshall, 1915).

Treatment of Snake Bite.—This must be very prompt. The wound should be ligated, expressed, excised or cauterized. Crystals of potassium permanganate should be rubbed in, or a solution of this, of chlorinated lime or of lead, should be freely injected into or about the wound. Medullary stimulants, and large doses of strychnine, are useful. The popular treatment with large doses of alcohol is empirical. Immunization by antivenin has been tried extensively.

Other Animal Poisons.—Various animals contain toxic substances belonging to different groups. They are reviewed by Faust, 1910; and the animal hemolytic poisons by Sachs, 1906. The toxins of Intestinal Parasites are discussed by Paulus, 1914. J. Couglin, 1917, describes scorpion, tarantula and scutulae bites, which were not fatal. Garcia, 1917, discusses the effects and treatment of spider bites.

Bee—poison.—Flury, 1920, confirms that this is not a protein. It appears to be a sapotoxin-like complex of lecithin and basic components.

Ascaris lumbricoides also contains a hemolytic substance. This is confined to the digestive tract of the worms and is probably used for the reabsorption of blood by the parasites. Its action is inhibited by serum, so that it is probably not concerned with anaemia.

CHOLESTEROL

The protective action of cholesterol against saponin hemolysis has led to therapeutic trials in hemolytic diseases. The results have not been decisive.

Characters.—Cholesterol is a non-atomic alcohol, C₂₉H₄₈O, with the soluble characters of fats. It is therefore but poorly absorbed (Studwedehann, 1859; Kies, 1912). Its oxidation products produce effects (digitals and saponins) resembling those of bile acids and of the poisons of toads and snakes. Indeed all these are probably derivatives of cholesterol (Faust, 1911; Flury, 1917). Cholesterol itself is somewhat stimulating to the heart-muscle, but without slowing (Danielwsky). Cholesterol and its fatty esters lessen phagoctysis; lecithin removes this effect for cholesterol, but not with the esters (Steulher, 1913).

A bibliography of cholesterol is in Merck’s Report for 1914, vol. 28, pp. 9 and 41.

Occurrence.—Cholesterol is an essential constituent of all cells, and therefore occurs in most foods. Egg-yolk is especially rich; one yolk containing about 0.25 Gm. (Kies, 1910). It is generally prepared from call-stones. Its esters and homologues constitute Wool-fat (see Index).

Cholesterol is present, partly free and partly as esters of the higher fatty acids, in the blood plasma, red corporcles, and especially in the leucocytes, in fairly constant quantity under normal conditions. Cholesterol plates may be found in any tissue when the cell have undergone slow destruction and where absorption is poor.

Cholesterol Income.—The cholesterol content of the body is increased by feeding cholesterol (Lehmann, 1914; Wacker and Husee, 1913). Mice can synthesize cholesterol when it is absent from their food (Degani, 1914); but it is now believed that it is not
CHOLESTEROL

ordinarily formed in higher animals, but depends upon the food and therefore eventually in plants. Ordinary food contains adequate amounts; but when the diet is restricted, when there are extraordinary demands, as in growing children, it may conceivably be deficient (Mendel, 1914).

Fate.—Cholesterol is absorbed from the alimentary tract into the lymph, being demountable in the thoracic duct. During absorption from the intestines, free cholesterol is partly esterified, and the esters are partly hydrolyzed (J. H. Mueller, 1915). A part is converted into esters before absorption (Mueller, 1915). The excretion in man, with various diets, was studied by Ellis and Gardner, 1912. It is first oxidized into oxycholesterol, and a part probably into the cholic acid of the bile (Liefschutz, 1914).

Hypodermic injection into rabbits produces marked inflammation and necrosis of the subcutaneous tissue. This gradually subsides with the disappearance of the cholesterol, which is absorbed mainly through the leukocytes (Lassen, 1915).

With intravenous injection, it leaves the blood rapidly, being deposited in various organs, and partly excreted by the bile and urine. The kidneys show degenerative changes and local infiltration with cholesterol (K. Dewey, 1916).

Relation to Fat Metabolism.—Cholesterol probably plays some rôle, but this has been defined (Bloor, 1917).

Cholesterol Content of Blood in Disease.—This has been studied by Klikert, 1913; Gouger and Beumer, 1913; Garham and Myers, 1917; etc. Increase of the cholesterol content of the plasma was reported for diabetes mellitus, icterus and some other diseases; decrease in infective diseases.

It is also increased by partial or complete excision of the suprarenals; at the same time, increased quantities are excreted by the bile (Rothschild, 1924).

Blood-Cholesterol in Hepatic Disorders.—In obstructive icterus by gall-stones, the cholesterol content of the blood is markedly elevated, apparently proportionally to the intensity of the icterus, but not to the amount of bile pigments in the blood. In other hepatic disorders the blood-cholesterol is not increased, but usually diminished. It has been suggested that the liver regulates the cholesterol content of the body through the biliary ducts (Rothschild and Felsen, 1917).

Blood Cholesterol after Ether and Chloroform.—With dogs, ether anesthesia of 60 to 90 minutes, on successive days, increases materially the serum-cholesterol, persisting for several days after the inhalations have been discontinued. Chloroform produces a smaller increase for 2 or 3 days, and then decreases the serum cholesterol (Ducosschi, 1914).

Blood-Lipoids in Anemia.—These appear to retain approximately their normal ratio, if the reduction of corpuscles does not exceed half of the normal. Beyond this point, abnormalities occur, in the following order of magnitude and frequency: (most marked) high fat in plasma; low cholesterol in plasma and sometimes in corpuscles; low lecithin in plasma (least marked). These changes have been attributed to deficient fat assimilation, conversion of fat into lecithin being one of the functions of the corpuscles (Bloor and MacPherson, 1917).

Effects on Growth.—The continued administration of cholesterol to white mice causes marked retardation of growth in early life, acceleration in later life (E. R. Robertson, 1919, 1916). Its administration to mother-mice markedly retards the growth of the sucklings (Robertson and Cutler, 1916). Burnett, 1913, states that its injection accelerates the growth of experimental cancer. The division rate of paramaecium is greatly increased (Browder, 1912).

Robertson and Burnett, 1918 believe that the growth accelerating action of cholesterol and of ethionine are conditioned on their OH group.

Phagocytes and Antibodies.—In rabbits and guinea pigs, cholesterol injections lower phagocytes by direct action on the leucocytes. They also delay antibody formation (Dewey and Nurnm, 1914).

Afternum.—Feeding or injections of cholesterol produce arterial lesions in rabbits (Walker and Hueck, 1913; Ignatowsk and Chalutow; Adler, 1913; Denny and Frothingham, 1914); also degenerative changes in the suprarenal cortex (Knack, 1915). Less marked arterial changes are produced in guinea pigs (Bailey, 1915).

By intravenous injection over long periods, Adler, 1917, produced arterial lesions resembling closely those of human arteriosclerosis. They were most marked in the pulmonary artery. Adler is inclined to attribute them to the intermittent but very extensive blocking of the vessels by the injected oil, and therefore not to the chemical properties of cholesterol.

Protection Against Poisons.—Free cholesterol neutralizes a number of poisons, especially hemolytic (saponin, tetanus). It is also said to protect against strychnin, but only if the two substances are mixed (Pizzoni and Perucci, 1919).
MANUAL OF PHARMACOLOGY

Therapeutic Use.—In paroxysmal hemoglobinuria, Pringheim, 1912 and 1913, reports partial success from six intramuscular injections, on alternate days, each of 5 c.c. of 10 per cent. cholesterol emulsion. The action did not outlast the administration. Reicher, 1908, in pernicious anemia, administered it by mouth, 3 Gm. in 100 c.c. of olive oil, daily, in tablespoon doses. The preparation of a watery emulsion for intravenous injection is described by Dewey, 1916.

ACONITE

General Statement.—Aconite owes its activity to the rather unstable alkaloid aconitin. This is a peripheral and central stimulant and depressant. Vascularly, the peculiar stimulation (tingling) and anesthesia (numbness) of sensory nerves, without inflammatory phenomena, is used against neuralgic and rheumatic pains. Systematically, therapeutic doses produce mainly a slowing of the heart (central vagus stimulation) which is employed to some extent in sthenic fevers. Larger doses are highly toxic, producing great general depression, extreme irregularity of the heart (mainly by direct action on the cardiac muscle), and death by arrest of the respiration or heart.

It is very doubtful whether the systemic use of aconite is advisable. Effective doses are practically toxic; and safe doses are practically ineffective. The tincture, the most commonly used preparation, now contains 10 per cent. of aconite, in both the U.S.P. and B.P. (In the older edition, the strength was 35 per cent. U.S.P., 5 per cent. B.P. These differences must be remembered in connection with the older clinical papers.)

Historical.—The toxic properties of aconite were known to the ancients; however, there is considerable confusion, since the Roman poets used "Aconite" to denote vegetable poisons generally (Fleming). Various species, most of which are toxic, grow in different parts of the world. They were used as arrow-poisons by the ancient Chinese and Gauls. The therapeutic use dates from Anton Storck ("Observations on the use of Conium, Stramonium, Aconite, and Colchicum," 1761), who described the tingling without reddening or corrosion, the salivation and sweating, and proposed its use against rheumatic and neuralgic pain, and for "disjutting" swellings and healing ulcers. Alexander Fleming, of Edinburgh, 1845, published a comprehensive experimental and clinical "inquiry" of Aconitum Napellus, which is still a good model for therapeutic observation. Aconite is a favorite remedy of the homeopathic school.

Chemistry of Aconitum.—The chief active constituent of Aconitum Napellus is the alkaloid Aconitin, which occurs in a crystalline and amorphous form. It is chemically an acetyl-benzoyl-ester of aconin, a base derived from quinolin (Ehrenberg and Par- furst). It decomposes readily, even on boiling, with water, into benzoyl aconin (Pinnaconit, Iso-aconitin) and this again into aconin (Freund and Beck, 1894). They have the same actions as aconite, but picoxconit is only about 1/4 as strong as aconite, aconin 1/400. These and probably other decomposition products persist in the drug, and are probably formed in its extraction and especially in the manufacture of the alkaloid.

Commercial "Aconitum" therefore may represent mixtures of varying strength, some being a hundred times more active than others. This enormous variability is most unfortunate in a substance of so great a toxicity; and several fatal accidents, to which it gave rise, have led to the practical abandonment of the internal use of aconite in therapeutics.

Variability of Tincture.—The tincture is also subject to variation, even when it is chemically assayed for total alkaloids. Robinson, 1913, for instance, found a chemically assayed sample practically inactive. Haskell and pupils, 1915, find the activity to vary nearly 200 per cent. Solid extracts varied even more widely, some being 1000 times more active than others (A. R. L. Dohna, 1918).

The chemical assay is therefore useless, or rather harmful, and should be replaced by the bio-assay described in the U.S.P., IX.
Aconite

Other species of aconite contain related alkaloids, with similar actions: Pseudoaconitin or Nepaila; Indacoonitin; Bikacaoconitin; Japacoonitin, etc.

T. R. Fraser, 1873, showed that the effects of aconitin and pseudoaconitin are qualitatively alike; but that aconitin acts much more on the heart, pseudoaconitin on the respiration. He further reports in 1916 on some East Indian species.

Local Actions.—In the mouth, aconite, even a small quantity of dilute solutions, produces a peculiar warm and tingling sensation, a sour rather than bitter taste, followed by numbness and anesthesia. The lips, tongue, and mucous membrane of the mouth and throat feel as if swollen. The flow of saliva is increased reflexly. The apparent irritation is not accompanied by redness, pain, objective swelling, or other sign of inflammation. It is therefore purely sensory.

Analogous effects—heat, tingling and succeeding numbness, without inflammation, are produced in any other situation to which the drug may be applied; and even on the systemic administration of large doses.

From the skin, watery solutions are but slightly absorbed, and friction must be employed to secure the local effect. Oily solutions and ointments are absorbed readily.

Bio-assay.—The tingling sensation in the mouth was proposed by Squibb for the identification and estimation of aconite, and is still one of the most satisfactory methods. Perfusion of the isolated frog’s heart is sensitive to aconitin in dilution of two in a million (G. B. Roth, 1943). The fatal dose for guinea pigs has been adopted by the U.S.P. as the most practical test.

Eye.—Fleming claimed that the application to one of the temples or one side of the forehead may produce more or less (temporary) blindness on that side. The pupils are then dilated, presumably to admit more light. The application to the conjunctiva constricts the pupils. In systemic poisoning, they are also constricted until the final asphyxial dilatation.

Therapeutic Use of the Local Action.—This is used for the relief of toothache, neuralgia, migraine, rheumatic and other similar pain. For this purpose it may be employed by thorough friction of the tincture, undiluted or with the addition of 1 to 10 parts of soap liniment. This is probably as effective as the expensive Unguentum Aconitum (2 per cent.).

Fleming claimed that the internal use of the tincture is often more effective in neuralgia. He started with increasing from about 1 c.c. of the U.S.P. tincture, three times daily and increased the dosage until the full therapeutic effect (pulse of 54, lethargy, etc.) is obtained.

Systemic Effects of Therapeutic Doses.—These consist mainly in a more or less pronounced slowing of the heart rate, to 60 or 50 beats per minute, according to the dose and the susceptibility of the individual. The pulse is also softer and weaker, but remains regular as long as the dosage of slowing is not surpassed. The blood pressure falls slightly.

The therapeutic slowing (which is often absent in anesthetized dogs) is due mainly to stimulation of the vagus center, for it is practically absent if the vagi have been divided (S. A. Matthews, 1897).

The typical slowing, which occurs in one and one-half to two hours if the tincture has been taken by the mouth, is preceded by subjective sensations of evanescent warmth, and persistent numbness and tingling, beginning in the finger tips, and extending along the arm, as the dosage is increased. The respiration is moderately slowed, and more or less labored. With the full therapeutic dosage, the patient is weak, giddy, confused, lethargic and cold. These phenomena last for three to five hours, and are as far as the therapeutic action should be carried. They
are produced by doses corresponding to 0.15 to 0.3 gm. of aconite (Fleming) i.e. by to 1.5 to 3 c.c. (20 to 45 minims) of the 10 per cent. U.S.P. or B.P. tincture.

Sweating may occur but is not constant. The urine is not increased. The temperature is not markedly affected by the therapeutic doses. Digestion and peristalsis are not disturbed. There is no cumulative action.

Vasomotor Center.—This is not affected by non-toxic doses. Toxic doses, however, produce a maximal stimulation, more intense than can be obtained from stimulation of sensory nerves (Pflüger and Sollmann, 1912).

Inactive Tinctures.—Several recent observers (Price, 1911; Rudolph and Cole, 1913) have been unable to obtain effects on the pulse and blood pressure from small and fairly large doses, in a variety of clinical conditions. These negative results are probably ascribable to inactive preparations of the drug, as with Robinson, 1915.

Therapeutic Uses.—The slowing of the circulation has been utilized in heart disease, in hypertension, and in thentic fevers, but is of doubtful value, especially in view of the total inefficiency of the dose ordinarily given.

Sthenic Fevers.—In these, it is supposed to "calm" the overactive heart, and to promote the action of mild diaphoretic agents (spirits of niter, ammonium acetate, etc.). It is used in this way during the sthenic stage of acute fevers; especially in children, for the "abortion" of colds. According to Ringer, it is administered in small and frequent doses (3 to 5 drops of the 10 per cent. tincture for adults, at first every fifteen minutes for two hours, then every hour, until the pulse returns to normal), and only for the first day of the fever, to avoid depression. It is difficult to judge its usefulness under such conditions.

Cardiac Conditions.—Aconite is plainly contra-indicated in incompensated valvular lesions, since it would reduce the already defective mass-movement of the blood. Therapeutically, it might be indicated in functional overactivity of the heart, in excessive hyper trophy, and in acute inflammatory conditions of the heart. In all of these, a slowing of the beats is desirable. In fact, however, the same effect can be obtained by the more desirable expedient of simple rest in bed. The use of "cardiac depressants" is not almost obsolete. Other drugs which have been employed for this purpose are: Sparis, Veratrum, Colchicin and Potassium salts.

Hypertension.—Fairly large doses of the tincture (15 to 25 drops, four times daily) have been tried, but with doubtful results. Thomson, 1914, claims that it lowers blood pressure and increases the elimination of urea in interstitial nephritis. Pierson, 1917, obtained very little result.

EFFECTS OF LARGER (TOXIC) DOSES OF ACONITE

Mammalian Circulation.—If the therapeutic dosage is exceeded, the primary slowing of the heart rate turns rather suddenly into quickening, accompanied by arrhythmia, which finally becomes extreme.

Toxic doses greatly increase the force and especially the rate of the heart, at the same time rendering it extremely arrhythmic. The beats may occur in groups, as with digitals. The heart finally goes quite suddenly into delirium cordis, and stops. During the earlier stages of this action the blood pressure is extremely variable, according to the varying force of the heart, and the successive stimulation and depression of the vasomotor center. Toward the later stages, the pressure drops severely (Matthews, 1878; for further details of the interesting cardiac irregularities consult Fleming, page 37; and Cushman, 1905).

The cardiac effects are due partly to stimulation and depression of the vagus and accelerator mechanisms, but mainly to direct action on the cardiac muscle. The excitability of the latter is greatly increased, somewhat as with digitals (which see). The quickening occurs even in the nerve-free heart of the embryonal chick; in mammals also it is seen after all the nerve endings in the heart have been paralyzed by aposedalin.

The isolated mammalian heart (Hedbom-Langendorff) shows the following: The first effects are inconstant; the frequency is then enormously increased and the amplitude lessened below what is accounted for by the quickening (increased irritability and weak-
ned muscle). Then follows a transient increase of amplitude (muscular stimulation), and the slight ventricular and auricular systole a few more contractions. Caffeine may start a few beats.

Perfusion of Medulla in Turtle.—Aconitum stimulates the cardio-inhibitory center (Bush, 1920).

Action of Aconite on the Frog's Heart.—These are practically identical in the intact frog and in perfused excised heart. They are therefore peripheral. They consist essentially in heightened irritability of the auricular, and especially of the ventricular muscle; disturbed conduction; lessened contraction intensity, and finally paralysis. The successive effects are described as follows (Boehm, 1871; Hartung, 1913; Fuehner, 1911):

1. Preliminary slowing is sometimes observed. It is probably due to stimulation of the vagus endings.

2. Acceleration.—Rather suddenly the beats become quickened and at first strengthened. The acceleration is attributed to heightened irritability of the cardiac muscle. The time of contraction and the refractory phase are shortened.

3. Incoordination.—Ventricular extra-systoles appear (even when the auricles are unexcited). The rate of the ventricles increases above that of the auricle, at first in a regular ratio. The combination of the two rates results in "periodic dissociation" or proxal beats. As the rate continues to increase, the contractions can not be maintained regular, and become extremely incoordinated, resulting in the characteristic "peristalsis" of the heart-muscle. This begins in the auricles, but soon extends to the ventricles. It consists in pendular movements, in which the blood, instead of being propelled, is merely moved about in the heart. The localised contractions may lead to a mulberry appearance, etc. Sometimes the contraction sequence is reversed so that the ventricular contraction initiates the auricular beat. These irregularities may alternate with periods of quite normal beats. The regular rhythm can often be restored by stimulating the accelerator nerve.

4. Standstill.—The extreme irregularity always passes off after a time, and is succeeded by a slow, broken, and at barely regular contractions, except that the ventricles beat much slower than the auricles. Eventually the ventricles stop relaxed, and then the auricles, usually rather suddenly. Atropin, accelerator stimulation, or direct stimulation may start a few rhythmic beats, but the contractility is soon lost completely.

Heart-test for Aconitum.—The peculiar heart "peristalsis" is the most delicate and characteristic test for aconitin. Fuehner, 1911, could thereby detect 0.001 mg. in intact frog and 0.0001 mg. in excised hearts. Similar effects are produced by the related Delphinium. The Digitalis group also produces peristalsis, but this is of short duration and followed by systolic standstill.

Stimulus Muscles and Motor Nerves.—Strong concentrations of aconitin at first stimulate and then paralyze the motor nerves peripherally. The stimulation is manifested by "sphygmatic tail-raising", occurring in muscle-nerve preparation, spontaneously or especially after stimulation of the nerve. The threshold of stimulation is lowered. The twitchings do not occur after curare, and must therefore be in the endings. They may be seen in living animals. The subsequent paralysis of the nerve, and eventually of the muscle substance, can not occur during life, since the dose and the time required are greater than what would paralyze the heart (Hartung, 1911). The allied Delphinium, however, has been recommended as a substitute for curare in frog work (Schille, 1904).

Infusoria and plants are also killed by aconite (Fleming).

Respiration.—This is progressively slowed in proportion to the dose (Fleming). It is also abolished and the later stages become irregular. The slowing bears a superficial resemblance to that of vagus stimulation; but while its occurs after section of the vag (Boehm and Wartmann, 1875), it must be due to direct-depression of the respiratory center. It is characterized by long inspiratory pauses. Primary increase of respiration has been claimed (Cash and Dunstan; Anrep); but it is small and inconstant, and probably due to other factors (Hartung, 1915).

Temperature.—This falls in severe poisoning, because of the collapse and consequent paralysis of heat regulation. The temperature of the animal falls and rises with the external temperature (Brunton and Cash, 1856).

Summation of Dosage.—The influence of this on temperature has been studied by Cas, 1906. He found an imperfect summation of effect if the dose is repeated at sufficiently close interval. But if this exceeds two hours, the later doses may produce equally less effect, i.e., the temperature may not fall as low as with the first dose.

Repeated administration produces some tolerance in rabbits (Hartung, 1912).

Reflexes. These are diminished, on account of the sensory paralysis.
SYMPTOMS OF ACONITE POISONING IN MAN

With very large doses death may occur almost instantly—probably from paralysis of the heart. With moderately toxic doses the following picture is seen: tingling in mouth, stomach, and skin (the most important diagnostic feature); excessive salivation; nausea, retching, vomiting, and diarrhea (the mechanism of the emesis is central; Egleston and Hatcher, 1915). The burning passes into anesthesia. There is great restlessness. The pulse is slow and feeble, later arrhythmic and very rapid. Respiration is dyspneic. There are muscular weakness, incoordination, vertigo. The skin is cold and livid. The pupils are first constricted, then dilated from the asphyxia and convulsions. The intelligence does not usually suffer, but there may be stupor and even unconsciousness. The special senses and speech may be impaired. Convulsions are common. Death may occur by heart paralysis or by paralysis of the respiratory center (the heart beating after death; Fleming). The symptoms may appear almost instantly, and are rarely delayed beyond an hour. In fatal poisoning death occurs usually in two to six hours. There are no constant postmortem changes.

Etiology. Accidental poisoning from the fresh plants—which as monk’s-hood and the related larkspur are quite common in gardens—as also from liniments, etc., is fairly frequent. On account of the small dose, the absence of postmortem signs, and the difficulty of chemic proof, aconitin became quite a favorite for suicidal purpose. The use of the plant for criminal poisoning is widely spread in the East. The symptoms are so unmistakable—especially the tingling—that it has not found many users in civilized countries.

Subtoxic Effects in Man. According to Fleming, 0.5 Gm. of Aconite produces aggravation of the therapeutic effects, of the subjective symptoms, and lethargy with anxiety. The pulse may either be very slow (to 30) and regular, or more often increases suddenly to 70 or 80, and becomes small, weak, and more or less irregular. The quickening may occur without any preliminary slowing. Robinson, 1915, observed extra-systoles without other effects. The respiration is also irregular. The temperature falls further. There is generally vomiting. These symptoms do not entirely subside for one or two days.

Dangerous Effects. With doses of 0.5 Gm. of Aconite, the collapse becomes pronounced, with pale sunken face, froth at mouth, and extreme prostration. Consciousness remains, perhaps with slight delirium. The voice is weak or lost. The pulse is very small, weak, and irregular; the respiration very imperfect. The skin is cold and clammy. The patient may recover with treatment.

Fatal Effects. The patient is either conscious or mildly delirious, and becomes entirely blind, deaf and speechless. The pupils are dilated. There are general muscular tremors or slight convulsions; the heart beat becomes imperceptible. The temperature continues to fall. Finally, the heart stops, more or less abruptly.

The fatal dose is uncertain. According to Lewin, death has occurred from 3 to 4 Gm. of Aconite; recovery from 7 Gm.; with aconitin, death has occurred with 4 mg., recovery with 12 mg. Fothergill states that it is more fatal for young rabbits than for adults.

Absorption and Excretion. The absorption occurs readily from mucous membrane; alcoholic and oily solutions are absorbed from the skin. Lewin states that it is excreted promptly by the urine, feces, saliva and intestinal mucus.

Treatment of Aconite Poisoning. The common alkaloidal antidotes and evacuation should be employed. The symptomatic treatment should be mainly stimulating: warmth, ammonia, brandy, strychnin, atropin. Artificial respiration is often life-saving (Lewin, 1895). It is extremis, cardiac stimulants (epinephrin or strophanthin) should be used intravenously.

Antagonism of Aconite and Digitalis. This was proven by Fothergill, 1879, but he also showed that the effects of digitalis with ordinary administration are too slow to be of practical value.
PREPARATIONS—ACONITE GROUP

Aconitum, U.S.P.; Acon. Rad., B.P.; Aconite (Wolfbane, Monkshood).—The dried herbage root of Aconitum Napellus, yielding not less than 0.5 per cent., U.S.P., 0.4 B.P., alkaloids. Frequently cultivated in gardens. All parts of the plant are poisonous.

*Est. Aconit., U.S.P.—A powdered extract, representing about 2 per cent. of alkaloids. Dose, 0.10 mg., 1/3 gr., U.S.P.

Festuca Aconit., U.S.P.—About 0.5 per cent. of alkaloids. Dose, 0.03 c.c., 1/4 minims, U.S.P.

Tinctura Aconiti, Tr. Aconit., U.S.P.; Tr. Acon., B.P.—to per cent. of drug, 0.05 or cent. of alkaloid, U.S.P.; 0.04 per cent., B.P. Miscible with water or alc. Dose, 3 c.c., 5 minims, U.S.P.; 0.12 to 0.3 c.c., 2 to 5 minims, B.P. Maximum dose, 0.5 c.c., minims. The tinctures of the older pharmacopoeias were of different strength: 35 or cent. in U.S.P. until 1890; 5 per cent. in B.P. until 1915.

Lin. Acon., B.P.—0.2 per cent. of alkaloids, 3 per cent. of camphor, in alcohol.

Aconiti, U.S.P., B.P.; Aconitin, CaH3NO5.—The most active "crystalline" contain. Very slightly sol. in water, sol. in alc. (1:10). Dose, 0.15 mg., 1/40 gr. U.S.P.; maximal dose, 0.5 mg., 1/40 gr. If its internal use is not advisable.

Us. Aconit., B.P.—to per cent.

Delphinium.—The various species of Larkspurs contain alkaloids, which are closely related to Aconitin, chemically and pharmacologically. They were used for the destruction of body-parasites since antiquity. They have been cause poisoning in children, and in cattle and horses (Marsh and Clason, 1930).

Stephania, U.S.P.; Stephania Sem., B.P. (Stavesacree).—The ripe seeds of Delphini-um Stephaniae. Dose, 0.06 Gm., 1 gr., U.S.P. It is used locally against pedicu-losis capitis or pubis, in the form of the 10 per cent. Ointment (B.P.), or as the Fluid-extract (U.S.P.) diluted with 8 to 10 parts of soap liniment or bayrum. It must not be used if the skin is broken. It causes considerable local irritation, and sometimes cema (Levin).

Festuca Stephaniae, U.S.P.; Us. Stephaniae, B.P.—to per cent.

VERATRIN (CEVADIN)

General Statement.—Various species of Veratrum (Green and White Hellebore), Cevadilla, Zygadenus, and other Liliaceae plants contain mixtures of related alkaloids. These are ests of definite bases and acids, related to Aconitin both in structure and action.

"Veratrin" is a mixture of alkaloids, extracted from "cevadilla" seeds, which owes its activity mainly to Cevadum. It must not be confounded with Veratrum and its active constituent, Protovaternin, since their actions differ in important particulars.

Veratrin produces a characteristic prolongation of muscular contraction of considerable physiological interest. Therapeutically it is rarely used as a counterirritant in neuralgic conditions, and as a parasiticide against pediculi capitis.

Composition of Veratrin.—This has been studied especially by Wright and Luff, 1913, and Allen, 1926.

The principal constituent, both in quantity and activity, is the crystalline Cevadum C21H19NO5, the methylene or ester of the base cevadin. It is not present in Veratrum drum; traces are said to occur in Veratum viride, but this is doubtful.

The second important alkaloid of "veratrin" is the amorphous Veratridum C21H19NO4, the ester of verin. This is the "veratrin of Wright and Luff." It adjuncts agree qualitatively with those of cevadum (Boehm and Issauer).

The commercial "veratrin" contains small quantities of at least three other alkaloids: Cevadulin, Sedatin, and Sabadinum. All these are but weakly active.

Zygadenus (Death Camas), Liliaceae, a poison plant of Western stock-ranges, owes its toxicity to veratrin bases. It contains at least sabadin, sabadinum and veratralbin (Boehm, 1905). The actions of the Zygadenus alkaloids have been studied by Mitchell and Smith, 1921. A comprehensive literature is given by Marsh and Clason, 1925.
Action on Striped Muscle.—This consists in a characteristic modification of the muscle substance, so that it responds by a prolonged tonic contraction, even to a single stimulus.

Phenomena in Intact Frogs.—When an animal, and especially a frog, has been poisoned with veratrin, it shows very striking peculiarities in its movements. It can contract its muscles with ordinary quickness, but it can not recover its former position for some little time (v. Bezold, 1866).

**Fig. 21.—Normal veratrin curves, showing primary (a) and secondary (b) contractions**

Gastrocnemii of different frogs; air temperature; natural size.

Form of the Muscle Curve.—The reason for this behavior can be demonstrated in isolated muscle. Frogs are most convenient for this purpose, but identical phenomena occur in mammalian muscle (Quaglino, 1919): If a veratrinized muscle is stimulated with a single shock, the ascent of the muscle curve is as abrupt as usual, but the relaxation is enormously prolonged (Fig. 21). The muscle remains in what appears to be complete tetanus, although it is really a single contraction.

The Contracture is not a Tetanus.—If the nerve of a normal muscle-nerve preparation is laid on the veratrin muscle, a single shock sent into the latter causes a single twitch of the normal muscle, and not a tetanus as would be the case if the veratrin muscle were really tetanized (Fick and Bochm, 1872).

The Contracture is Active.—The muscle is able to sustain a considerable weight throughout its contraction; the prolongation of the curve is therefore not due to a more loss of elasticity, but is an active process. This is also shown by the fact that the formation of heat and the use of material is increased (Fick and Bochm). The tension, the height and quickness of contraction, the irritability, the lifting and sustaining power of the muscle are all raised by veratrin (Dreer, 1900), so that we must look upon its action as an increase of functional activity. It also lessens the effects of fatigue.

**Fig. 22.—Effect of fatigue on veratrin curve:** a, normal veratrin tracing; b, after partial fatigue.

35 natural size.
Influence of Conditions.—The effect of veratrin is enhanced by agencies which stimulate the nerve, or by moderate heat.

It is diminished by depression of the muscle, produced by cold or excessive heat; by fatigue (Fig. 22); or by muscular depressants, such as potassium or ether.

(If the veratrin action is weak, cold increases the contracture, probably by adding its en contraction to that of the veratrin.—Sollmann.)

Double Peak Curve.—A careful inspection of veratrin-curves generally reveals two contractions (Fig. 21): a primary contraction (a), which occurs with the normal rapidity, but is somewhat higher than normal, and which tends to relax quickly; and a secondary contraction (b), which occurs more slowly and lasts longer. The two contractions are sure or less fused (v. Bezold), but the form varies with conditions (Mostiński, 1904).

Revend, 1888, attributed this phenomenon to the different contraction velocity of the fine and red muscle fibers. Cervello and Weiss, 1899, showed, however, that uniform muscles exhibit the same phenomenon.

Bottazzi, 1901, suggested that the veratrin curve is due to the fusion of two contractions: the first peak representing the normal contraction of the fibrils, and the further portion of the curve the contraction of the sarcolemmal substance, which he assumed as the properties of smooth muscle. According to this the veratrin action would consist essentially in raising the excitation of the sarcolemmal substance above the threshold. There is, however, no direct evidence that the sarcolemmal has contractile actions (Mueller, 1908); and the modern theories of muscle contraction render this improbable. Woebecke, 1915, has modified the theory somewhat. He believes that muscle has two distinct functions, but that these are not specifically connected with the histologic constituents. Verdar and Felter, 1914, attribute the action to increased sensitivity to normal stimuli.

Veratrin acts directly on the muscle substance, for the effects occur after curare (Prevost, 1887), and in the nerve-free end of the sartorius muscle. When a muscle is immersed in a dilute solution, a single stimulus produces at first a normal contraction, but after a short interval a second and third, etc. The excitability of curarized muscle to direct electric stimulation is not increased; it is diminished by large doses (Boehm, 1913). Activated veratrin, however, paralyzes the motor endings without previous stimulation.

Spontaneous Contraction of Muscle.—The immersion of a muscle in veratrin causes slow-developing contractions, even in the absence of extraneous stimulation. High concentrations paralyze all forms of muscle completely (Kodlicker, 1870).

Other Substances Producing Veratrin Effects.—The prolonged contraction which is so characteristic of veratrin is by no means confined to this alkaloid, but is also produced by Digitalis, Helichoreis, Muscaria, Strychnin; by alkaloids (Vonner and Felter, 1911), etc., by cold, and by very strong electric stimulation. This wide occurrence signifies that the phenomenon is of fundamental physiologic importance. These facts also prove the contraction of cardiac and smooth muscles.

The Action of Glycerin on Muscle.—The muscles of frogs poisoned with glycerin exposed to single stimuli by prolonged contraction, the curve having a superficial resemblance to that of veratrin, but being rather more irregular. The glycerin contraction is, however, a true tetanus, due to greater irritability of the muscle substance; the action-current of each contraction sufficient to start another contraction. The phenomenon occurs also after curarization (Santesson, 1903).

Nerve Trunks.—Direct application of veratrin lessens their excitability (Boehm, 1914).

Circulation.—The effects are complex. Those on excited hearts resemble aconite and digitalis (slowing with increased systole). In intact animals, stimulation of the vagus center (Fig. 23) predominates at first marked slowing); later, the fall of pressure from vasomotor paralysis predominates prominent.

Mammalian Circulation.—Small doses sometimes cause primary quickening of the heart. With larger doses (0.025-0.05 mg per Kg.) there is sudden and marked slowing of the corresponding fall of blood pressure (Bezold and Hirt, 1874; Lissauer, 1887; Felter and Sollmann, 1915). The slowing is greatest soon after the injection, often marked arrhythmia or temporary arrest. This acute effect is due to stimulation of the vagus center (see, however, under Veratrum), for section of the vagi largely abolishes and stimulation of the vagus trunk does not produce further slowing (Busquet, 1907). With divided vagi, large doses may cause primary quickening and generally moderate rise of blood pressure (Bezold; Felter and Sollmann). The fall of blood pre-
sure is mainly due to the slowing, although some fall may occur independently (Lissauer). The vasomotor center is moderately stimulated by the respiratory embarrassment, even when the vagi are cut. The stimulation does not occur if artificial respiration is maintained (Pflüger and Sollmann, 1913). Reflex stimulation causes vasoconstriction.

Late Effects.—The acute effect soon passes off. The heart then beats with a steady, moderately slowed rate. This slowing is not removed by atropin and is therefore cardiac.

The blood pressure falls progressively, occasionally interrupted by spasmodic rise from central vasomotor stimulation. The strength of the heart is not impaired, for it reacts well to compression of the aorta, and beats efficiently just before death. The fall must therefore be vasomotor; and accordingly, sciotic stimulation or asphyxia fails to raise the pressure (Lissauer, 1887). The vagus remains excitabile. The cerebral vessels are constricted (Dixon and Halliburton, 1919).

The isolated mammalian heart (Hedbom-Langendorff) shows a primary slowing from stimulation of the peripheral vagus mechanism; then irregularity, and finally paralysis of the cardiac muscle. The tone is increased.

**Fig. 43.—**Cevadin (Veratrin) on Blood pressure; showing the stimulation of the vagus center. Intravenous injection of 0.02 mg. per kg. into anesthetized dog; artificial respiration.

**Frog’s Heart.**—The effects resemble aconite and digitalis. They involve mainly the ventricle and consist in slowing (no further slowing on vagus stimulation; Buquet, 1907); prolonged systole and increased tonus; sudden change in the rate to one-half; “peristaltic” contractions; and final median standstill. High concentrations cause prompt systolic standstill, with continued shortening. The auricles continue much longer. The same effects occur on the excised and perfused heart (Lissauer, 1887; Bohm, 1913).

De Boer, 1917, attributes the slowing and halved rhythm to increase of the refractory period of the ventricle.

**Peripheral Action on Blood-Vessels.**—Veratrin produces powerful constrictions, which may be removed by atropin or quinin. Since these antagonists do not prevent contracture by barium, it has been concluded that veratrin must act on the nerve-endings (Kondo, 1919).

**Collapse Action.**—The impairment of circulation, combined with the emetic action, result in varying degrees of collapse, and thereby fall of temperature, analogous to veratrum.

**Expiration.**—This is influenced by the circulatory and convulsive actions, and also directly. It is temporarily arrested during the acute fall of blood pressure, but may be depressed without any change of blood pressure. The respiratory embarrassment is generally diminished by atropin or division of the vagi (Pflüger and Sollmann, 1913).
VERATRUM

chial Muscles.—These constrict in intact animals (Dixon and Brodie), but not isolated trachea (Tweeddale and Laub, 1913). Titone, 1913, observed that veratrin solubilized bronchial muscles.

sections.—These are commonly present in mammals and frogs, and are prob-

bral Functions.—These are scarcely affected.

al Action.—Cevadin is a strong irritant, resembling aconite. It to the skin, it produces burning, later a cold sensation and partial

ia, with reddening and sometimes discrete vesication. On mu-

embranes it causes acute catarh—sneezing, coryza, gastroenteritis, etc.; sometimes with corrosive lesions. The vomitings,

is mainly central (Eggleston and Hatcher, 1915). In frogs, retention of mucous from the skin is greatly increased.

irritation is especially strong on the abraded skin; 1:100,000 solution produc-

and “shooting” pain (Sollmann and Pichler, 1916).

apeutic Uses.—Veratrin is used locally as counterirritant, in

as and similar conditions, as 2 to 4 per cent. ointment. Sabadilla are employed against pediculosis capitis (Salve, 1:4; Decoction, 1:16).

The irritation is severe, and absorption has caused serious

ms. The internal use of veratrin (against fever), even in mg.

cessation: Burning in mouth, spreading to stomach; increased salivation, diar-

a, abdominal pain; anxiety, headache, giddiness; pupils dilated; pulse

febrile, later irregular; weakness; twitchings in muscles. Death by respiratory

ary collapse. Consciousness preserved till the end. Postmortem, often

necropsies.

nal doses, the symptoms are very slow in disappearing, and a double case of

ing by continued small doses is on record: The two patients became very

d thin, suffered from bloody diarrhoea, insomnia, disturbance of the intellect, etc.

iment is the same as in aconite-poisoning. As the veratrin is believed to be excreted through the urine, it is well to administer hot tea as a diuretic.

PREPARATIONS—VERATRIN

wine, U.S.P.—A mixture of alkaloids obtained from the seeds of Asagren

s. Very slightly sol. in water (1:1760); freely sol. in alc (1:2.8). Its internal

advisable, but it has been given in doses of 2 mg., 15 gr. Externally, it is

lents of 2 to 4 per cent. Maximum dose, 3 mg., 1/2 gr.

Powder.—The flowers of Chryanthemum Cinерeum contain an active

inhibitor (Fujita, 1909), a neutral N-free syrnap substance, with actions

veratrin.

veratrin.—This is an N-neutral principle, isolated by Plugge from

d and similar plants. It seems to belong to this group (Mountain Laurel-

poisoning; Crawford, 1903).

VERATRUM

eral Statement.—Veratrum viride and album (Green and White

re) seem to be mere varieties (the green American, the white

an), with practically identical actions and composition (Salzberger, 896). They owe their activity mainly to the alkaloid, protovatrin.

ber of other related but less active alkaloids are present. There
are, however, wide differences of opinion as to the constituents of Veratrum viride (Cramer, 1915).

The effects of protoveratrin, and therefore of veratrum, are qualitatively similar to those of cedadin; but they differ very materially in their relative significance: The characteristic muscular and irritant actions of cedadin are insignificant in protoveratrin. The most important effects of veratrum are on the medulla, and especially on the circulation, resulting in vagus stimulation, slowed pulse, fall of blood pressure, sweating, "collapse-action," and reduction of temperature. It is therefore employed as a "cardiac depressant." Protoveratrin is more toxic than cedadin, approaching aconitine; but the prompt evacuation of overdoses by emesis (central) renders veratrum practically safe.

**Constituents.**—The most important alkaloid of Veratrum album, although not the most abundant (0.01 to 0.02 per cent.), is *Protovatrum, CalaNO*. It occurs not in a crystalline and amorphous form (Salisberger, 1890). The other alkaloids are: *Leris*, 0.1 per cent., weakly active; traces of *Rubijervis* (almost inactive); the inactive *paradoxieus* or protoveratrin, which is probably a decomposition product; the glycoid *veratrin*; and *veratrodin* and *veratrinin*, which are probably mixtures of amorphous bases (Bull. Am. Pharm. Assoc., 1911, p. 105; Robert). Traces of cedadin have been reported in *V. viride*, but are doubtful.

**Black Helleborine,** Helleborus niger is in no way related to the above veratrum species. Its active principle, Helleborine, belongs to the Digitalis group.

**Experimental Effects on Respiration and Circulation.**—The typical effects of intravenous injection of veratrum viride consist in brief but marked depression of the respiration, slowing of the pulse, and lowering of blood pressure. These effects are largely prevented by section of the vagi, and do not recur if further doses of the veratrum are injected. The repeated injections generally produce marked rise of blood pressure, especially if the vagi are intact. The effects are probably due to protoveratrin.

Cramer, 1915, believes that the effects are produced by the stimulation of the afferent vagus endings, producing reflex inhibition of the respiratory center, and reducing from thence to stimulate the vasodilator and the cardioinhibitory centers; the afferent endings being then paralyzed, so that subsequent injections become ineffective. Comparative doses are so different from those found necessary by other investigators, that comparison of the results is difficult. His explanation is probably correct as to the respiration; but requires confirmation as to the circulatory changes. At present, it is simpler to suppose direct stimulation of the vagus center, slowing the heart, and thus lowering the blood pressure. At least Pücher and Sollmann, 1915, did not observe any significant changes in the vasomotor center. The rise of blood pressure on repeated injection is probably due to paralysis of the cardiac vagus endings, resulting from large doses.

**Respiration.**—Moderate doses of veratrum viride (2.5 to 5 mg. per kilogram) injected intravenously into dogs produce brief but marked slowing or arrest of the respiration. This effect is generally absent if the vagi have been divided, and may therefore be attributed to stimulation of the afferent vagus endings (Cramer, 1915; Pücher and Sollmann, 1915). Cramer finds that this does not occur on repeating the injection, and therefore believes that the stimulation of these endings is followed by their paralysis. He also finds veratrum ineffective after atropin, which would indicate that atropin also paralyzes the afferent vagus endings. Very large doses of veratrum depress the respiration after any of these conditions, presumably by a direct action on the respiratory center.

**Moderate Doses on Mammalian Circulation.**—In dogs with intact vagi, the intravenous injection of veratrum viride, 2.5 to 10 mg. per kilogram, produces a prompt sharp fall of blood pressure and marked slowing of the heart, with prompt return to normal. The fall of blood pressure is due essentially to the cardiac slowing through stimulation of the vagus center, for if the vagi have been divided, the pressure falls but slightly. The afferent vagus endings are not stimulated. The vasomotor center is not directly
but is sometimes moderately stimulated by the fall of blood pressure and especi-
ally by the respiratory embarrassment (Flicher and Sollmann, 1915). It is also
observed by R. Cramer, 1915, that the fall of pressure depends chiefly on the slowing, but
y more persistent. Both disappear on section of the vasa cava. Cramer, 1915,
believes that the fall of pressure depends chiefly on the slowing, but rather on
on; for he states that the fall starts first; that cats may show the fall without
; that the fall occurs after atropine; and that it is accompanied by intestinal
. He confirms that the depression of the circulation and respiration are
by section of the vasa cava; and assumes that veratrum acts by stimulating the
depressant vagnus endings. The effect does not involve the depressor nerve,
nositation occurs in rabbits after section of the depressor trunks, but not after
were divided.

(1999, observed that epinephrin prevents the fall of pressure after
vitro (just as it does that of depressor stimulation). On the contrary, three
sially a rise of pressure.

as described on the Circulation.—These produce considerable rise of pressure,
the vasa cava are intact; less if they are divided (Flicher and Sollmann). Wood
this occurs also after section of the cord. It is partly explained by quickened
from paralysis of the vagus endings. Cramer obtained no effect whatever
second injection, and believes that the first dose, after first stimulating, the
vagus endings.

Doses on the Circulation.—These produce at first exaggeration of the vaga
marked slowing, irregularity, arrest; with corresponding fall of blood pres-
sis is followed by sudden extreme acceleration and rise of pressure (partly
paralytically spasmodically). The rise may last for several minutes, and is succeeded
progressive fall and death. In man, excessive doses also quicken the pulse and
found the results inconsistent; due, as he believes, to an intermixture of the
and depressant effects on the afferent vagus endings. The blood pressure
to zero, remain normal, or rise; or follow the convulsive respiration. The heart
be slowed, but is more often quickened. The inhibitory vagus endings are
.

Subsequent injections have but little effect on the pulse.

Actions.—Dried veratrum or potovveratrin are irritant, provoking sneezing,
has irritating effects are very slight. These have a marked action
lasting forty-eight hours, on the cornea (Eden).

Symptoms in Mammals.—The first effects are nauseant and emetic, often
is to obscure other symptoms. Of these, the respiratory changes are character-
the nausea is in rabbits. They consist in periodic dyspneic attacks, culminating
as of a medullary type. The respiratory disturbance is probably due to the
influence of the respiratory and other medullary centers, circulatory changes
ular exhaustion. In the intervals the respiration is regular. Death occurs
in the circulation fairly preserved and consciousness present to the end (Eden).

Action.—The combination of the central, circulatory and
depression, nausea and dyspnea, results in more or less collapse.
the profuse sweating lowering the temperature, proportional to the
symptoms (Eden).

Doses of Therapeutic Doses on Man.—Collins, 1915, 1916, has made
tive clinical study of a 10 per cent. tincture of veratrum album
1 to 2 c.c. or divided doses of 1 c.c. every hour, to a
4 c.c. Full doses produce constantly a slowing of the pulse to
per minute (irrespective of the original rate); and very generally
systolic and diastolic blood pressure of about 35 mm.
slowing and fall are proportional to the dose. Electro-cardio-
no effect (Collins and Hanzlik, 1918).

blood flow in the arm is markedly lowered by therapeutic doses
blood供给 is not disturbed. Headache, gastric burning, nausea and
c may set in, but come after the depression of the circulation, and
come not its cause. The effects last for several hours. Large
within half an hour) may produce more serious and lasting
collapse, with a pulse rate of 40 or 30, suddenly returning to normal after eight or nine hours.

**Veratrum Poisoning.**—Although protoveratrin is very highly toxic, veratrum is vomited so promptly that death is rare even with large doses (Wood). It has, however, been reported after 1 to 2 Gm. of the powdered White Hellebore (which is used as insect powder), and in enfeebled patients from a teaspoon of the Tincture.

**Symptoms.**—These consist in burning, vomiting and diarrhoea, dyspnoea, collapse, paralysis or light convulsions.

**Treatment.**—The stomach should be emptied by warm water or lavage, and the collapse treated along the usual lines.

**Therapeutic Uses.**—Veratrum is probably the most active and reliable cardiac depressant, and was formerly much used to slow and soften the pulse, and lower the blood pressure, especially in eclampsia and other conditions of high blood pressure. Pesci, 1906, j.s., claims that it lowers the blood pressure by 7 to 50 mm., slows the pulse, increases diuresis, and lessens uremia. Haultain, 1914, makes similar claims. It was used for the same purposes, and to lower the temperature, in the early stages of septic fever (pneumonia) and other acute infections. The effects are probably mainly due to the cardiac slowing from vagus stimulation and to the nausea. Veratrum with other cardiac depressants has rather gone out of fashion—perhaps undeservedly. It is commonly indicated in asthenic conditions (cardiac weakness, general debility, typhoid, etc.).

**Response in Pathologic Conditions.**—Collins, 1916, observed the most marked effects in cases of hypertonus, the systolic pressure falling more than the diastolic. Little or no response was obtained in arteriosclerosis, paroxysmal tachycardia, or heart-block.

**Diuretic Action.**—This is not produced in animals (Cramer, 1912). If it occurs in eclampsia, as claimed, it is probably due to the correction of the circulatory abnormalities.

**Administration.**—Veratrum is best given in repeated doses—e. c.c., 15 minutes of the Tincture (U.S.P.) every half hour or hour—till the skin becomes moist, the pulse slower and slight nausea is present. It may then be stopped.

The desirable range is 0.3 to 0.4 c.c. (Collins and Hanelt, 1918). Caution is necessary if a total of 0.4 c.c. is exceeded. If vomiting should appear before the other effects, 5 to 10 drops of Op. Opii are administered with each dose of veratrum. Repetition of the dose does not inhibit the action (as occurs with intravenous injections in animals).

**Bio-assay.**—Commercial preparations vary considerably in activity. As the frog contains a number of active principles, its efficiency cannot be estimated by alkaloidal assay. The determination of the minimum fatal dose for frogs or guinea-pig is a convenient method. It averages about 2.3 mg. of drug per Gm. of frog, and 0.24 mg. per Gm. of guinea-pig. (Pilcher, 1917).

**PROTOVERATRIN.**

The effects, as described by Eden, 1892, are similar to veratrum, the reported differences being perhaps explainable by dosage and interpretation. Often doses by vein produce temporary fall of pressure, absent if the vagi were cut. Eden attributes this to reflex depressor stimulation, but vagus stimulation is a more probable explanation. This action is short, the pressure rising rather suddenly 40 to 50 mm. above normal, with increase of pulse rate, and inequality of the vagus. The frog is probably due to vagus paralysis. This is also of short duration. With repeated injections, the vagus paralysis becomes permanent, and the primary fall of pressure is absent—there being instead a small rise. Toxic doses produce cardiac arrhythmia, with period of stoppage and corresponding changes of blood pressure. The rate in the intervals is at first rapid, then falls with the blood pressure. The vasomotor center becomes paralyzed.

**Frog's Heart.**—The effects are mainly depressant; the systoles are somewhat prolonged, but the tone is scarcely increased. Soon the venous return is reduced by half, as with cevadin, aconite or digitalis; but this is interrupted by short periods of total
VERATRUM

rest of the ventricle or auricles, apparently due to exhaustion of the muscle. Finally the heart stops in diastole, with relatively small doses (Boehm, 1913).

Motor System.—In frogs poisoned by protoveratrin, the reflexes disappear early, as paralysis is largely central, for it occurs also if the poison is excluded from the muscle by ligation. However, there are also peripheral effects; the muscles may respond initially to a single stimulus or contract even somewhat more quickly and efficiently; if they fatigue very rapidly (Eden, 1892). The prolonged contraction characteristic of veratrum is indicated very faintly, if at all, under ordinary conditions; but it may be noted in excised muscles if precautions are taken against fatigue (Boehm, 1913). Nerve trunks are paralysed only by concentrated solutions; the negative variation aid to be prolonged.

JERVIN

The effects also resemble veratrum, but the quantity of this alkaloid in the drug is too small to have any noticeable effect on circulation (Wood, Jr., 1906). With effective doses, the heart rate is first slowed then rapid. The blood pressure falls progressively, presumably by depression of the cardiac muscle and vasomotor center. The inspiration fails simultaneously (Wood, 1874).

RUBI JERVIN

Wood, 1874, found that "veratroidin," which varies probably an impure rubijervin, acts mainly on the respiratory center, with some cardiac depression. Its quantity is too small to be important.

PREPARATIONS—VERATRUM

Veratrum Viride, U.S.P. (Green Hellebore, American Hellebore).—The dried rhizomes of Veratrum viride. Dose, 0.06 Gm., 1 gr., U.S.P.

Veratrum Album, U.S.P. (White Hellebore).—This is probably a mere variety of the former, growing in Europe. It is used in the same doses.

Festuca Verat. Vir., U.S.P.—Dose, 0.4 c.c., 15 minims, U.S.P.

Tinctura Veratris Viridis (Tr. Verat. Vir.), U.S.P.—10 per cent. Dose, 0.5 c.c., 8 minims, U.S.P. Till 1920, the Tincture was of 40 per cent. strength. Norwood’s acuir was supposed to be a saturated solution of the fresh root.

COLCHICUM

Colchicum (Meadow Saffron), and its active alkaloid Colchicin, are credited to have a specific effect on acute attacks of gout. Their use is sporadic and has no pharmacologic explanation. Toxic doses produce a characteristic late gastro-intestinal irritation, even on hypodermic administration. The action is probably due to conversion into oxydicolchin. The vomiting, purging, and intestinal congestion may be so intense as to lead to fatal collapse, so that the plant (all parts) is of toxicologic importance. The other actions are relatively insignificant, and are related to aconitin.

THERAPEUTIC USE IN GOUT

Colchicum is credited with prompt effects on acute gouty attacks; lessening the pain in one or two hours, the heat and swelling subsiding on after, and the attack ending in a few days instead of weeks. It must be used early and rather freely. It does not prevent recurrence, soon sees its efficiency, and is often unsuccessful; so that many clinicians are together skeptical.

Historical.—The toxic properties of colchicum are mentioned by Dioscorides; it is used against gout or rheumatism by the Arabian school (sixteenth century), and or then in domestic practice; but was abandoned in regular practice on account of poisonous action, till it was reintroduced by Stoeckel, 1763.
Attempted Explanations of Its Use in Gout.—These are all unsatisfactory. It has no definite effect on the elimination of urine, uric acid or urea. The purgation may contribute to the relief; but it is not essential and other purgatives lack the specific effect. The changes in the leucocytes have recently been invoked, but are not convincing. Circulatory and analgesic actions are also unsatisfactory suggestions, since they have not been demonstrated directly, and since colchicum has no effect on other inflammations, or on acute or chronic rheumatic pain, neuralgia, etc.

The weakness of the pharmacologic explanations is reflected in the references of S. Loewe, 1920.

Metabolism.—The urine secretion is something slightly increased, sometimes greatly diminished, probably depending on the catharsis. The statements as to uric acid and urea (e.g., Noel Paton, 1886; Maurel and Arnaud, 1910; Abi, 1913) are so contradictory, that they can have little importance. With the modern methods, Denis, 1915, found neither increased elimination of urates in the urine, nor diminished concentration in the blood. The bile flow is slightly increased (Kionka, 1906). For about an hour after administration, the leucocytes in the blood are decreased; this is followed by a remarkable increase, especially of the polymorphs, which reach two to five times the normal in twelve hours (Dixon and Malden, 1908).

Administration.—Tincture or Wine of Colchicum Seed or Corn, have been given in divided doses, 0.5 c.c., 8 minims, every three hours (advantageously with an equal quantity of magnesium carbonate or sodium salicylate), until a therapeutic response or slight gastro-intestinal disturbance and weakness occur. Some disturbance of digestion and soft stools are the rule; and in susceptible patients there may be considerable purging and faintness. This may be lessened by atropin, but if possible should be avoided by proper dosage. A single large dose, 2 to 5 c.c., 1/2 to 1/3 of tincture, acts more promptly, but may cause severe nausea, diarrhea and great muscular weakness. Prolonged administration is generally harmful and therefore inadvisable. Colchicus, which is readily obtainable, permits more definite dosage. It may be given, 0.5 to 1 m, 1/29 to 1/90 gr., three times daily, for one or at most two days. This usually causes considerable diarrhea, beginning on the second day, and with its appearance the drug should be discontinued. The stools will remain loose for another day.

COLCHICUM POISONING

Symptoms.—These set in only after three to six hours, even with large doses. They begin with abdominal discomfort, followed by violent and uncontrollable vomiting and purging and great prostration. The stools are at first normal, but become dysenteric and bloody. They are not especially painful but exhausting; so that the patient passes into collapse, with the nervous and muscular symptoms of cholera. Death occurs in seven to thirty-six hours from exhaustion, consciousness being preserved to the end.

The fatal dose varies; 1/4 ounce of the Tincture has been fatal. This would correspond to about 8 mg. of colchicine; but recovery has occurred from much larger doses, presumably with imperfect absorption.

Treatment.—This involves evacuation by enemis and cathartics, if necessary, and diuresis. Tamox is a chemic antidote, but not very effective. Opium and belladonna are given against the gastroenteritis, and the collapse is treated as usual. Autopsy reveals intense and often hemorrhagic congestion of the intestines, especially the lower portion.

Gastro-intestinal Irritation.—The mechanism of the intense congestion and violent peristalsis has been variously explained. They occur even on parenteral administration, but little significance, since the colchicine is exerted into the intestine (Speyer, 1879; Labrousse and Houdé, 1887). The action is not directly on the muscle or its innervation, for excised intestine is deprived in tone and excursions by colchicine or oxydocolchicine (Fuchner and Rehem, 1914). Roosbach, 1876, stated that the motor response to the intestinal vagus or splanchic is not affected. The persistence of vagus response has been confirmed by Fuchner and Rehem. Jacoby, 1896, co-
dured experiments with intestines exposed under a saline bath. These showed increa-
ses in peristaltic of a normal type, inhibited by atropin. He concluded that the action
consists in enormously heightened response to the normal peristaltic stimuli. Dixon and
Mallen, 1908, also described immediate peristaltic, which was arrested by atropin, and
which they therefore attributed to parasympathetic stimulation. Fuehner and Rebhan,
1915, repeated these experiments, but failed to confirm the results. Increased peri-
staltic occurred only exceptionally. It appears therefore that the peristaltic increase
observed by Jacobb and Dixon was accidental, due to causes other than the colchicum.
Fuehner and Rebhan refer the entire action to an irritative capillary vasodilatation
malignous to the local actions elsewhere, and produced by contact with the drug, reach-
ing the intestine directly or by excretion. They find this hyperemia of the stomach
and intestines even with small doses.

Local Action.—Strong solutions applied locally to the conjunctiva or subcutaneous
areas, produce hyperemia, irritation and anæsthesia.

Central Nervous System.—This is gradually paralyzed from below upward, partly
firstly and partly by the collapse.

No appreciable direct effect is exerted on the circulation (therapeutically, it is some-
what slowed by the relief of the symptoms); nor on the glands, striated muscles, or motor
nerves (Rosenbach; Dixon and Mallen).

Explanation of the Delayed Action.—The long period before the symptoms appear
an not be materially shortened by increasing the dose (Schöfl and Rosbach, 1896),
or by intravenous injection. Colchicin itself has relatively little effect on frogs; but
is toxicity for these can be increased 50 times by raising the temperature to 37°C.
(Sano, 1917). The reason for this is, according to Jacobb, 1890, that it is not the
colchicin itself which produces the symptoms, but an oxidation product—oxygen-
ized colchicin—which is formed from it in the mammalian organism—even by circulating it
through excised organs—but does not seem to be capable of formation in the frog’s at
low temperature. Once formed, whether in the above manner or artificially by the
action of oxygen, it is toxic to frogs also.

Bio-assay.—The toxicity for mice or heated frogs may be used (Fuehner, 1910).

COLCHICIN DERIVATIVES

The structure of colchicin has been established by Zeisel, 1888, and Windaus (Fueh-
ner, 1913). By treatment with acids, a methyl group is easily split off as methylic alcohol
yielding colchicine. This and various other derivatives have been
studied pharmacologically by Fuehner, 1913. The relative toxicity for various animals
show interesting differences.

PREPARATIONS—COLCHICUM

Colchici Curnum, U.S.P., B.P.; Colchicum Corn (Root).—The dried corn of ColcI-
icum autumnale (yielding not less than 0.35 per cent. of colchicin, U.S.P.).
Dose, o.25
Gm., 4 gr., U.S.P.

Est. Cohl. Curr., U.S.P.—A powdered extract, 1 Gm. representing 4 Gm. of drug,
as about 1.15 per cent. of colchicin. Dose, 0.06 Gm., 1 gr., U.S.P.

Est. Colch. B.P.—The juice expressed from the corn and evaporated to a soft
extract. Dose, 25 to 60 mg., 0.5 to 1 gr., B.P.

Vum. Colch. B.P.; Wine of Colchicum.—10 per cent. of corn. Dose, 0.6 to 1.8 c.c.,
2 to 30 minims, B.P.

Colchici Semen, U.S.P.; Colchici Semina, B.P.; Colchicum Seed. The dried ripe
seed of Colchicum autumnale (yielding not less than 0.45 per cent. of colchicin, U.S.P.).
Dose, 0.5 Gm., 3 gr., U.S.P.

Tinctura Colchici Seminis (Ex. Colch. Sem.), U.S.P.; Tinct. Colch. B.P.; Tincture of
Colchicum (Seed).—10 per cent. Dose, 2 c.c., 30 minims, U.S.P.; 0.4 to 1 c.c., 5 to 15
minims, B.P. Maximum dose, 2 c.c., 30 minims.

Colchicins, U.S.P., C$_{2}$H$_{14}$N$_{4}$O$_{4}$—Pale yellow amorphous scales or pale yellow amor-
phous powder, turning darker on exposure to light; odorless or nearly so. Sol. in water
(1:22); freely sol. in alc. Dose, 0.2 mg., 312 gr., U.S.P.
APOMORPHIN

General Statement.—Apomorphin is an artificial alkaloid, formed by dehydrating morphin through the action of concentrated mineral acid:

\[ C_{17}H_{19}NO_3 \cdot H_2O = C_{17}H_{17}NO_2 \]
Morphin Apomorphin

This causes profound changes in both the structure and action. The peculiar narcotic effect of morphin is almost completely lost. In its place there appears an excitant effect on the nervous centers. In therapeutic doses, this is confined to the vomiting center, apomorphin being the preeminent centrally acting emetic, useful especially for hypodermic administration, in poisoning, etc. It is not so useful as a nascent.

The emesis is accompanied by the usual side effects of vomiting. It often causes considerable general depression, and sometimes dangerous cardiac depression.

Smaller doses produce a prompt hypnotic effect under certain conditions (acute alcoholism).

Larger doses produce excitement, convulsions, and death by asphyxia.

On direct application it paralyzes the heart and skeletal muscles.

THE EMETIC ACTION OF APOMORPHIN IS CENTRAL

The specific emetic action of apomorphin was announced by Gee 1869, in the same year as the discovery of the substance by Mathiessen and Wright. The emesis is produced by very small doses and is very prompt, with but little preliminary nausea. The fact that there is no evidence of gastric irritation (Gee, 1890), and that apomorphin is now effective hypodermically than by mouth (Siebert, 1871) suggested strongly that its emetic action is not a reflex from irritation of the pharyngeal or gastric mucosa, as is the action of most emetics; but that the apomorphin emesis must result from a central action, a direct stimulation of the hypothetical vomiting center in the medulla. Other evidence also tended strongly to the same conclusion. The absolute proof has been brought by Eggleston and Hatcher, 1932, who found that the typical phenomena of vomiting could be produced by the injection of apomorphin into animals from which the whole alimentary canal had been removed, from the cardia to the anus. These eviscerated animals show the retching, the vomiting movements, and the expulsion of mucus from the mouth and esophagus. Direct application of the apomorphin to the esophagus or pharynx does not produce vomiting.

OTHER EVIDENCE THAT EMESIS IS CENTRAL

Absence of Irritant Action.—Siebert, 1871, gave daily emetic doses of apomorphin to dogs for six weeks, and found no signs of any inflammation at autopsy. Bechert, 1879, showed that solutions do not produce irritation even on the sensitive conjunctiva.

Greater Efficiency on Hypodermic Administration.—Siebert and all subsequent workers showed that administration by mouth requires larger doses and a longer time to produce vomiting. Eggleston and Hatcher found that dogs require by vein only 0.05 to 0.15 of the oral dose, and vomiting occurs in one-half the time. The effective doses are (milligrams per kilo): by mouth, 6.7 in four to ten minutes; hypodermic, 0.2 in two and one-half to ten minutes; intramuscular, 0.05 to 0.075 in three to seven minutes; intravenous (without anesthesia), 0.05.

Division of Both Vagi.—These constitute the sole afferent paths for the reflex of local emetics (Oenchowski, 1889). With locally acting emetics therefore vomiting
APOMORPHIN 527

ur if both vagi are divided, but this does not prevent the apomorphin emesis
ἀρνακτικά, and others; the contrary results of some investigations are explained
by certain errors, i.e. constrained positions of animals). The splanchics do not
respond to

phyn is Not Reabsorbed into Stomach.—Many locally acting emetics pro-
ting when injected hypodermically or intravenously, by being excreted
via or stomach, and there producing the local action, although this naturally
iger doses than oral administration (Tartar emetic, etc.: Kleinmann and
sch, 1872). Rechert believed that apomorphin is also reabsorbed; but this
be confirmed by subsequent workers, and has been disproved by Eggleston et
ents of Stomach in Emesis.—This has been investigated in cats by the X-ray
annun, 1896). The same events follow apomorphin and mustard; the first
inhibition of the tone of the cardiac portion, which becomes a flaccid bag,
and is shut off by a deep contraction ring. The contents are then expelled
contraction of the diaphragm and abdominal muscles. As the expulsions
of the gastric walls tighten around the remaining contents.

Stomach by Pig's Bladder.—Magendie found apomorphin effective under
methods. This would not exclude the possibility of intestinal irritation.

Application to the Vomiting Center.—Thumas, 1891, found that the applica-
morphin to a limited area of the medulla produces vomiting.

of the Vomiting Center.—Opechanski, 1886, believes that the center
inulated by apomorphin lies in the corpora quadrigemina, and that Thumas
merely the effenter fibers on their way to the splanchics. He also believes
quadrigemina are not concerned in reflex vomiting. The nature of the central
of the vomiting reflex is too obscure for further discussion.

ents of Excised Stomach.—Schultz 1886, found that apomorphin and other
olice strong reversed peristalsis in excised stomach; but Batelli, 1896,
movement without giving any drugs, and they may be attributed to

vation of Pharyngeal Region.—Valenti, 1911, asserts that emesis, by apo-
well as by local agents, is prevented by coagulating a certain pharyngeal
trods the cardiac sphincter. He suggests that apomorphin increases the
the center so that it responds by vomiting even to the normal impulses
ate from this pharyngeal region. However, this may merely mean that the
of the cardiac sphincter, which is controlled from this region, is indispensable
ents (Mellinger, Opechanski, Cannon, Magnus, 1914). Discredit the
aperinephraingeal vomiting center.

ility of Different Animals to Emetic Action.—Animals which are incapable
ble (rabbit, rat, guinea pig, horse, cattle, etc.) do not do so under apomorphin;
animals which vomit more or less readily in response to local irritants, are
ly insensitive (pigs, birds, frog) or relatively insensitive to apomorphin.
ens require about 50 times more per body-weight, hypodermically, than
on and dog are the most susceptible. Continued administration does not
ience (Siebert). Insensitiveness to the emetic action does not imply
the other central actions of apomorphin, to which all animals are susceptible.
ant Stage.—Excessive doses of apomorphin are not as effective as moderate
uding emesis, and may render the animal completely recalci-trant to the
re (Rechert, Eggleston and Hatchet).

etic Drugs.—Apomorphin vomiting is not affected by local sedatives (bis-
but is prevented by narcotics. With chloroform and chloral, full narcotic
ed; but with morphin and its esters, very small, non-narcotic doses suffice.
ineffective (Ruth, 1913); also atropin.

central Actions.—If apomorphin is given in larger doses it produces a series of
effects, especially in animals which do not vomit (Harnack, 1874). At first
restlessness, gnawing, excitement and terror. These are perhaps due to
and to the unaccustomed sensations. The gnawing is not seen with rabbits,
the hemispheres have been removed, so that it must be of cerebral origin
h. The respirations are quickened (even under chloral narcosis), but
apomorphin also disturbs heat regulation, so that animals do not respond to
aline and shivering (Magn, 1914). With larger doses (larger than are
in man), there are ataxia and then violent irregular convulsions. These
respiration, and the animal dies in asphyxia. Death occurs also if the
are suppressed by chloral, but then requires a dosage twenty times as high.
the same phenomena. Hattori, 1910, finds that the reflexes from the
and brain are increased.
Local Application.—Harnack, 1874, showed that this paralyzes cardiac and skeletal muscles in frogs.

Hypnotic Action of Apomorphin and Use in Acute Alcoholism and Hysteria.—C. J. Douglas, 1899, claimed that apomorphin, in small, non-emetic doses (2 mg.), acts as a safe and certain hypnotic, effective even in delirium; natural and refreshing sleep occurring usually in five to twenty-five minutes. Coleman and Polk, 1902, experimenting on an extensive series of acute alcoholic patients, confirmed the claim. They employed hypodermic doses of 2 to 6 mg. Other observers (Roscheirch, 1900) report similar results; the tendency, however, has been to use doses (5 mg.) which produce an emetic action (Kosswasser, 1907). This perhaps aids the therapeutic effect by breaking into the fixed ideas of such patients. The sleep occurs in a few minutes after emesis. Hypodermic administration secures by far the best results.

Velocity of Action.—In man, the hypodermic injection of 5 to 10 mg. (1/2 to 1/6 gr.) of apomorphin produces severe nausea and vomiting within ten or fifteen minutes, generally without other effects. By mouth, twice this dose is uncertain. The emesis may be repeated several times. The nausea is intense and is apt to persist longer than with the retic emetics, since the apomorphin is not removed.

PHENOMENA OF NAUSEA

These are common to all emetics. They consist in a feeling of sickness, lassitude and weakness; pale skin; increased secretion of sweat, saliva, mucus and tears; sensation of excessive heat; increase of respiration and pulse rate; fall of blood pressure. During the emesis proper, the contraction of the abdomen will raise the blood pressure temporarily—a fact which contraindicates emesis in apoplectic patients, etc.

Circulation and Respiration in Nausea and Vomiting.—Traube, 1867, described as initial fall of pressure, with slow vagus pulse, succeeded by quickened pulse toward the end of the emetic action. The details have been studied by Brooks and Luckhardt, 1915, on unanaesthetized animals. Their results were confirmed by Miller, 1915.

They found emesis accompanied by marked disturbances of the circulation and respiration. There is sometimes a period of elevated pressure; but commonly, at the moment of emesis, the heart is inhibited, with sudden severe fall of blood pressure. This is interrupted by periods of great oscillations. These great and sudden changes may rupture blood vessels, which would resist more radical changes of equal degree.

The changes are somewhat different in the two types of vomiting.

Rapid projectile type, with short nausea: During the nausea, the blood pressure is slightly raised, the pulse rate increased, its amplitude diminished. During the vomiting, the pressure falls sharply with practically complete arrest of the heart, or asystole. The respiration is suspended. After the expulsion, rapid recovery occurs to normal.

Slow, labored type, with more marked nausea, etc.: During the nausea, there is deep breathing and salivation. During violent retching, the blood pressure and the intrathoracic pressure oscillate greatly. The pulse is slow and irregular. During the vomiting, the changes are as described.

The slowing and fall of blood pressure are due to inhibiting vagus stimulation, since they are prevented by atropin. The oscillations are indirect results of the muscular efforts, and are generally diminished by curare.

The Acceleration of the Heart in Emesis.—Ackermann, 1856, showed that all kinds of emesis are accompanied by this acceleration. Harnack, 1874, observed some acceleration even after atropin, so that there must be a reflex stimulation of the accelerator mechanism; the vagus mechanism is probably also reciprocally inhibited.

The stimulation of the salivary centers has been studied by V. E. Henderson, 1910.

ACCIDENTS IN THE THERAPEUTIC USE OF APOMORPHIN

The apomorphin nausea may produce considerable depression, varying in degree in different individuals. It is characterized by muscular debility, and rarely collapse (Harnack, 1908). These may precede or follow the emesis, and are especially liable to occur in the rare cases in which
AEPHOMPHIN SOLUTIONS

Dosage.—For emetic effect, 5 mg. (½ gr.) or at most 10 mg. (½ gr.) be crystallized hydrochlorid, in ½ to 1 c.c. of water, should be given oedematically and repeated in fifteen minutes if necessary. As a seant expectorant, it is inferior to ipecac, but may be used by mouth, yrep of citric acid, in doses of 2 to 10 mg. (½ to ½ gr.) for adults; to 2 mg. (½ to ½ gr.) for children. This dosage does not cause resision.

The therapeutic use of emetics will be discussed later.

A P R E P A R A T I O N S — A P O M O R P H I N

A porphine. Hydrochloricum (Apomorph. Hydrochl.), U.S.P., B.P.; C₂H₅NO₃ — ½ H₂O, U.S.P., (C₂H₅NO₃.HCl) + H₂O. B.P.—Prepared from morphin by the action of one molecule of water. The preparations of different manufacturers differ or less in composition and activity (Harnack, 1909). Minute, white or grayish, glintenng, presns; odorless, acquiring a greenish tint upon exposure to light and Soln. in water (1:10) and in alc. (1:50). Dose. Expectorant, 3 mg., ½ gr.; emetic, 0.66 mg. by mouth; hypodermic, 5 mg. 0.1 gr. U.S.P. 0.1 to 0.6 mg.: 0.1 to 0.3 mg. hypodermically; by mouth, 0.1 to 0.6 mg., 0.1 to 0.3 mg. B.P. Maximum dose, 10 mg.

Inejl. A porphine. Hyp., B.P.—1 per cent. Dose, 0.3 to 0.6 c.c., 5 to 10 minns.

A P O C O D E I N

A analogous derivative of codeine, apparently variable in composition and us. Kober finds that it acts qualitatively like apomorphin. Dixon, 1903, as that it paralizes successively the nerve-endings of the vagus, vasomotors, other oth muscle, striated muscle, and cardiac accelerator, as well as the nerve-centers, its action does not seem to be absolutely specific. Magnus, 1905, found both stimud and paralytic peripheral effects on peristalsis. It has been used as expectorant, dt, hypnotic and cathartich (Fraenkel).
ASPIDOSPERMA (QUEBRACHO)

The bark of Aspidosperma Quebracho-blanco, contains several alkaloids with very similar actions: fall of blood pressure, increased heart rate, clonic convulsions with muscular weakness, and a very great and persistent increase of the rate and depth of respiration. The lungs are markedly hyperemic (Harnack and Hoffmann, 1884; Wood and Hoyt, 1901; Wood, 1910). These actions are partly central, partly peripheral. Wood, 1908, attributes the respiratory effect to intense irritation of local areas of the lung, which is observable at autopsy. The alkaloid quebrachin is mainly responsible for this effect. One of the alkaloids, aspidospermin, produces emesis; the others only nausea, with its usual accompaniments.

Cow, 1914, finds that larger doses paralyze the nerve cells of the autonomic system, brain and spinal cord. Still larger doses paralyze the vague, sympathetic and motor endings, similarly to nicotine and curare. Death occurs by paralysis of the respiratory center when the motor nerves still respond to stimulation.

Heuse claimed to have isolated six alkaloids; but of these only two are well characterized, namely aspidospermin and quebrachin, the latter identical with yohimbine. The others were probably impure mixtures and cleavage products (Ewans, 1914).

Aspidosperma has been used as a respiratory stimulant in all forms of dypnea and asthma; but its usefulness is doubtful. Its irritant action on the lungs, and the great circulatory depression should be borne in mind. The dose of the fluidextract is 2 to 4 c.c.; of the amorphous aspidospermin (a crude mixture), 0.06 to 0.1 Gm.; of the crystalline (true) aspidospermin chloride, 5 to 30 mg., at first every hour or two, then less frequently (S. Solis Cohen).

PREPARATIONS—ASPIDOSPERMA

Aspidosperma, U.S.P. (Quebracho).—The dried bark of Aspidosperma Quebracho-blanco. Dose, 4 Gm., 60 gr., U.S.P.

Fliedr. Aspidos., U.S.P.—Dose, 4 c.c., 1 dram, U.S.P.

IPECACUANHA AND EMETIN

General Statement.—Ipecac, the root of a Brazilian plant, contains several alkaloids, of which two, Emetin and Cephalin, produce local irritation and nausea and emesis, by central and local actions, without danger of side effects. The drug is therefore very useful therapeutically. Large doses produce specific effects in amebic dysentery. The systemic actions (central and cardiac depression; stimulation and depression of smooth muscle) do not occur when the drug is administered by mouth, since there is but little absorbed.

Nauseant and Emetic Actions.—These are produced much more slowly than with apomorphin. In man, vomiting occurs only after one-half to one hour. The drug is therefore more useful as a nauseant expectorant than as an emetic. As expectorant, the Syrup is used (1 c.c.). An infusion, used as a gargle, has been recommended to avoid irritation of the stomach. For emesis, the powdered ipecac may be used, 1 to 2 Gm. in warm water, repeated in half an hour if necessary; or the Syrup (tablespoon for adults, teaspoon for infants, especially in spasmodic cough).

It has some advantage over the mineral emetics in that it causes less gastric irritation and less general depression.

Location of Emetic Action.—It has generally been stated that this is purely local, mainly because emesis occurs more promptly on gastric than on hypodermic administration; the efficiency of hypodermic administration being explained by exclusion of the alkaloids into the stomach (Valenti, 1917) and intestines (d'Ornella, 1871).

However, Eyglectic and Hatcher, 1915, found that the emetic dose is nearly the same by either channel; moreover, they observed the occurrence of vomiting movements
IPEAC

525

as evacuated animals. It is clear therefore that the vomiting is of central origin: it was because of the prompt action of the gastric injection, which was confirmed by these observers, it follows that the local action facilitates the emetic response. Emetin and cephalin act alike, except that cephalin is twice as active.

Irritant Action.---Ipecac irritates all mucous surfaces, sometimes to an exaggerated degree. It may therefore produce conjunctivitis, bronchitis, skin eruptions, asthma, diarrhea, rectal irritation, etc. Some persons are extremely sensitive to these effects. In the abraded skin, 1 per cent. solution of emetin raises a wheal (Sollmann and Pilcher, 1916). Hypersensitive patients also react with urticaria to systemic administration ativan and Ativan. (1919).
The subcutaneous dose is but little subject to irritation by ipecac (Zepf, 1903), perhaps because the drug is too rapidly absorbed. Renal irritation occurs rarely.

Use in Dyspepsia.---The gastric hyperemia, produced by small doses, is sometimes utilized in dyspepsias (a drop or two of the syrup in a teaspoon of water, every fifteen minutes). The benefits are doubtful.

Use in Aemic Dysentery.---Ipecac, emetin or cephalin, when administered in adequate doses usually cause the prompt disappearance of all the clinical symptoms, generally with absolute and often permanent disappearance of the entameba histolytica from the stools. The most complete and permanent effects are obtained in early acute cases (Ross, 1916). In chronic cases, relapses and carriers, the amebas occur as resistant, encysted forms, against which hypodermic injections appear to be rather ineffective; oral administration is then distinctly more successful, but may also fail.

The response to the ipecac alkaloids has been attributed to a specific aemebicidal action. This appears to be incorrect; the dysentery ameba tolerating direct contact with high concentrations of emetin. The mechanism of the clinical action is therefore obscure.

Musgrave 1912, and some others, have referred the clinical results to the intestinal irritation, and believe ipecac effective in all forms of dysentery, whatever the etiology. This view has not obtained acceptance.

Harris, 1890, claimed that ipecac more or less freed from its alkaloids ("de-emeticized") is equally effective and less disagreeable. This is now generally denied.

Formerly, the opinions of the value of ipecac treatment were divided; but the later medical investigators are practically in agreement. The older failures are probably attributable largely to faulty administration and inadequate dosage.

Experimental Aemebic Dysentery.---Ipecac treatment proved quite ineffective against the symptoms or course of aemebic dysentery transmitted to kittens (Dale and Dobell, 1917).

Aemebicidal Action.---Entameba histolytica in the stools of dysentery patients are quite unaffected by contact with emetin in dilutions of 1:1000 for one or 2 hours, and even 1:250 often fails to kill in this time (Allan, 1920). Dale and Dobell, 1917, also found that the emetin alkaloids affected the ameba less than quinain, although quinain has little effect on the disease. The older claims of high efficiency (Venter, 1911; Wherry, 1911; Rogers, 1912) were doubtful errors due to the undeveloped technique.

Related Alkaloids.---Pyman and Wenyon, 1917, and Walters, Baker and Koch, 1917, have investigated the efficiency of emetin and its derivatives on cultures, especially of ameba limax. Emetin and cephalin were about equal. Psychotrin was much inferior.

Some emetin derivatives with higher alkyl esters were more efficient than emetin. The action is quite slow, so that some organisms, especially of the encysted forms, are likely to survive when most have been killed. Entameba buccalis often survives on contact with 7 per cent. emetin hydrochloride.

Papaverin and Narcotic.---Emetin is probably an anchoinolin derivative (Windaus), and therefore related to papaverin and narcotic. Pick and Wasicky, 1915, find these opium alkaloids also kill protozoa.

Bacterial Action.---Emetin is fairly efficient in vitro, but acts very slowly and is therefore, useless in vivo (Kolmer and Smith, 1916).

Administration in Dysentery.---Whatever may be the explanation of the ipecac effect, its action must be exerted in the intestines. These are
difficult to reach by oral administration of soluble preparations, for the large dose that are necessary would produce very unpleasant symptoms.

Several methods may be adopted to circumvent this difficulty: Salol-coated pills; diffusely soluble preparations; and hypodermic administration.

Opium Method.—This is now obsolete. A preliminary full dose of opium was followed by 1 Gm. of ipecac every 4 hours; or by 0.5 Gm. every half hour for 6 doses.

Salol-Pills.—These constitute probably the most effective and safest method. A careful technic must be followed; such as the method of S. K. Simon (1908, 1918).

The patient is directed to bed during the treatment (which takes about two weeks), and is kept on a light, mainly liquid diet. After an initial Castor oil purge, he receives a single dose of ipecac, as salol-coated pills, in the evening, three hours after the last meal. The first dose is of 3 or 4 Gm. This is reduced by 0.3 Gm. daily, until 0.5 Gm. is reached. This last dose is then continued for two weeks, and is supplemented by colon irrigations with salt or boric solution. If ulceration has been extensive, the colon is later washed with a dilute silver nitrate solution. Toxic measures are always necessary.

In normal individuals, 3 Gm. of ipecac, given by this method, produces generally diarrhea, lasting some days; often considerable abdominal pain and slight tenesmus (Musgrave, 1920); no depression and rarely vomiting. A patient took 300 gr. in three days without apparent discomfort (Dock and Lyons, 1910).

Direct Intestinal Administration.—Ipecac has also been administered by the duodenal catheter (Boek, 1912), by rectum, and through the stumps of an operated appendix.

Rectal Administration.—Lawson, 1918, claims successful results from an enema of 4 to 8 Gms. of ipecac, suspended in a pint and a half of water.

Diffusely Soluble Preparations.—Two types of these have been introduced: Emetin-fuller’s earth adsorbate; and emetin-bismuth iodid.

Emetin-Adsorbate.—The alkaloids of ipecac are adsorbed by the fuller’s earth. The product ("Allerista ipecac") is insoluble in water and dilute acids and therefore avoids the direct gastric irritation. It was originally claimed that it would be dissolved by the alkalinity of the intestines. This is incorrect (Sollman, 1919). It is now claimed that some of the emetin is dissolved in the intestines in some other manner, perhaps by the soaps (Clowes and Walters, 1910); but there are no data as to the quantity dissolved and the entire absence of systemic effects, clinically as well as experimentally (Eaglestone and Hatcher, 1915) shows that it cannot be large.

Emetin-Bismuth Iodid.—This was suggested by Du Mes, 1915. It contains about 20 per cent. of emetin, and is but slightly soluble in water or dilute acid; but the result is dissolved by dilute alkali (Sollman, 1910). It therefore causes relatively little gastric disturbance, and is often efficient in chronic cases and in carriers. (Report Committee Pharm. and Chem. J.A.M.A, 1918, Dec. 14, page 2925; Critical Bibliography).

Hypodermic Treatment with Emetin.—This was introduced by Rogers, 1912, and has been found more promptly effective and less disagreeable than oral administration (review by Vedder, 1914).

Efficiency.—Even the first injection causes the disappearance of blood and mucus from the stools, decrease of diarrhea, and relief of pain. The symptoms often disappear completely within a week, but other cases are more resistant. Practically all patients unless moribund, are clinically cured. This holds also for the hepatitis. Some retain the amebe in the stools, probably because the emetin does not reach the lamens of the intestines; but they may suffer no symptoms or recurrence. These carriers may be treated by local irritation with quinolin or silver nitrate.

Dosage.—Vedder advises 20 mg., 1/2 gr., of the Emetin Hydrochlorid, hypodermically, three times daily for about ten days. It would be suspended with the cure of the clinical symptoms, and resumed on recurrence. The dose may be increased, if necessary, to 2 or 3 gr. per day. Care must be used that the solution is not introduced into the eye, as it is very irritant (Blue, 1915).
IPECAC

527

effects.—The ordinary dose does not produce any gastro-intestinal or general 
effects, and practically no local reaction if the solution is neutral. The larger 
somes, vomiting, depression and pain—more with intramuscular than 
c. Even 0.25 Gm. at one dose produced only persistent nausea (Allan), 
would not be used, because of its greater emetic action.

Diarrhea.—Bloody diarrhea in consequence of therapeutic hypodermic 
action is probably more common than was formerly supposed; being easily 
for recrudescence of the dysentery. Kilgore and Liu, 1917, describe several 
children who received excessive doses under the mistaken notion that they 
more tolerant than adults.

et al.—A number of toxic and a few fatal cases have been reported clinically 
Collard, 1914; R. L. Levy and Rowntree, 1916; Dalmier, 1917; H. H. 
of Murphy, 1917.)

again exhibit intestinal, paralytic and edemic symptoms. The heart may 
Id. The dangers are greater in disused subjects (Pellini and Wallace, 1916). 
occurrences do not appear to be connected with variability in the commercial 
(Lake, 1916), but appear to be explained by cumulative action. Walters 
1917, found in animals that doses only 3% of the minimal single fatal dose, 
animals when repeated daily for three weeks.

in after Hypodermic Injection.—Emetin appears in the urine within 20 to 40 
the excretion outlasts the treatment by 5 to 9 weeks. It must therefore

in the fatal intravenous dose for rabbits (2.5 mg. per kilogram). The fatal 
a dose is much higher (50 mg. for rabbits).

Inj. of Commercial Emetin Hydrochloride.—The occurrence of two fatal 
led R. L. Levy and Rowntree, 1916, to investigate the toxic effects. They 
ifferences in the toxicity of commercial samples. They describe the toxic 
in animals, and the clinical toxic cases.

in Pyorrhea Alveolaris.—The supposed causation of Rigg’s 
y endamebæ promptly the trial of emetin. Many observers 
good results; but neither these, nor the etiology, are beyond 
Price and Bensing, 1915).

and Barnett, and others, found endameba buccalis constantly present in the 
introduced the local use of ipecac. Bass and Jones, 1914 and 1915, were 
enthusiastic. They report the amebæ destroyed by hypodermic injections 
only for three to six days; or 2 or 3 Alcres, ipecac tablets (each of 0.65 
crad ipecac) two or three times daily by mouth, for the same period. This 
duce nausea, but often some abdominal discomfort or diarrhea. The lesions 
be time to heal, and may become reinfected, when the treatment must be 
prophylactic, they recommend a daily mouth wash of 1 or 2 drops of 
ipecac in a half-glass of water. Evans and Middleton, 1915, also report

Other Parasitic Conditions.—Emetin has been unsuccessful in syphilis, 
panosomes and bacillary dysentery. Marked improvement was reported for 
chmiitler, 1915.

and Tumors.—It has been reported that these may disappear after local 
emetin. However, this is due merely to the caustic action (Lewishon, 1918).

alosis.—Raeburn, 1914, suggests its use (1.5 mg. hypodermically) to lessen 
congestion, expectoration and congestive hemorrhage. The rationale is not 
requires confirmation.

optryasis.—Emetin has been tried in tubercular hemoptysis, the 
eing often favorable, but not very critical. The mechanism is 
1, 1913, claimed immediate arrest after the hypodermic injection of 0.04 Gm. 
pleasant symptoms. The injection may be repeated in intervals of twelve 
hours. Valassopoulos, 1913, used 0.02 Gm. (also in rectal carcinoma).
Nicola, 1914, employing the same dosage as Piandin in hemoptysis, obtained variable results. Apparent success (arrest in forty-eight hours) was obtained mainly in the early stages, with scanty hemorrhage or high blood pressure. Bleeding from venous congestion or with low blood pressure was not influenced.

**Superficial Capillary Hemorrhage.**—Intravenous emetic checks this only as it lowers blood-pressure. Local application increases bleeding (Hamelik, 1918).

**Systemic Effects.**—These occur only after very large hypodermic or intravenous doses. They consist in *paralytic symptoms*, among the earliest in mammals being *sinus motor paralysis* with fall of blood pressure. This is further aided by weakening of the heart muscle due to its direct muscle action (it produces diastolic arrest of the isolated frog heart; Meulliner, 1914). Death occurs mainly by central paralysis. *Systemic and Pulmonary Circulation.*—Pumier and Clermont, 1910, found no effect with hypodermic administration. Non-toxic intravenous injections lowered the cardiac pressure, but increased the pressure in the pulmonary artery and vein, and also the pulse rate. Larger doses diluted the pulmonary vessels, but generally less than the systemic vessels. The heart was also depressed. If the action has lasted any time, the autopsy will show a marked *gastro-enteritis* with ecchymoses and even ulcers. There are also hemorrhages into the lymph glands, spleen, kidneys, etc. (Kilgore and Liu, 1912). However, even fatal doses produce only slight degeneration of the renal parenchyma (De la Pay and Montenegro, 1916).

**Smooth Muscle.**—Maurel, 1914, describes for the intestines, stomach and blood vessels a primary increase of tonus, large doses paralyzing. Pick and Wasicky, 1916, point out that emetin is related to papaverin, in action as well as in chemical constitution. It paralyzes the smooth muscle of the digestive tract, bronchi, uterus, heart and vessels (but small doses stimulate peristalsis). The depressant action is exerted directly on the muscle substance, emetin being mutually antagonistic with harrim.

**Uric Acid Excretion.**—This is increased by ipecac, as by other gastro-intestinal irritants (Abl, 1913).

**COMPARATIVE ACTION OF EMETIN AND CEPHAELIN**

Emetin is methyl-cephalin (Carr and Ryman, 1913). They also describe the chromic properties.

The actions of emetin and cephalin agree qualitatively; but emetin is the stronger amebicide, whilst cephalin is more irritant, more emetic (about twice, Eggleston and Hatcher, 1915; Meltzer, Eckler and Koch, 1917) and about twice as toxic (Podwyssotski, 1879; Wild, 1895; Paul and Cownley, 1901; Lowin, 1902). Emetin was said to be more depressive to the heart, and cephalin is somewhat hemolytic.

**Other Cephalin Esters.**—Walters and Koch, 1917, tested a series of derivatives. They found only quantitative differences.

**Psycotrin.**—The third alkaloid of ipecac is also chemically related to cephalin. (That is, it contains 2 atoms less of hydrogen). It has a very low toxicity (Walters and Koch). The amount in the drug is small and unimportant. Lloyd has announced a colloidal alkaloid ("Kryptonin") in ipecac.

**IPECACUANHIC ACID**

A further constituent, ipecacuanhic acid was, until recently, considered a heart of the action of ipecac in dysentery. It has been shown, however, that this tannin is inactive. The ipecacuanhic acid possesses all the chromic characters of caffeic acid (see Index), from which it differs only by one atom of oxygen. The pharmacological action of these two tannins also agree perfectly (and differ from ordinary tannin) as they are neither antiseptic nor astringent (Kimura, 1903).

**IPECACUANHIN**

Ipecacuanhin is a crystalline glucosidic constituent (Finnemore and Braithwaite, 1912).
IPECAC

PREPARATIONS—IPECAC

"Ipecacuanha (Ipecac.), U.S.P.; Ipecac. Rad., B.P.—The dried root of Cephalis ipecacuanha (Psychotria ipecacuanha, B.P.), Rio Ipecac. The U.S.P. also recognizes rhizome Ipecac from Cephalis acuminata. Ipecac must yield not less than 1.52 cent. of alkaloids, U.S.P.; 2 per cent., B.P.—Walters and Koch, 1917, find that both species contain about twice as much emetin as cephalin. The drug was introduced into Europe about the end of the seventeenth century. Dose, as Emetin, 1 Gm., 1/4 gr.; as Ipecac., 2 Gms., 1/2 gr., of the powder, stirred into warm water. As expectorant, etc., 0.03 to 0.12 Gm., 1/8 to 1/2 gr., B.P.

"Ipecac. Syrup of the U.S.P. is only 1/2 the strength of the U.S.P. Ipec. Ipecac., B.P.—0.015 Gm., 1/8 gr.

"Ipecac, B.P.—1 per cent. Dose, 0.06 to 0.08 cc., to 10 minims; as Emetin, 0.20 cc., 4 to 6 drops, B.P.

"Emetine Hydrobromatum (Emet. Hydrobrom.). U.S.P.; C₂H₁₈N₂O₂·2HCl.—Consists of variable amounts of water of crystallization. White or yellowish crystalline der. Freely sol. in water or alc. Dose, 20 mg., 1/4 gr., U.S.P., hydromed, by th., as Expectorant, 5 to 10 mg., 1/2 to 1/4 gr.; as Emetic, to 10 to 20 mg., 1/4 to 1/2 gr. Care must be used to keep it from contact with the eyes, as it is highly irritant. Emetine Bisulphuricum, N.N.R.—Odorless, orange-yellow powder; somewhat bitter but slightly soluble in water or dilute acid; emetin is liberated by dilute alkali. 0.2 Gm. (5 grains), daily for four days, administered in capsules, with meals. Cephalina, N.N.R., C₁₉H₁₈O₄N.—Dose, 5 mg., 1/12 to 1/8 gr., in pills or as powder in sugar. Chaparro Amargosa (Sinuarbaceae), a Mexican plant (Castella Nickolsonii) has a used in amebic dysentery, with successful results, and without bad effects. The emetin in it is said to act by throwing off bile and thus increasing the flow of mucus. It affected cures in cases that had been refractory to emetin (Shepherd and Lillie, 1916). Seidler and McVier, 1918, isolated a product toxic to small animals, which is aptly glucosidal. They also give an abstract of the early literature.

THERAPEUTIC USE OF NAUSEANT EXPECTORANTS

Small doses of emetics produce only some increase of the bronchial salivary secretion and sweat, which is useful in the early, congestive dry stage of colds and in dry coughs. The dose should be sufficiently small to minimize general depression and noticeable gastric distress, although this sometimes can not be avoided. The nauseants sold be given every two to four hours. For the “abortion” of colds, ipecac is often employed in the form of “Dover’s Powder,” 0.5 Gm, at night. In the congestive stage, the use of ipecac may be used. Tartar Emetic may be substituted, but is less depressant, and its continued use may give rise to poisoning. Its expectorant dose is 5 mg. (1/4 gr.) or 1 c.c., 15 minims of the Vinum timonii (= 4 mg., 1/12 gr.). This is also one of the constituents of Mistura Glycyrrhiza Composita.

Vesic, adherent mucus may be thinned by Ammonium Chlorid or Druside (0.2 Gm.); or Potassium Iodide (0.2 Gm.); or by the irritant tincture of Syrups Senece (2 c.c.). The Compound Syrup of Squill c.c. savors of “shot-gun” prescribing.
The reactions of the salivary center have been studied by V. E. Henderson, 1910. He finds that this is readily depressed by anesthetics and by morphine, even in small doses; iodides and other salts do not cause acute stimulation, but may act reflexly. Emetis stimulates both directly and reflexly, also ammonium salts, but with these the reflex stimulation is the more important. Antimony acts only reflexly, Apomorphine only centrally.

_Bronchial Secretion._—J. L. Miller, 1914, could not demonstrate any effect with therapeutic doses of emetin, ammonium chloride or carbonate. Large doses produced an increase, even when administered by duodenum.

Site of Action of Miscellaneous Emetics.—This has been investigated by Eggleston and Hatcher, 1915. A drug may be considered to act directly on the center if emesis occurs with smaller doses and more rapidly when the drug is given by vein than by mouth; and if the phenomena of nausea and the motions of emesis occur after the whole alimentary tract has been removed. According to these criteria, they found that the emetic action of most alkaloids is central; namely, apomorphine, morphine, nicotine, lobeline, acosin, veratrin, pilocarpin, quinin and ergot; as also picrotoxin, digitalis, and sodium salicylate. With ippea, the local action probably contributes to the result.

**LOCALLY ACTING EMETIC**

The afferent paths which may reflexly stimulate the vomiting center are very numerous; but for practical therapeutic purposes only those of the pharynx and gastric mucosa are available. Not every form of gastric irritation results in vomiting—the kind, rather than the degree, of irritation being important. This, and the necessity of avoiding severe local and systemic effects, limits the number of irritants which may be used as therapeutic emetics. However, there is still a wide choice, adapted to the various indications.

**CUPRI SULPHAS AND ZINCI SULPHAS**

These act practically alike, provoking the vomiting reflex before there is time for any other local irritant action. They are not absorbed (unless the stomach is corroded), and therefore do not lead to any systemic effects. Vomiting occurs with certainty in a very few minutes. The nausea is therefore short, and the after-depression is small, constituting an advantage over apomorphine. They are especially useful to empty the stomach of indigestible food or poisons (provided that these are not corrosive). Copper sulphate is of especial value in phosphorus poisoning if any of the poison is still in the stomach, since the metallic copper is precipitated and forms an impermeable coating over the unabsorbed phosphorus particles.

The emetic dose of copper sulphate is about 0.25 Gm. in 1 per cent solution; that of zinc sulphate is about 1 to 2 Gm. They may be repeated in fifteen minutes if necessary.

**MUSTARD**

A teaspoonful of powdered mustard in a cup of warm—not hot—water, repeated every fifteen minutes is a rather uncertain emetic, but a useful emergency remedy in poisoning, when the patient is already disposed to vomit. Salt water, or even plain warm water, or tickling of the fauces, may be similarly useful.

**ANTIMONY**

In the form of Antimony and Potassium Tartrate (Tartar Emetic), antimony acts similar to Copper, by a purely local effect, but its use should be avoided, since it is very depressing. It is fairly easily absorbed, so that 0.2 Gm. has repeatedly proven fatal. The ordinary emetic dose is 30 mg.; and if this not effective in half an hour, it would be well to give tannin as an antidote.
EMETICS

occur with Digitalis, Squill, Apocynum, the Salicylates, Senega and a
number of other drugs. The action may be local or central, often both.

THERAPEUTIC USE OF EMETICS

Emetics are employed especially for the following purposes:

Acute Poisoning.—The need for evacuation of the stomach, and
lative advantages of gastric lavage, has been discussed under the
l Treatment of Poisoning (see Index). It must be remembered
etics are ineffective in profound narcosis (by chloral or chloroform,
ck, 1874; by morphin, bromid, etc.).

Acute Indigestion.—Here also lavage would deserve the preference,
omorphin is often very effective in exposing malingering.

remove solid bodies from esophagus, pharynx, or upper air-passages. How-
cording to de la Pza and Garcia, 1910, emesis does not dislodge solid bodies
ere trachea or bronchi, but may drive them deeper. Plugs of mucus, however,
displaced by increased secretion of mucus. Emesis may cut short an attack of
(Hoover and Taylor, 1912). It may also arrest paroxysms of tachycardia.
ause compression of the liver, for the removal of bile and small gall-stones from
l-bladder and ducts: The usefulness of this measure is doubtful; since the
es are also compressed, the added vis a tergo can not be very effectual, and on
er hand it might rupture a distended gall-bladder.

ntraindications to Emetics.—These are mainly due to increase of
re and to debility, and are as follows:
Severe heart-defects, or aneurism of the aorta, since the sudden and
crease of intrathoracic and intraabdominal pressure may result
rupture of these organs.
Atheroma. The sudden changes in blood pressure are apt to burst
el and produce apoplexy.
Similarly, they may lead to hemorrhages in phthisis.
Abortion may result, in advanced pregnancy.
Tendency to hernia.
In all debilitated conditions there is danger of collapse.
Caustic poisoning.

THE PHARMACOLOGY OF HEAT REGULATION

eral Statement.—In warm-blooded animals, any departure from
ormal temperature disturbs a variety of functions more or less
indly. These disturbances tend automatically to restore the nor-
temperature. Heat production and heat dissipation both have a
in this regulation, and may be brought into play either directly,
ough reflexes. The automatic compensation or regulation is very
under ordinary conditions and with normal animals. It may
c inadequate if any of the factors entering into it are powerfully
, whether this alteration be central or peripheral. The tempera-
ture thus rise or fall. The changes usually involve several factors,
secondarily. These vary with conditions, which are often difficult
tyze. Many of our data are therefore incomplete, confusing and
contradictory.

prehensive bibliographies can be found in the review of O. Loewi, Ergeb. Physiol., 1904;
Calhoun, Harvey Lect., 1908; and Kreidl, Pathol-Physiol.
It is attractively convenient to assume a special heat regulating mechanism—a physiologic, if not anatomic “heat center.” This would be located particularly in the corpora quadrigemina, but diffused more or less throughout the whole midbrain. The center could be conceived as a sort of thermo-regulator which is ordinarily “pitched” for the normal temperature, but which may be adjusted, by stimulation, to maintain a higher temperature; then brought back by depressants to its normal pitch, or perhaps even adjusted lower. However, there is no hiding evidence for such a specialized “center,” and its acceptance is not necessary for the explanation of the phenomena. Indeed, it may rather interfere with a clear understanding of the facts. On the contrary, the mechanism of heat regulation may be conceived as analogous to blood-pressure regulation; any departures from the normal will alter the physiological conditions, and therefore the functionation of a number of organs and centers; and these alterations generally tend to restore the normal level of the temperature.

Many of these facts belong rather to the domain of physiology and pathology, but it may not be amiss to summarize those which are necessary for presenting the pharmacologic phenomena.

**Heat Production.**—Heat is evolved in the destructive metabolism of the tissue, particularly the muscles and glands, and this furnishes the “chemical factor” in heat regulation. The production of heat is thus a part of ordinary metabolism. It may be increased by greater activity of the organs; as by digestion, by muscular work, or even by increased muscular “tone.” It may also be increased by overfeeding and by injury and other destructive changes, as, for instance, the increased tissue destruction in infectious fevers.

Conversely, the production of heat may be diminished by reducing metabolism; by quieting the muscular movements with morphin; by lowering their tone with ether; or paralyzing them with curare; by starvating or by depriving an animal of its glycogen; by reducing nitrogen-metabolism with quinina; by reducing the circulation by vasodilator or cardiac depression (collapse), etc.

**Importance of the Chemic Regulation.**—This may be judged by the fact that animals become practically poikilothermal when they are paralysed by curare (Phrey, 1876) or by high section of the cord; that glycogen-free animals are not rendered torpid by “heat puncture,” etc.

The “Specific” heat production (as distinguished from that incidental to ordinary physiological activity) is doubtless under the control of the central nervous system, the muscular tone, for instance depends on the spinal cord. The special relation of the corpora quadrigemina to heat production is seen in “heat puncture.”

**Heat Dissipation.**—Heat is lost mainly by the respiration and skin—partly by losing the air, and partly through the aqueous vapor of the lungs and perspiration. The relative importance of these channels of heat loss differs in different animals and in the same individuals, according to circumstances. In man, the skin is the chief means of regulating the heat-loss; this would be increased by cutaneous vasodilatation and by diaphoresis. These are therefore the “physical factors” of heat regulation. On account of their quick response, and lesser interference with the body at large, they naturally constitute the main means of regulation under ordinary conditions. Vasodilatation of the cutaneous vessels may be brought about directly by the local application of heat and cold; but this also acts reflexly—so that the entire skin responds to strictly local variations of temperature. The regulation of sweat is predominantly central; but the quantity of available fluid in the body is also an important item (Barbour and Howard, 1912).

**Regulation of the Heat Loss Through the Skin.**—This generally involves a specific action, central or peripheral, on the tone of the cutaneous vessels, often combined with the opposite change in the tone of the systemic vessels. Such changes are a conspicuous feature of the various fevers, and may take either direction. The pyretic agent may conceivably act either directly on the controlling center; or indirectly, by calling for compensation against altered heat production, etc. The cutaneous circulation may also be influenced by a specific central action of certain drugs, especially in the sense of vasodilatation. This is seen most typically with antipyrin and the related antipyretics.
The Hypothetical Thermoregulating Centers.—The heat regulation is disturbed by perative interference with certain parts of the central nervous system. High section of the spinal cord destroys heat regulation completely. Ablation of the cerebral hemispheres has little effect. Traumatic or electric irritation of various parts of the midbrain (partly the corpus striatum, optic thalamus, and the postero-bulbar junction) reduces a rise of temperature (Hale White, 1890).

Direct Application to Heat Centers.—Heat regulation is markedly affected by the direct application of heat, cold, or drugs to the region of the caudate nucleus. The temperature is thus raised by cold, corrosive poisons, caffeine, etc.; it is lowered by heat, chloral, antipyrine or quinin applied to this region (Barbour and Wing, 1913; Coott and Waser, 1914; Hashimoto, 1914; Prince and Hahn, 1918). Indeed, the effects are more effective in this way than intravenously.

Influence to the corpus striatum of rabbits diminishes the oxidative metabolism and the respiratory volume; local cooling of this region produces the opposite effects, also shivering and fall of body temperature. The oxidative changes are contributory causes, rather than effects of the change of body temperature (Barbour and Prince, 1914).

Heat Centers of Rabbits.—Inschmidt and Schnitzler, 1914, find the tuber cinereum the most important. The efferent fibers lie in the caudal portion of the midbrain, widely scattered over the ventral and median parts of the cross-section.

The tuber cinereum is not the only center concerned in temperature regulation; but this fails if this portion is destroyed, whilst the preservation of a part of the fibers suffices for the function.

The fever produced by cooling of the corpora striata is accompanied by vasomotoric stimulation in the hind limb, chiefly of the skin vessels. This would diminish heat loss and thus contribute to the fever. Heating of the center produces the opposite effect (Prince and Hahn, 1918).

Direct Heating and Cooling of Center on Response to Drugs.—This has been investigated by Hashimoto, 1915. He found that it has no influence on the febrile reaction to tetra, ephedrine or large doses of coca (sympathetic stimulants); but that it modifies toxins, and particularly emetine, fever.

The antipyretic action of antipyrine and salicylate is markedly increased by heat, removed by cold. After quinin, heat is effective, cold not. Morphin removed the response of heat and cold.

Direct or Incidental Regulation.—The fact that the corpus striatum or tuber cinereum is intimately concerned in heat regulation has been taken as evidence that the regulation of heat is centralized in these divisions of the midbrain. Strictly speaking, however, it proves only that these lie in the nervous path of some of the factors concerned in heat regulation; the heat changes might be an incidental, rather than a specific part, of their function.

The evidence for the "temperature centers" is not absolutely convincing, and their existence has been questioned by many investigators. The literature is reviewed by L. M. Moore, 1918. She showed that the puncture and similar fevers are rather the result of general operative procedures; and that rabbits maintain a normal temperature after the caudate nucleus have been destroyed.

Such and Green state that faradic stimulation of the caudate nucleus does not produce any temperature changes, in animals or human.

Apparent the strongest argument for a center, or set of centers, having for their specific function the regulation of the temperature, lies in the surprising accuracy and adaptability of this regulation. The maintenance of a constant temperature seems to call for a thermo-regulator of some sort. Even more impressive is the remarkably efficient, we might say intelligent, adaptation of the means to the end. Of the numerous possible ways of compensating any departure from the normal heat production or dissipation, the organism seems to choose that which will most effectively and conveniently accomplish the purpose, under the given set of conditions. This holds not only for the maintenance of the normal temperature, but whenever there is a departure from normal, there is a similar efficiency; when the temperature is to rise in fever, the rise is accomplished, on the whole, by a judicious selection of the most effective or convenient means; if the acme, the interplay is readjusted, most intelligently, to preserve this higher temperature; and when it comes time for the temperature to fall, the choice of means is made with similar wisdom.
In brief, we appear to have a thermo-regulator, adjustable to various temperatures—
to 37° in health; to 40° in fever; to 37° again by antipyretics; and this regulator works
with a discriminating judgment and choice of means which seems to demand a superior
order of intelligence and "free will." These psychologic attributes being scarcely
conceivable in a physiological function, the very perfection of the mechanism tends to
become a reification of a specific heat-regulating center.

Analogies of Blood-pressure Regulation.—One must turn to a simpler explanation; and
here a pretty fair analogy presents itself in the maintenance of the normal blood pressure.
This also involves a number of factors—the work of the heart and the tone of the
vessels—which may be altered in a number of ways. When one of these factors is
altered, compensatory changes occur in the other factors, so that the resultant blood
pressure is generally fairly level, just as is the temperature; and like the temperature,
its height or "pitch" can be "attuned" to various levels. The essential features of
blood-pressure regulation therefore appear quite analogous to those of heat regulation,
but no one speaks of a specific "blood-pressure center." The difference lies in this, that
in the case of the blood-pressure regulation, we have a fair knowledge of the factors
involved, whereas with the heat regulation, our knowledge is much less. One differ-
ence may be urged between the two functions, namely, that the temperature runs much
more constant than does the blood pressure. It is dangerous, however, to institute
quantitative comparisons between two things whose nature is so dissimilar. But even
if this difference be important, it need only mean that the compensating functions are
affected more powerfully by changes in temperature than they are by changes in blood
pressure, which is likely enough. The essential thing in either case is this: that the
regulation is not effected by a specific presiding center; but that changes in any one
factor alter the physiologic state of all the other factors, central and peripheral, and thus bring
about changes in their function, which generally result in compensation; and these changes
continue until the original physiologic state of all the factors is restored; that is until the
whole condition has returned to the normal.

It is scarcely necessary to add that the share, and therefore the practical importance,
of the different factors is unequal. In this sense, we may speak of the corpora nigrna
as one of the important "heat centers," meaning thereby only that they have a very
important relation to heat production; but in the same sense, the center of the cutaneous
vessels, and for muscular tone, or for convulsions, are also important "heat centers."

It is one advantage of this conception, that it emphasizes the impartial study of the
actual phenomena of heat regulation. These are complex enough, but one may hope
to trace, eventually, the primary cause, the starting point, of a given change, and the
changes and changes to which this gives rise. These will vary under different
conditions, each of which will need to be investigated by itself. This accounts for the
many imperfections of our knowledge and for the many apparent contradictions. It
will therefore be wisest to restrict ourselves to those data which are pretty definitely
established.

Methods of Studying the Mechanism of Heat Regulation.—Calorimetric
measurements give the most comprehensive information of the relation
of heat loss and heat production. The calorimeter gives directly the
quantity of heat lost; and from this, and the changes in internal tempera-
ture of the animal, the heat production can be readily calculated. The
share of the nitrogen and carbon metabolism in the heat production may
be deduced from the nitrogen and carbon dioxide excretion, and from the
consumption of oxygen. The changes of the cutaneous vessels and their
share in the heat loss may be deduced from direct inspection of the skin,
from comparison of the dorsal and internal temperature, and from
plethysmographic observation. The means for localizing the effects
centrally or peripherally will be discussed as occasion arises.

REACTIONS WHICH RAISE THE TEMPERATURE (PYRETICS)

Any increase of heat production or diminution of heat loss would
tend to raise the temperature; but ordinarily, the tendency is offset by
compensatory reactions. A significant rise of temperature, i.e., fever,
will occur only if the change exceeds the capacity of compensation, either
because it is extraordinarily great or because it involves more than one factor. This break in compensation may be caused by a large number of agencies, acting through different mechanisms; only a few of these need to be considered here.

**Heat Puncture.**—The essential element of "puncture fever" seems to be increased heat production, by increased carbon metabolism, especially of hepatic glycogen. The compensatory heat loss is not adequate; but it is not known whether this disturbance is direct or indirect.

I. Ott; Richtet; and Arsoohn and Sachs, 1884 to 1885, nearly simultaneously discovered that a stab into the corpora striata of rabbits causes a rise of temperature, lasting in a few hours, reaching a considerable height, and lasting for some days (Tschic in Arsoohn and Sachs). The effect can then be repeated by a fresh puncture of the skull if the destruction is extensive. It can also be evoked by electric stimulation of its region, so that it consists evidently in the stimulation of a function concerned in heat evolution.

**Relation of Heat Production and Dissipation.**—Calorimetric experiments show that the rise is due to increased heat production (Richtet, 1893), with partial compensation by increased heat loss. During the ascent, the heat formation and loss are both increased, but the loss lags behind. When the high level is reached, the heat formation lessens somewhat, and the dissipation increases, so that the temperature runs constant. In the descent, both decrease, but especially the heat formation (Schultze, 1890).

**Mechanism of the Increased Heat Production.**—This is due to increased carbon metabolism (increased CO₂ excretion). The nitrogen excretion may also be increased but this is not essential, and is probably secondary to the hyperpyrexia.

The rise occurs in cataralized animals (Hirsch and Mueller, 1903) so that the muscular metabolism is not essential, though it may play a part. Glycogen-free animals do not show a rise (Kolly, 1903). The liver temperature is high. These facts indicate that puncture acts mainly by increasing the hepatic metabolism. Walbaum, 1913, however, believes that the main factor is central stimulation of the cutaneous vessels.

**Regulation.**—The uniform course of the temperature shows that the disturbed functions have struck a balance—in other words, that there is some "regulation." When the temperature is lowered artificially, by external cold or by antipyretics, it recovers its former high level (Schultze).

The Ponto-bulbar "Center."—Tschichichin, 1866, observed that the temperature rises when a section is made at the junction of the pons and medulla; the same result follows electric stimulation of this region (Heidenhain, 1870) and irritation of various other parts of the midbrain.

**The Hyperpyrexia of Infection.**—The essential element of infective fever appears to be a disturbance of the central tone of the cutaneous vessels rather than the heat loss absolutely or relatively inadequate. The heat production, and particularly the nitrogen metabolism, are generally increased; but this is not essential, and does not exceed the limits which are easily compensated in normal animals.

**Heat Production.**—In the ascent, this is generally increased; but it may be normal or even diminished. The same holds true for the plateau. In the descent, it is generally diminished, particularly if the fall occurs by lysis.

Increased heat production is therefore a characteristic, though not a constant feature of the rise; but this does not prove that it is the essential cause of the rise. The greatest increase is witnessed in the initial chill, and is largely due to the shivering movements. This ceases disappears as the temperature rises; but now the increased activity of the heart and respiration furnish further causes for increased heat production. The higher temperature of the body must also accelerate oxidation. The toxins of the infections undoubtedly cause more or less cell destruction, and this material must be oxidized. A large share—possibly all—of the increased heat production is thus purely incidental; yet whilst it doubtless facilitates the rise of temperature, it cannot be considered as the essential element.

**The site of the heat production** is the same as in normal animals; for the temperature of internal organs show the same relation as in health—the liver, for instance, being the warmest. From this it can be affirmed that the glands and muscles both participate
in the increase, but not necessarily in the normal ratio—presumably this would differ according to circumstances.

Oxidation.—The energy for the increased heat production is furnished by oxidative changes; and with adequate food, the main source consists of non-nitrogenous material. The glycogen in particular tends to disappear. However, the nitrogen metabolism shows a characteristic relative increase from a number of causes.

Total Nitrogen Excretion.—Increased nitrogen metabolism is a nearly constant feature of infectious fevers. The increase, however, does not run parallel to the fever; it may start before or after the rise; and it generally reaches its maximum after the fever has started to decline. It must therefore be an incidental, rather than an essential feature of the process.

Explanation of the Febrile Increase of Nitrogen Metabolism.—The increased nitrogen excretion denotes increased tissue destruction. Simple overheating also increases the nitrogen excretion, but relatively much less than in fever, and this may be accounted for by the partial inanition, which is so commonly enforced in fever; Indeed, the nitrogen loss can be entirely prevented by an ample diet; but to do this requires more food than in health. It may therefore be accepted that the nitrogen excretion in fever is always greater than that for the same diet in health. This leaves as the only explanation, direct toxic effects of the infective agents, leading to cell destruction.

Intermediate Nitrogen Metabolism.—Very little is known as to whether this takes the same course as in the normal. Presumably it is somewhat different; for the urea excretion is relatively low (though the absolute value may be high); whilst ammonia, uric acid, purin bases and creatinin are relatively high. The urine often contains creatinin, albumen, acetone bodies, oxazid, etc.

Protein-quantiy of Serum.—The albumin-glubamin ratio of the serum is not altered by the rate of nitrogen-metabolism; for it undergoes no change after thyroid administration, which accelerates metabolism; nor after quinin or sodium calodylate, which retard it; nor after antipyrexa through antipyrin and coal tar antipyrine (Harrison and Mc Quran, 1917).

The Course of Heat Dissipation.—The heat loss is always deficient in infectious fevers, although not in the least relative; and this deficiency or failure of the heat loss to compensate the heat production, must be considered the essential factor in the high temperature. In man, these changes run parallel with the cutaneous circulation—a pale, cold skin, implying a diminished heat loss; and the converse (Kraus, 1891; Maragiano, 1888).

In the ascens, the heat loss is conspicuously decreased, leading to the characteristic "cold" of the sepsis; the vasoconstriction cooling the skin, whilst the internal temperature is high.

During the continuance of the fever, the loss is generally increased, absolutely, as partly to balance the increased heat production—but the increase of heat dissipation is small as compared with what would occur if a normal animal were producing the same amount of heat. One may therefore say that the dissipation remains relatively decreased. In the descent of temperature, the heat loss is increased relatively, as well as absolutely. This is the main element of the "fall by crisis." Alteration of the Ration of the Cutaneous Vessels.—The altered behavior of the cutaneous vessels, which seems to be the essential element of fever, finds expression in other directions. They are more easily affected by chemical and mechanical irritation (Baumel, 1873); they constrict more strongly in response to reflexes (Heidenhain); they are apt to undergo alternate contraction and dilatation, with little apparent cause; a slight degree of cooling produces chilliness, etc. These phenomena all indicate that the innervation of these vessels is disturbed.

Anhydremia.—Fever is often paralleled by diminished water content of the blood, as indicated by increased solids and hemoglobin. This would interfere with perspiration and thus with heat dissipation. Conversely, the injection of dextrose tends to be antipyretic by producing hydremia (Barbour and Howard, 1920). This may be the basis of the old use of alkalies as "refrigerants."

Heat Regulation in Fever.—The fact that heat regulation is disturbed—because one or more of its factors are disturbed—does not mean that all regulation is abolished. The disturbed functions will eventually find a new level, so that fevers generally run a more or less regular course, which is interrupted by adventitious changes, but an adjustment, generally in the same direction as in normal animals.

Fever shows the normal daily variations, the rise during the day, and the fall during the night; although these variations may be smaller or larger than normal.
Artificial cooling and heating and the administration of antipyretics provoke the same compensatory reactions as in health, though these are less effective. The febrile temperature can therefore be more easily lowered or raised, the changes are more extensive and more lasting; but when left to itself, the temperature will tend to assume its original level. It might therefore be said that the temperature of fever is adjusted to a higher level (Liebermeister); which means nothing more, however, than this: that when the altered functions become constant, the resulting temperature must also become constant.

**Localizing of the Febrile Process.**—Considering fever as being essentially due to disturbed innervation of the cutaneous vessels, the site of action would presumably be the centers controlling the tone of these vessels. In accordance with this it is found that fever does not occur when these centers are cut off by high section of the cord, or if they are paralyzed by deep narcosis, or even if they are depressed by the antipyretics.

**Heat Centers in Anaphylaxis.**—In sensitized animals, the injection of the specific antigen into the heat-puncture region produces fever. This does not occur in normal or immunized animals. The centers therefore are specifically sensitized in anaphylaxis (Hirshimmer, 1915).

**Comparison of Heat Puncture and Infective Fevers.**—These two forms of fever have considerable resemblance. Both may show increased heat production with inadequate heat loss; but in puncture, the production seems to preponderate; in infections, the disturbance of heat loss. Both forms are central; both react similarly to antipyretic drugs.

**Indirect Hyperpyretics.**—Quite a large number of substances are apt to set up fever, particularly on subcutaneous injection in rabbits; and in infants, in which the temperature is more labile. To this class belong plain saline solution or plain water, albumose, egg-white and other proteins, irritants, etc. Many of these produce albumosuria (Krehl) and they probably act by causing tissue decomposition, with the formation of products (albumoses, etc.) which act similarly to infections.

**Tetra-hydro-beta-Naphthylamin.**—This substance produces a very considerable rise of temperature, with increased heat production and diminished heat loss. It is not known which is the essential element. The hyperthermia differs from infective fever and heat puncture in that it is not reduced by the ordinary antipyretics, but only by profound narcosis.

**Composition, Dosage and Efficiency.**—The substance has the structural formula

![Chemical Structure](image)

The subcutaneous injection of 0.04 to 0.05 Gm. raises the temperature 38 rabbits several degrees, the rise starting in an hour and persisting over four hours; but it fails completely in some animals. Dogs react similarly. In man, non-toxic doses do not produce a rise.

**The pyrexic efficiency of various derivatives has been studied by Wasde, 1919. The non-methylated base is more active than the ordinary "tetra."

The phenomena have been extensively studied by R. Stern, 1889 and 1900; Hale White, 1892; Sachseff, 1909; A. Black, 1911; Feri, 1911, and others, but without clearing up the mechanism of its action. Clotetta and Waier, 1913, have investigated its derivates to compare the structure and actions.

**Other Actions.**—Aside from the rise of temperature, it produces dyspnea and restlessness, sometimes convulsions. It revives rabbits from light chloral sleep (Ariila, 1913). It wakens even decerebrated animals from chloral sleep—whilst coca and caffeine have this effect only on normal animals (Morita, 1915). It also has important sympathomimetic actions (Jonescu, 1909): Stimulation of the cervical sympathetic (hydrasias, exophthalmos); a general vasomotor action involving both cutaneous and venous vessels (rise of blood pressure), mainly of peripheral origin. It has a moderate peripheral dilator effect on bronchioles (Jackson, 1914). Elliott, 1914, describes the rapid production of gastric ulcers in rabbits from hypodermic injection.

**Mechanism of Pyresis.**—Calorimetric observations show increased heat production and diminished heat loss. The latter is perhaps explained by the vasconstriction; and
the increased heat production may possibly be ascribed entirely to the increased muscular movements. In accordance with this, the carbon dioxide excretion is greatly increased, whilst the nitrogen excretion is but little affected. The heat production is apparently the main element in the rise, for curarized or deeply morphinized or etherized animals do not respond to the drug (Mutch and Pembrey, 1911). The temperature rise in the medulla, for no fever occurs if the carotidis have been blocked by paraffin (Ott and Scott, 1928).

To what extent therefore the effects resemble those of heat puncture; but whilst the puncture fever is readily lowered by antipyretics, none of these, i.e., quinin, antipyrin, etc. or small doses of morphin, have any marked effect on the tetra-fever (Feni, 1911).

Cocain Hyperthermia.—The effects of cocain, so far as they have been analyzed, appear to agree with those of Tetra-hydro-naphthylamin.

The rise of temperature is due essentially to increased heat production, mainly from increased movements, for these go parallel (Richet and Langis); and the rise can be prevented by curare or chloral, but not by the ordinary antipyretics (Mosso). The heat dissipation is slightly increased.

The cocain fever does not occur after excision of the caudate nucleus, suggesting that its action is at least in part upon the same nervous centers which are concerned in "heat puncture."

Atrofin Hyperthermia.—This may fairly be attributed to the muscular excitement, and to the suppression of sweat.

Caffein Hyperthermia.—Large doses of caffeine produce a slight degree of fever (Bina, 1878; Ficher, 1927). This could be explained by the increased muscular use and by the dilation of the intestinal and consequent constriction of the superficial vessels.

Muscular Exercise.—All muscular movements increase the production of heat. In health, this is nearly compensated by increased heat loss (sweating, etc.), so that the temperature is but little increased.

Convulsives.—All convulsive poisons (santonin, picrotokin, strychnin) produce characteristic changes in heat regulation. Small doses cause increased heat loss and a slightly smaller heat production. Larger doses cause increased metabolism, though muscular action, and hence increased heat production, which is accompanied by a further increase of heat loss. Paralytic doses diminish the heat production very greatly. The temperature is accordingly variable: Small doses tend to lower it; moderate convulsive doses increase it; paralytic doses lower it greatly. The heat loss is particularly conspicuous in small and young animals, whilst larger animals tend to show a rise of temperature, with moderate doses (Harneck, 1909). In traumatic tussis, thernic fever, etc., the temperature may rise greatly, usually when there is a general disturbance of heat regulation.

Excessive External Heat.—This diminishes the heat dissipation, and thereby tends to raise the temperature. This calls forth the compensatory reactions—sweating, cutaneous hyperemia, quickened respiration, etc., mainly through the direct action of the heated blood on the centers (e.g., Moorehouse, 1911). This is seen when the internal temperature departs but a fraction of a degree from the normal; about as readily in fevers as in health. The compensation is more or less effective for a time. When it breaks, there results the phenomena of "thermic fever."

REACTIONS WHICH LOWER THE TEMPERATURE (ANTIPYRETICS)

The temperature may be lowered by anything that lessens heat production or increases heat loss. Here again, as the temperature tends to fall below normal, compensatory reaction are set up, which ordinarily suffice to keep the temperature at the normal level. Indeed, it is highly difficult to depress the temperature materially below the normal, except by means which effect profound and extensive changes, such as deep narcosis general vasomotor paralysis, or other collapse conditions.

On the other hand, it is relatively easy to lower an abnormally high temperature; for this coincides with the natural tendency to return to the normal physiological state—a tendency which must be always present, even in fever, although it is not effective unless supported by extraneous means.
HEAT REGULATION

Accordingly, the practical antipyretics become such only when the emmurance is excessive. They have very little influence on normal temperatures, partly because their effects would result in more powerful compensations and partly also because the primary effects themselves are less powerful when they have to overcome a normal state, than when they are assisting an abnormal state to the normal.

Response of Slight Hyperpyrexia.—The increased response to antipyretics is not confined to high temperatures, but occurs also in infections when the temperature averages but little above normal, such as chronic tuberculosis, osteomyelitis and emphysema (Barbour, 1919).

Action of Therapeutic Antipyretics.—The therapeutically available antipyretics act in several distinct ways: The application of cold (baths, etc.) results in the direct abstraction of heat; antipyrin, acetanilid, phenacetin, etc., increase heat dissipation by dilating the cutaneous vessels; their action is central and consists presumably in a specific depression of the central tone of these vessels. Quinin diminishes heat production by a direct (peripheral) depression of nitrogenous metabolism. Aconite and arsenum probably lessen heat production by slowing the circulation.

Relation to Heat Centers.—All the antipyretics depress temperature very effectively when applied directly to the cutaneous nuclei (see page 440). When the central control is excluded, quinin is still antipyretic, while antipyrin and salicyl tend to raise the temperature (Ieschmisch, 1913; Barbour and Deming, 1913).

Hyperpyrexia and Hydremia.—Several antipyretic drugs, i.e. salicylates, quinin, antipyrin produce hyperpyrexia in dogs, both normal and febrile. In febrile, not in normal, dogs this is accompanied by hydremia and fall of temperature. The hydremia would facilitate heat dissipation through evaporation, through respiration, and in man by the perspiration (Barbour and Herrmann, 1920).

External Cold.—Regulation against external temperature is effected, in the first place, by reflex constriction of all the cutaneous vessels. This in itself produces the sensation of chilliness. If this physical regulation is not effective, the chemical regulation sets in, the heat production being increased by involuntary shivering. Indeed, the carbon dioxide and heat production are increased before it comes to visible movements, by a mere increase of "tone."

Vigorous individuals, when the external cold is withdrawn in time, usually present a "reaction," with cutaneous hyperemia, etc.

Febrile patients compensate against cold by the same mechanisms as the normal; but the compensation is not as effective, so that abnormally high temperatures are reached.

Quinin.—Therapeutic doses have little or no effect on normal temperature. The same doses lower febrile temperature (although not quite as effectively as the antipyrin group). The mechanism of action consists primarily in diminished heat production, through limitation of the nitrogenous metabolism. This is especially marked in fever. This action of quinin is peripheral, i.e., directly on the heat-producing foci.

The diminished heat production tends to set up secondary changes, particularly a limitation of the heat loss. These are adequate to preserve the normal temperature; but in fever they respond very imperfectly, thus accounting for the fall of temperature (Literature, S. Weber, 1904).

In malaria, and possibly in some other infections, the superior efficiency of quinin is due to its specific destructive effect on the infectious agent.

Large doses of quinin (not necessarily toxic) lower even the normal temperature, sometimes with a preliminary rise. Toxic doses lower the temperature proportional to the collapse which they induce.

The relation of heat production and heat loss with normal and febrile temperature is well known. The following quantitative data from the calorimetric experiments of Oottphie, 1891:
Quinid. 0.1 Gm.

Heat Production.—This is diminished in normal animals and much more in fever. The decrease concerns practically exclusively the nitrogen metabolism.

Nitrogen Metabolism.—This is diminished quite materially by small doses, even in normal animals; with large doses the reduction may reach 30 per cent. The reduction is faster process, a primary rise. The decrease is marked without exception. The ratio of urea to total nitrogen is not altered by moderate doses (Prior, 1884). One would be tempted to ascribe this diminution of nitrogen to the diminished utilization of food. Although this undoubtedly plays a part, the diminished excretion is out of all proportion, so that the nitrogen content of the body increases. Large doses of cinchonid have a similar action.

Oxidation.—This marked influence upon nitrogen metabolism is in conspicuous contrast to its want of influence upon oxidation. The quantity of oxygen absorbed and CO₂ given off is practically unaffected by medicinal doses (up to 0.5 Gm.). There is a slight increase, but not more than can be accounted for by the excitement, chilliness, etc.

The abnormally high gaseous metabolism of fever is reduced to normal by quinin; but this is probably the result of the antipyretic effect (Strassburg, 1872).

Nitrogen Metabolism as a Source of Energy.—The fact that quinin lessens heat production without lessening oxidation is interesting. We are accustomed to look upon the excretion of CO₂ as an index of chemical changes resulting in the liberation of energy and consequently of heat; and the excretion of CO₂ is not affected by quinin. But since the calorimeter shows conclusively that the production of heat is diminished by it, especially in fever, it follows that oxidation is not the only source of heat; that heat may also be liberated by other changes—by the splitting or hydration of nitrogenous molecules, in the course of which the nitrogen is converted into urea; and that these changes are those which are hindered by quinin. The reduction by quinin would naturally be greater when this nitrogenous metabolism is excessively high, as is the case in fever.

Heat Loss.—In normal animals, this is variable, generally slightly increased by cutaneous vasodilation. In fever, the heat loss generally undergoes very little change.

The essential share of the diminished heat production is also demonstrated in several other ways. The quinin fall occurs even when the factor of heat loss is practically eliminated by high external temperature (Lewitsky, 1869); it occurs when variations in the cutaneous circulation are excluded by high section of the spinal cord (Nanson and Quincke, 1869); indeed, it is here even more marked, because it can not be compensated by diminished heat loss.

The Action of Quinin is Peripherial.—This is shown by the observation of Bins, 1870, that quinin prevents the postmortem rise of temperature which ordinarily occurs when the spinal cord is divided and heat loss is prevented. This conclusion is also in harmony with the fact that quinin is a general proteplasmatic poison, reducing the metabolism (for instance the hippuric acid synthesis) in perfused organs, lessening the oxidation is excised muscle (Sepia, 1908), and retarding the action of ferment generally—which of course play an important role in the chemical changes by which heat is liberated.

Effect on Compensatory Mechanism.—The fact that the normal temperature is not lowered by quinin shows that it does not impair the normal compensation. This effect is already influenced by the intensity of heat production; but the table shows that it is fairly effective. Not much weight can be attached to slight quantitative differences.

Acetanilid, Phenacetin and Antipyrin.—These, as also their numerous derivatives, and the whole series of "coal-tar antipyretics," act essentially by reducing the pyretic process, that is known as "cold" or "fever". This gross effect is similar to that of quinin: Therapeutic doses have little or no effect on normal temperature; in fever, the same doses reduce the temperature toward or to normal. The mechanism of their action, however, is quite different
HEAT REGULATION

from that of quinin. Their primary effect consists in dilating the cutaneous vessels, thus increasing heat loss; the action being central, presumably a specific depression of the centers which control the tone of the cutaneous vessels. This entails secondary changes in heat production, etc. which suffice to prevent the temperature from falling below the normal level, but which are not sufficient to prevent the fall to normal.

Large doses cause considerable fall, even of the normal temperature, with evidences collapse.

The relation of heat production and heat loss may again be illustrated by the caloric data of Gottlieb, 1892. A comparison of this table with that for quinin (see above) shows at once the striking differences which were emphasized in the preceding paragraph.

Heat Loss.—This is considerably increased in normal animals, and the increase is real times greater in fever (see the preceding table).

Heat Production.—The calorimetric data show a moderate compensatory increase, as marked at normal temperature than in fever. The metabolism data are contradictory (Review, S. Weber, 1904). Excessive doses (0.75 Gm. in rabbits) diminish at production, presumably by incipient collapse.

Nitrogen Metabolism.—With therapeutic doses, and normal temperature, the results are variable, generally negative or some fall. Large doses often increase the nitrogen excretion, especially in man. In fever, therapeutics decrease the excessive nitrogen metabolism.

Carbon Dioxide Metabolism.—Therapeutic doses with normal temperature produce no change or some decrease. Larger doses (2 to 3 Gm. of antipyrin for man) produce a fall but unmistakable in both gaseous exchange and nitrogen excretion (incipient collapse?). The effect on carbon dioxide metabolism is also inconstant in fever: enepeptic doses may somewhat increase or diminish the CO₂ excretion, or leave it actually unchanged.

After the fall of temperature has set in, the carbon and nitrogen metabolism are anomalously lowered. This may be ascribed to the removal of the hyperpyrexia, for metabolism is naturally less active at the lower temperature.

Antipyrin, and especially Phenacrin and Arseniulid, decrease the arterial oxygen; CO₂ is less changed (Piccin, 1917).

The respiration of excited muscle is not affected by antipyrin (in contrast to quinin of salicylate) unless very high concentrations are used (Senta, 1908).

Mechanism of the Fall of Temperature.—The constant feature in the action of the pyrin group is the increased heat loss; and this must therefore be considered a specific element in their antipyretic action. The inconstancy of the variations of heat production indicates that these are secondary results.

Mechanism of the Increased Heat Loss.—This might occur through an increased proportion of sweat, or by exposing a larger amount of blood to the cooling influence of the surroundings by dilatation of the cutaneous vessels. In the case of this group it is accomplished by the latter means.

The dilatation may be deduced from the hot and reddened skin; it can be plainly seen by the plethysmograph (Maragliano, 1880). And since the reduction occurs even in atropine, which suppresses the secretion of sweat, the latter is not essential. The dilatation is confined to the cutaneous vessels, and this is important, since, if the blood cells in the remainder of the body were also diluted, the circulation through the skin would be diminished rather than increased. This limitation of the vasodilatation to the skin concerned with the regulation of temperature also indicates that the action is peripheral.

Localization of Action.—Antipyrin does not lower the temperature or high section of the spinal cord (Sawadowski, 1858), even if the tem-
perature is artificially raised by external heat. This constitutes a con-
spicuous difference from Quinin, which latter is effective under these
conditions. The result shows that the vasodilator action of antipyrin
is located above the spinal cord.

Antipyrin also does not increase the natural rate of fall which occurs
when the brain is divided at the posterior margin of the corpora striata.
This may mean that its normal action is not above this region; but we
know too little about the results of this operation to make conclusions
safe.

Antipyrin does not interfere with the normal compensation agains-
increase of external temperature; in fact, it renders the compensation
rather more efficient. This goes to show that its action does not consist
in a depression or narcosis of heat regulation as such. (Toxic dose,
however, render the compensation less perfect—a natural result of exten-
sive toxic action.)

Nature of Action.—A priori there are several possibilities:
1. A direct action (presumably depressant) on the center presiding over the tone of
the cutaneous vessels. This would be more marked in fever, because it would coincide
with a spontaneous tendency.
2. Depression of the hypothetical specific heat regulating centers. This would be
more marked in fever, because the "excited" centers are more subject to fatigue and
hence to depression.
3. Restoration of the abnormally high "pitch" of the specific regulating centers to
their normal pitch (Richter).

The first explanation accounts for all the facts so far established; the others would
fail with the superfuous conception of specific heat-regulating centers.

Salicyl.—The antipyretic action is of the acetanilid type, i.e., by in-
creased heat loss.

In normal man, at complete muscular rest, 1 Gm. of acetyl-salicylic acid, produce
generally some increase of CO₂, i.e., increase of heat production; the heat dissipation is
practically unachanged; the temperature does not fall.

The response is quite different in febrile patients, even when the temperature is
merely unstable. In these the temperature falls; the heat dissipation is greatly in-
creased (by 38 per cent.); the heat production is slightly decreased (CO₂ = —5.5 per
cent.: Barbour, 1919).

The nitrogen excretion is primarily increased (Webber); although there is often a late
decrease. The oxidation of excited muscle is retarded by small concentrations.

Morphin, Opium and Codein.—Small doses, according to Gottlieb
1899, act analogous to acetanilid, i.e., by increased heat loss (cutaneous
hyperemia). There is, however, at least one important difference: the
fall is as great from normal as from febrile temperature.

Narcotic Doses.—These cause a much more marked lowering of the temperature
(sometimes this may be preceded by a slight rise). The fall may be as large as 3°C
with large doses, the extent depending, however, more upon idiosyncrasy than upon the
dose. The cooling is particularly great if the animal is kept in cold surroundings.
The cause of the fall is a diminished heat production, which may be reduced by 50 per
cent. in extreme cases, reaching its minimum in the third hour. The heat loss is dimin-
ished (up to 50 per cent.), partly through the effort of the heat centers to compensate
for the diminished production, partly through the depressed circulation.

Apomorphin.—This disturbs heat regulation, inhibiting the polymorpha and shivering
reactions to artificial fever (Magne, 1914).

Alcohol.—This also increases heat dissipation by dilating the cutaneous
vessels. This warms the skin, and hence produces the sensation of heat;
but the internal temperature tends to fall. Even small doses therefore
lower the resistance to cold. With larger doses, the compensatory heat
n is also impaired, and the temperature falls rapidly. This is
conspicuously in:

or Chloroform Anesthesia.—In these, some fall occurs even when
it is protected against loss of heat, showing that diminished heat
is an important factor (Scheinsson). This is reflected in the
carbon dioxide production, and is due to the muscular paralysis
used muscular tone. In the final stages, the dissipation is also
d by the failure of the circulation, but this is not sufficient to off-
wered production. If the animal is not artificially heated, and if
is of long duration, the temperature may reach a very low level.

s and Operative Procedures on Rabbits' Temperature.—L.W. Moore, 1918,
the normal temperature of rabbits ranges between 38.2 and 41.4°C, averag-
ue animal to a board caused a fall of 1 to 2°C. in 1 or 2 hours, after which the
remained stationary, with a subsequent rise of 0.5° above normal.
During the administration there was an average fall of 1.4°C. with a subse-
d 1° above normal.
Oxid caused similar, but smaller changes.
ms (trophining) gave an average fall of 1.9°C., with subsequent rise of more
ve normal.
Compression.—This produces hyperthermia identical with puncture-fever.
ably stimulating the vasomotor center (in common with other centers),
shing heat dissipation by contraction of the surface vessels. Fatal compres-
zes the vasomotor center, and the temperature then falls (Moore, 1919).

ory Collapse.—Any reduction of the circulation—whether
vasomotor—lowers heat production, and also tends to lower
ation, since less blood circulates through the skin. The ad-
ades of this action correspond to what has just been described
etic coma. The slighter grades are produced therapeutically
, Veratrumin, Colchicum, Digitalis, etc., but practically they are
effective unless the dosage exceeds the safe limit.
Collapse phenomena are particularly important, because febrile
—especially when weakened by a prolonged infection, with their
ulation and poor heat production—are very subject to them.
apse may result spontaneously, or by the withdrawal of the
ffects of the high temperature, or by antipyretics in doses
uld not be dangerous in normal individuals.

ature Fall and Blood Pressure Fall.—These run independently, in a vary-
apse. In the slowly progressive collapse of dysenteric toxin, the central
rcting against overcooling is disturbed when that against overheating
(Diehl, 1920).

he TREATMENT OF FEVER

tment of fever has always been tinged with the views which have success-
ded concerning its nature. When fever was considered mainly as a subjec-
, attention was directed principally to the sensations of heat and thirst,
rose the class of refrigerants, including the dilute mineral acids. They are
ow, especially carbonated drinks, in conjunction with other treatment.
other hand, alkalies and organic acids have been used to counteract the ten-
dious.
real observation came more into fashion, the quickened pulse of fever fixed
of the clinicians, and it was attempted to combat all the conditions of fever
the pulse. The so-called class of cardiac depressants came into vogue. They
stances acting in various ways:

and urea, producing vagus stimulation and general fall of blood pres-
als, producing a slowed heart, but increased blood flow. Nux vomica, as
ic, acting secondarily through the nausea. Potassium salis, which have a
on the heart.
When the thermometer was introduced into medicine, and it was recognized that an elevation of temperature was the best index to febrile conditions, antipyretic measures came into prominence.

In regard to the application of antipyretic measures in fever, it is essential to bear in mind that they have no direct effects on fever, except upon the temperature.

Exceptions to this general statement are the actions of quinin in malaria, of salicylates in acute articular rheumatism, and the analgesic action of the coal-tar products.

For the rest, they strike neither at the cause of the fever nor at any symptoms other than those resulting from the hyperpyrexia. They make the type of the disease neither less severe nor shorter.

In malaria, e.g., antipyretics may prevent the development of a paroxysm of fever; but they do not attack the cause of the disease as does quinin; for their effect is not lasting, nor does their continued administration lead to a reduction in the size of the spleen. They are a symptomatic and not a specific mode of treatment. And symptomatic treatment must always be carried on with great care, lest more harm than good should result. But where it is not possible to attack the cause, it is often advisable to remove objectionable symptoms. The question then is, May a reduction of fever temperature be useful? It must be borne in mind that hyperpyrexia is often a protective mechanism. This is shown by the onset of collapse in certain cases, if the stimulus of the high temperature is removed. Also, bacteriologic research has shown that with most bacteria the optimum temperature for development is confined within very narrow limits, which are exceeded by the temperature of fever. The tendency of fever may perhaps be salutary to be useful in all cases, but as a matter of fact it usually leads to more damage than good. The cells of the mammalian organism are not adjusted to work under the conditions of so high a temperature. It is detrimental to them as well as to the bacteria, and sometimes more so. Its effects consist in latissime and emervation, in general discomfort, motionlessness, irritability, and delirium. The respiration and heart are quickened. The metabolism, and especially the elimination of nitrogen, is greatly increased. This leads to emaciation, diminished alkalinity of blood, degeneration of important organs, etc. All these, joined perhaps to a delirious action of the increased metabolic waste-products, produce a condition highly detrimental to the patient. These conditions, in so far as they have not already passed into permanent anatomic changes, are promptly and totally removed by restoring the normal temperature. Measures for this purpose are therefore indicated whenever these symptoms arising from hyperpyrexia become very pronounced, and unless there are special contraindications. They should not be used, in instance, if there is ground for suspecting a masked collapse. Nor are they of any use in high continued fevers.

Antipyretic measures of this kind are mainly cold baths and the cold-tar antipyretics, and these have their respective drawbacks and advantages. The chief advantage of cold baths lies in the fact that there is no danger of a direct collapse action; but there is no need for this danger with antipyretics if their dose be properly adjusted. The latter save the patient the exertion, discomfort, and shock of a cold bath. As, in the case of baths, the temperature-regulating mechanism is not adjusted to normal, the patient experiences all the ordinary effects of an attempt to reduce the temperature below normal; chill, cyanosis, etc.; and the metabolism is increased rather than diminished. The action of the chemic antipyretics is also more pronounced and lasting (Fig. 24), and their analgesic action is of marked value in influencing the subjective condition of the patient. In regard to this narcotic action, antipyrin and acetanilid are about on a level; they are surpassed by phenacetin. This action is especially useful when the fever is associated with delirium.
HEAT REGULATION

The objections to cold baths are very greatly lessened if tepid baths are used. These are not so much antipyretic as stimulating, improving the blood pressure, digestion, and sleep. They increase the nitrogen excretion. It has been shown that cold baths cause a considerable rise of blood pressure in acute fever, whereas, camphor, caffeine, stroph- 
and, ether, or alcohol is generally ineffectual in this condition. As to the chemical 
antipyretics, the theory has been advanced that they interfere with the natural pro-
tective bodies of the serum. It has been shown, however, that this is not the case, at
least as far as the agglutinin of typhoid serum is concerned. In conclusion, it is pro-
table that the best general treatment of fever consists in a combination of antipyretics and
aqua tepida.

QUININ

General Statement.—Quinin, the principal alkaloid of cinchona bark, is a general antiparasitic. It is therefore toxic to all cells, and even to unorganized ferments; but it has a specially high toxicity for amoeboid cells, and is relatively non-toxic for higher organisms. It exerts a very selective action on the malarial parasites, and is therefore a spe-
cific against malarial diseases, provided sufficiently large doses are ad-
ministered. It is also a fairly effective antipyretic in other fevers, reducing heat production by diminishing nitrogen metabolism. It is use-
ful as an analgesic in colds, and in the form of quinin-urea hydrochlorid as a local anesthetic. Through its bitter qualities, it acts as a stomachic
and tonic. It stimulates the uterus. Full doses produce "cinchonism," charac-
terized especially by auditory and visual disturbances, which may
assume grave proportions with excessive doses; but very large quantities have been consumed without serious poisoning.

Cinchona and Its Constituents.—The bark of the cinchona tree (Pe-
ravum or Jesuits' bark) contains a number of alkaloids (cinchonin, cin-
chinidin, etc.) resembling quinin, but endowed with less of the desired
activity, and with more of the undesired side effects (convulsant, etc.,
Albortoni, 1882). It also contains considerable tannin, which interferes
with the systemic actions. (Cinchonin is much more depressant to the
heart, and more toxic than cinchinidin.)

The trees yielding cinchona are indigenous to the mountainous district of the Andes in South America, at a height of 3,400 to 12,000 meters. Trees growing below this level contain but little alkaloid. The natives were probably acquainted with the
medicinal value of this "tree of health," and the bark was brought to Europe by the early explorers. It received its name, cinchona, from the Countess Chinchon, who was
one of the first Europeans to receive its benefits (1638).

At present practically all the barks of commerce are from cultivated trees, the origi-
nal forests having been largely depleted. This cinchona cultivation is carried on in a
number of subtropical mountainous countries possessing a rather moist climate—espe-
cially in India and Java.

The U. S. Pharmacopeia does not discriminate between the different species. Be-
tween thirty and thirty-six of these are recognized; but many are probably mere vari-
ations and hybrids, and a recent author has attempted to reduce the species to four.
The most important are: C. Callisaya (yellow bark); succirubra (red bark); officinalis;
Acmelox; micrantha; crasphylia.

The alkaloidal content of the different barks varies greatly. It has been con-
derably increased by cultivation, some samples yielding to 13 per cent. of quinin. The
drugs are contained in all parts of the plant, in the parenchymal cells. The root bark
contains the most, then comes the ordinary bark.

The constituents are: Certain acids (quinic, quinovin, etc.); Tannin, as cinchonamin-
c acid (2 to 4 per cent.), which gives a green color with iron; cinchona red, a derivative
of the preceding (both are glucosides; gum, wax, resin, etc.

A large number of alkaloids have been isolated; some of these undoubtedly arise in
the course of the manipulations.
Most of the alkaloids are optically active, and occur also as isomers, as indicated in the following table:

- C₆H₅NO₃: Cinchonin, cinchonidin, homocinchonin, cinchonichin (cinchotoxin)
- C₄H₇NO₃: Cuprein (from cuprea bark)
- C₅H₇NO₃: Cinchonamin.
- C₅H₇NO₃: Quinain, conquinain
- C₅H₇NO₃: Quinim, quinain (= conquinain); quineline (= quinotoxin)
- C₆H₈NO₃: Hydroquinim; hydroquinolin (= hydroquinoline)

When the crystallizable alkaloids have been separated from cinchona extract, evaporation of the mother liquor yields a brown extract, Chinionidin (Quinoidin), which contains amorphous alkaloids, mainly Dicinchonin Dic-inquinain.

**Structure of Cinchona Alkaloids:** This is not fully understood, as they have not been synthesized; nor indeed has any substance with analogous actions been prepared synthetically. The structure of quinim is quite complex. It may be expressed as

\[ \text{CHO}, \text{C}_{12}\text{H}_7\text{N}, \text{CH}=\text{NH} \text{C}_{10}\text{H}_7\text{N} \]

It includes a quinolin ring (b) to which are attached in the para-position a methyl (a) and a pyridin derivative ("lupol") through a CH₉OH linkage (c). Replacement of the methyl by other alkyl groups does not destroy the action, but may even fortify it (Frinkel, Arzneimittelsynthese). Omission of the group, however, greatly weakens the antimalarial efficiency, but increases the convulsive action. This is cinchonin.

**Quinim and Cinchonin.**—When quinim or cinchonin are heated with acids, the linking CHOH, in (c), is hydrolyzed to CO, the H being transferred to the adjacent C and N of the lupol, forming an imid group, and breaking the benzo ring. These compounds were discovered by Pasteur in 1853 and named by him quinim and cinchonin.

Miller and Rohde, 1895, proposed to change these names to quinotoxin and cinchotoxin. The change has been largely adopted, but seems confusing and unjustified. The toxicity is not very high; and practically the same name, quinotoxin, had previously been applied by Ostermayer, 1884, to a quite different substance, diquinolin dimethylsulphate. This produces curare actions (Hoppe-Seyler, 1880; Durduf, 1880).

**The Quinotoxin Myth.**—Chemists, impressed by exaggerated estimates of the toxicity of quinim, have suggested that the toxic actions of quinim are due to the formation of quinotoxin by the gastric acidity; and that this formation in mixtures of quinim with organic acids would constitute a very dangerous incompatibility. These fears are quite unfounded; quinim or quinotoxin is not much more toxic than quinim itself; and only insignificant traces of it can be formed at ordinary temperatures.

**Formation of Quinim and Cinchonin by Acids.**—Pasteur prepared quinim by heating quinim with dilute sulphuric acid at 150°C. At 100°C, however, Biddle, 1912, found that dilute mineral acids (to ) convert only 2 to 3 per cent. of the cinchonin to quinim.

Whilst weak organic acid (acetic etc.) transform 95 per cent. The conversion is independent of the dilution or dissociation. Similar results were obtained independently by Rabe, 1912.

At 36 to 38°C, however, the conversion proceeds very slowly, even with organic acids; so that at most 0.2 to 1 per cent. are converted in 48 hours. The concentration of cinchonin probably does not increase with longer heating; for there is a parallel transformation of cinchonin into an insoluble resin (Biddle, Ad Kaufmann).

Some conversion into cinchonin occurs also in sunlight, and more slowly in diffuse light; but this also is converted into resin. The formation of cinchonin or quinim may be judged by the dark discoloration (Biddle).

Quinim behaves in all these respects essentially like cinchonin. It will be seen that under no conditions of the body could significant quantities of quinim be produced.
the action of acid, as supposed by Kaufmann and by Riddle. These overlooked in-
ntently that quinin is also toxic when administered in other ways. Nor need any
effects be feared from prescribing acid quinin mixtures. Discolored and precipi-
ted solutions should naturally not be used therapeutically, since they would lack the
ared actions of quinin.

**Actions of Quinin (Quinolinia).**—Hildebrandt claimed that this is not convulsive;
it has a digitoxin effect on the frog, heart, and that it raises the blood-pressure
ply. Biberfeld found the toxicity for mammals quite low (lethal dose, 15 mg.
Kg. by vein; 200 mg, hypodermically, corresponding to about 15 ounce in man),
this large dose it produced convulsions. It did not have a digitoxin effect on the
frog, heart, but depressed it like quinin. It also depressed other smooth mus-
perted local anesthesia similar to quinin, but was not antipyretic.

**Actions of Cinchonina (Cinchotinina).**—The toxicity of this is also low. Hildebrandt
ot the hypodermic lethal dose as 150 mg. per Kg., for mice (equivalent to 20 Cm. for

The same dose of cinchonin was not toxic. Hunt obtained about the same 
ber for cinchotinin (210 mg.) as for quinin (270 mg.). Rabbits seem considerably
re susceptible (Biberfeld, M.F.D. hypodermic, 10 mg. per Kg.; Frenkel, P.D. hypop-
mic, 50 mg. per Kg.; Hildebrandt, cat. F.D. hypodermic, 20 mg. pr Kg.). Death is
nded by violent convulsions.

Hildebrandt described a slight rise of blood pressure. Biberfeld found depression
the circulation. Frenkel on the exposed heart, observed first very strong contra-
then diastolic arrest.

**Toxic Action of Quinin on Protoplasm.**—This may be seen on lower
animals and isolated cells of all kinds. Quinin acts most strongly on cells
essed of ameboid and similar movement: on infusoria, white blood cells,
ated epithelium, spermatozoa, insectivoros plants, muscle, etc.

**Action on Leucocytes.**—A solution of 0.5 to 1 in 1,000 is sufficient to inhibit the move-
ets of leucocytes on the warmed slide, and a somewhat larger dose causes their disin-
Phagocytes is hindered by 0.001 per cent. (Hamburger and Hehma, 1903), but stimulated by very low concentrations (Masson and Kahl, 1907).

The depressant action is also observed in intact frog. When the mesentry of this
imal is exposed, leucocytes in active motion are seen inside and outside of the vessel.
quinin is now applied, the movement of the cells outside of the blood will be arrested,
those in the blood stream still emigrate. The result is an accumulation of cells
the blood wall. If the quinin is injected into the vessel, the reverse takes place.
ovement of the cells in the blood is arrested, preventing emigration, whilst those
side do not come into contact with the poison, continue to move away, and leave a
area zone about the vessel (Hlitz, 1907; Heehn, 1910) This action does not occur in
imals, since the necessary dose would kill the animal.

**In man and mammals,** it causes at first an increase of the lymphocytes, these being
ised into the circulation by the muscular contraction of the spleen and lymph glands.
this is followed after an hour by a decrease, and this is again succeeded by rather
ked leucocytosis. Continuous administration leads to leucopenia followed by
ocytosis (G. B. Roth, 1913). The opsinic index is slightly increased in man by doses of 15 gr. (T. B. Wilson, 1907).

**Antiseptic Action.**—Bacteria and yeasts are also killed by quinin, but
quire a higher concentration (2 to 8:1,000) than do the protozoa. The
ecency is not materially hindered by serum or pus (K. Taylor, 1915).

McDonald, 1915, considers its pernicidal efficiency about half that of phenol;
ese as an antiseptic it approaches mercuric chloride. He recommends 1:2000 for
le irritation, especially as prophylactic in cystoscopy. This concentration does
cause noticeable irritation.

**Concentrations used for Antiseptic Irrigation.**—The following are usually employed:
0.05 to 0.2 per cent; conjunctiva, dysentery, 0.5 per cent; gonorrhea, to per cent.; hay fever, spray, 1 to 2 per cent. (hydrochlorid).

**Wound Infection by Gas-bacillus.**—K. Taylor, 1915, recommends dressing with 0.1
a solution of quinin hydrochlorid.

**Quinin on Skeletale Muscle.**—Immersion in quinin solutions causes persistent con-
tion of the muscle, proportional to the concentration of the solution. If such a
in is omitted, the form of twitch is almost normal, at least with moderate con-
ations, and the peak of the contractions is higher than in an unpoisoned control
Circulation.—Quinin and the other cinchona alkaloids depress the excitability of the cardiac muscle. This action is being tried against cardiac-hyperexcitability. With normal individuals, moderate doses have little effect on the circulation. Toxic doses lower the blood pressure by cardiac depression and vasodilatation through peripheral action.

_Frog Heart._—This is depressed by quinin (Santesson); the heart is slowed by a 1:1,000 solution and weakened in its contractions; its instantaneous power is considerably diminished. The slowing occurs after atropin, and is therefore muscular. A 1:5,000 solution kills the heart in a few minutes.

_Isolated Turtle Heart._—All the cinchona alkaloids diminish the amplitude and frequency, ending in diastolic arrest. The levo-bases (quinin and cinchonidin) are more toxic than their dextro-isomers (Fredericq and Terroine).

De Arric, 1913; also found the turtle heart slowed by all doses, and the excursions diminished by the higher concentrations; but he describes them as increased by low concentrations.

_Mammalian Circulation._—In mammals and man small doses cause first a quickened pulse with rise of blood pressure (Literature, de Arric, 1912; Biberfeld, 1916).

The cause of the former is still under dispute, but is perhaps central. The rise of pressure depends mainly upon a vasomotor depression, but the cause of this is also still undetermined. It may possibly be due to a direct stimulation of the unstripped muscle of the blood vessels.

Larger doses (in man, from 1 Gm. upward) cause a fall of blood pressure and slowing and weakening of the heart from the onset.

The fall is due in part to vasodilation. The slowing and weakening of the heart are analogous to those observed in the frog. It is seen in the excited organ (Lange's method). In this it often causes irregularity, but may regulate the heart if it is already irregular.

The cardio-inhibitory center is stimulated when quinin is perfused through the medulla of turtles (Bush, 1920).

Perfused mammalian vessels are dilated by quinin, whilst those of the frog are contracted. Apocodine and yohimbin act similarly (Gunn, 1909).

Quinin also removes the constrictor effect of veratin (Kondo, 1919).

_The brain-nervelets_ are diluted in rabbits and fish (Berexit, 1916).

_Quinin and Quinidin against Cardiac Irregularities._—Starkenstein, 1907, found that the intravenous injection of quinin caused the disappearance of pulsus alternans produced by glyoxyl acid. He attributed this to diminished excitability. Frey and V. Bergmann, 1919, reported good clinical results from the use of quinin in auricular fibrillation. F. B. Hoffmann, 1920, investigated the effect of quinin on the auricle of perfused heart. He found considerable increase of the resistance to electric excitations and fibrillation. It also lowered the force of the contractions, without much change in rate. Larger doses abolish the contractions and render the muscle inexcitable. Perussi and Cleric, 1920, report favorable clinical effects from quinin against auricular fibrillation, paroxysmal tachycardia, and auricular fibrillation. They administer 0.5 Gm. by mouth, 2 or 3 times per day.

_Uterus._—Quinin stimulates the contractions and increases the tone. Satisfactory results have been reported from its use in all stages of labor and for therapeutic abortions.

_Escised Uterus._—This is strongly stimulated (Kardnowski; Kehrer, 1906) by concentrations as low as 1:10,000,000 (Lieb, 1924). Cinchonin and cinchonidin acts similarly; quinidin produces only relaxation. All these effects are the stronger, the more active the uterine movements (Sanda, 1915 and 1917). The relative efficiency of the cinchona alkaloids has been determined by Hall, 1916. Biberfeld, 1916, obtained only relaxation of uterus (also of the intestine) with quinin concentrations of 1:25,000 to 1:10,000; but this must have been a technical error.
**QUININ**

*Use as Emetic.*—Maurer recommended doses of 0.5 to 1 Gm., repeated in an hour if necessary. He claimed marked effects, usually within 40 minutes. Since then, it has been employed mainly intravenously, during labor and postpartum. Seggelke, 1921, found it satisfactory for therapeutic abortion. He employed “combined injections,” i.e., 10 c.c. of 0.25 per cent. quinidine hydrochloride by vein, plus the same dose intramuscularly. This did not start contractions when the uterus is quiet, and therefore does not induce abortion in normal pregnancy; but if contractions have started, these were reinforced promptly and effectively by the quinidine; thus often avoiding instrumentation. Chimohorism was fairly severe. Local necrosis occurred with hypodermic, but not with intramuscular injection.

*Egg-production.*—Quinin, when fed to doves, reduces the size of the yolk and albumen of the eggs. This continues for some time after the administration is stopped, and is then followed by a compensatory increase (Riddle and Anderson, 1918; Bähr et al., 1920).

*Contractions of the spleen and intestines may also occur.* Excised trochaed muscle is relaxed (Trendelenburg).

The peripheral nerves are not markedly affected, except the poison be applied directly, when it will irritate, depress and finally kill them just as other protoplasm.

**Local Actions.**—Quinin produces some local irritation and anesthesia. When given hypodermically it occasions severe pain, and may lead to *obscure formation.* When given by the stomach, large doses cause *gastralgia,* nausea, vomiting, and diarrhea. It also retards the *absorption* of salts, and probably of food. Its excretion through the kidneys may give rise, with large doses, to *albuminuria* and *hemoglobinuria.* The hemoglobinuria of severe malaria (black-water fever) may be partly due to increased sensitiveness to quinin.

*Ulcers.*—The sulphate has been used as antisepsic, styptic and stimulant dusting powder on ulcers.

E. B. Terrell, 1917, urges the injection of 5 to 10 per cent., quinin-urea hydrochlorid for the treatment of *hemorrhoids.*

**Quinin as Anesthetic.**—Quinin and its derivatives, when brought in contact with sensory nerves, produce local anesthesia. This is used clinically in the form of the more soluble and less irritant double salts, especially urea hydrochlorid. The anesthesia is more lasting than with other local anesthetics; it may persist for several days (Hertzler et al., 1909). However, the concentrations above 1/4 per cent. sometimes produce considerable irritation, edema and fibrous inductions and above 1 per cent. there may be sloughing. Its employment has therefore greatly diminished (E. Mayer et al., 1920); although some clinicians consider these fears as exaggerated (E. J. Brown, 1920).

Quinin-urea hydrochlorid is injected hypodermically, generally as 1/2 per cent., sometimes 1 to 3 per cent. Solutions of 10 to 20 per cent. may be used on mucous membranes. Quinin bismuthate, 2 per cent. has also been used in tonsil and throat operations.

**Data on the relative anesthetic efficiency are given by Sollmann, 1917 and 1918.** The anesthetic effect of cinchona alkaloids for the *cornnea* was investigated, by Morgenroth and Giesberg, 1912.

**Double Quinin Salts.**—The increased solubility of quinin hydrochlorid (3 parts) by uracinn (2 parts) was announced by Triulzi, 1897, and Santesson, 1897. Gaglio, 1916 and Giannini, 1926, advise the urethane compound as being less acid and less readily decomposed by boiling, than is the urea salt (Filipi, 1912). It is made with 1 Gm. of quinin hydrochlorid, 0.5 Gm. urethane, and 2 c.c. of water.

**Fernaments.**—Interference with ferment action may be seen in many directions. The most important are: the *oxydas* of blood and of protoplasm autolysis (Lagneur, 1906); slowed acidification of shed blood; lessening of the amount of hippuric acid formed when benzoic acid is circulated through the excited kidney. The various digestive ferments are hindered, but not to the same degree. It also lessens the glycogenetic function of the liver; i.e., the postmortem transformation of the glycogen into sugar (Hoffmann, 1877).
Hemoglobin.—This shows a characteristic change with strong quinin solutions (Mars, 1906); no methemoglobin is formed (Lewis, 1900).

Effect on Digestion.—Small doses of quinin (0.05 Gm., 1 gr.), taken before meals, act as a stomachic and tonic; but they are probably inferior to other bitters. Larger doses diminish gastric secretion (Klocman, 1912), and interfere with the fermentes and with absorption; even small doses when long continued lessen the utilization of food. Toxic doses stimulate the vomiting center (Eggleton and Hatcher, 1913). Tint. Cinchone Comp. (5 c.c., 15) adds the stomachic effect of aromatics and alcohol, and the astringent action of tannin. It may be useful in chronic gastric catarrh.

Metabolism and Temperature.—The effects were discussed on page 539.

Use in Fever.—The antipyretic action of quinin may be utilized in any fever. It has several theoretical advantages over the anilin antipyretics: It conserves energy by lessening metabolism, instead of dissipating it by increased heat loss; there is less risk of collapse, and its effects are more prolonged. On the other hand, the annoying cinchonism and occasional idiosyncrasies, eruptions, etc., limit its usefulness. It is employed mainly where the depressant action of the anilin derivatives is especially extraneous, as in influenza; or where only small doses are required, as in colds. The full antipyretic dosage is from 0.5 to 1 Gm., 5 to 15 gr. Like other antipyretics, it is most efficient when the temperature has a natural tendency to fall. It takes about two hours to act, and should therefore be given about that time before an expected fall of temperature.

It has been suggested that its efficiency in fever is due to an antispetic action in the blood. This is not probable since bacteria are rather resistant to it, and would scarcely be affected by it in the concentration in which it could exist in the blood.

Use in Asiatic Cholera.—Quinin has been especially recommended in this disease, in which conditions would be favorable for a direct bactericidal action (Fullerton, the Unser, 1906). The dry sulphate, 0.6 Gm., 10 gr., is administered every hour for two to eight doses until bile reappears in the feces. Further confirmation is required.

Use in Pneumonia.—This also is claimed to be especially benefited by quinin; but the natural course of this disease makes judgment very difficult.

S. S. Cohen, 1912 and 1913, recommends massive doses, 1 to 1.5 Gm., 15 to 25 gr. of quinin-urea-chlorid, dissolved in 2 parts of hot water, and injected into the muscles, followed by further injections of 1 Gm. doses every third hour until the temperature remains below 100° F., rarely beyond seventy-two hours. He claims that this does not produce cinchonism, gives great symptomatic relief (respiration, cough, pulse), and lowers the temperature at the ordinary time, but by bios instead of crisis. The autonomic changes are not affected, indicating that the action is probably not on the local process, but rather antipyretic and analgesic.

Bactericidal Action.—Although it is very improbable that quinin kills the pneumococci in the patient, the possibility that it restrains or weakens them is not entirely excluded; for these bacteria are especially susceptible to quinin and its derivatives (especially optochin). O. H. Brown, 1912, states that pneumococci cultures are killed in one-third to five hours by 0.01 percent. of quinin (especially basic), while other organisms (strepto- and staphylococci) require much longer. Cohen, Kolmer and Heist, 1917, confirm the bactericidal action for pneumococci in vitro. It is much weaker than that of optochin, but is not hindered as much by serum.

It is also noteworthy that the concentration of quinin, after hypodermic injection becomes higher in the pneumonic lung than in the blood (Cohn-Bronner, 1910).

Pneumococcus carriers.—Kolmer and Steinfeld, 1915, recommend part of sulphate or optochin hydrochlorid, 10,000 of saturated water

in Colds, Headaches and Neuralgias.—Like other antihistamine analgesic effect in these conditions. It is used in

0.2 Gm., 1 to 3 gr.
Central Actions.—The effects are not important, except with toxic doses. They consist in a rather slow general paralysis, probably preceded by stimulation; the latter is somewhat difficult to make out in mammals.

In frogs there is first an increased reflex irritability. This is followed by loss of spontaneous movement, then paralysis of respiration, and lastly of the cerebral centers. The depressing effects upon the hemispheres are much less marked in mammals, but a diminished appreciation of pain can be distinctly made out, and upon it rests the employment of quinin against neuralgic and rheumatic pains.

Its addition to morphin or urethane does not increase their narcotic effect.

Tentorial efficiency tests, in man, showed marked impairment after 1 Gm. of quinin (Münterberg, 1892).
Small doses increase the acuity of hearing (Macht et al, 1919).

Toxic Actions of Quinin.—With very high doses of quinin, the symptoms of cinchonism (see below) are accompanied by difficulty of speech, confusion of ideas, somnolence. Then loss of consciousness, alternating with delirium, coma, and at times convulsions.

It has been doubted whether the latter are really due to quinin or to the accidental presence of some of the convulsant cinchona alkaloids.
General paresis may appear, preceded by general depression and muscular weakness. The final symptoms are those of collapse, due to general paralysis of the central nervous system, and in part also of the heart. The respiratory center shows a short primary stimulation with following more marked paralysis. The latter is the usual cause of death. But since the medullary centers are not markedly affected until very late, quite large doses are often survived.

The fatal dose is usually given as 6 Gm., but 30 Gm., have been recovered from. It is doubtful how much of this really entered the circulation, since the sulphate is very insoluble, so that a large amount may not have been absorbed.

Fiseral Degenerations.—Cornwall, 1920, administered quinin to rabbits, hypodermically or intravenously over long periods. He found damage in the epithelium of the suprarenals and kidneys, and increased disintegration of red corpuscles in the spleen. These observations require confirmation.

Perfura hemorragica is a not infrequent phenomena of intolerance after large doses (Samaja, 1918; Van der Horst, 1918).

Quinin or Hemolysis.—Quinin is not directly hemolytic, but Rusznay, 1920, claim that it modifies the response to other hemolytic agents, for instance acidity. Confirmation is required.

Cinchonism.—Early symptoms of larger doses of quinin are headache, ringing in the ears, and disturbed vision, a complex of symptoms grouped together under the name of cinchonism. These are probably due to a selective action on the vessels of the eye and ear, which can also be demonstrated experimentally on animals. Toxic doses produce phoaphobia, deafness, and blindness, at first partial, later complete. These are probably partly central. Similar phenomena occur with salicylates and related drugs. Cinchonism is very subject to idiosyncrasy, being much more easily produced in some individuals. It is said that the minor symptoms may be somewhat diminished by bromids.

Anatonic Changes in Eye and Ear.—The retina is said to be anemic, whilst the internal ear is congested, postmortem (Kirchner). Harndack, 1918, also ascribes the eye change to spasm of the retinal vessels with subsequent optic atrophy. Wittmaak (1903) claims that this congestion is not due to quinin, but to death, and points out that changes of blood pressure produce deafness. On the other hand, he demonstrates changes in the cells of the spiral ganglion, by the Nissl stain. He is therefore inclined to ascribe the auditory effect to a specific toxicity of quinin to these cells. A corresponding origin is assigned by Alland, 1904, to the visual changes, the retinal cells being altered. This might be secondary to the ischemia.
Skin Eruptions and Eudermic Test of Idiosyncrasy.—Scorilatinal or urticarial rashes are not very rare after therapeutic doses of quinin... in such susceptible individuals, local reactions are also produced by the application of quinin solutions (1:1000 to 1:10) to the scarified skin. Normal individuals do not react, so that this may be used as a harmless test of quinin idiosyncrasy (Boerner, 1917).

Two clinically hypersusceptible subjects, studied by O'Malley and Richey, 1910, gave positive skin tests with quinin, but not with cinchonin, cinchonidin, lodid, salicylic acid, caffeine, atropin or epinephrin; nor were these subjects clinically hypersusceptible to other cinchona alkaloids. The quinin idiosyncrasies were not congenital, and did not exist in blood-relatives. Edlavitch, 1916, also describes the endemic reactions.

Desensitisation.—This was proposed by Heran and St. Giron and partly confirmed in the cases of O'Malley and Richey, with parallel changes in the skin-reaction. Further confirmation is desirable. They start with the oral administration of 5 mg. of quinin bisulphate plus 0.5 Gm. of sodium bicarbonate; after 1 1/2 hours, they give 0.5 Gm. of bicarbonate with 0.1 Gm. of quinin. The double dosage is repeated daily, leaving the desensitising dose at 5 mg. and increasing the second dose by 0.1 Gm. every day.

Actions of Minor Cinchona Alkaloids.—These are qualitatively similar to quinin, but show important practical differences that make them therapeutically less desirable. Cinchonin and Cinchonidin.—These produce clyonic and tonic convulsions, located below the optic thalami. They are more depressant to the heart than is quinin, an action more eteric, and less resistant against malaria (Albertoni, 1882).

Cinchonamisc.—This is more toxic than quinin (F. D. 75 mg. per Kg. of dogs or rats). It produces salivation, hallucinations, and epileptoid cerebral convulsions. It has little effect on blood pressure (Ehring).

Coprocin.—This is said to be about half as toxic as quinin (Koberb). Quinin in Malaria.—Adequate doses of quinin kill the plasmodia in the blood, and this ends the infection, and all the phenomena of the disease. A single dose usually suffices to arrest the malaria; but a few of the protozoa are usually not reached and survive, tending to produce reinfection, or render the patient a dangerous carrier. It is therefore necessary to continue the administration for some time.

Action on Plasmodia.—These are especially susceptible to quinin: On a single dose of 10,000 solution immediately arrests the movements of the parasites, and similar phenomena occur in the body. About three hours after the administration of quinin by the mouth, the endoglobular forms of tertian and quartan fever become immobile, granular, lose their nuclei and their affinity for certain stains. Several hours later they may be seen deformed and fragmented (Lo Monaco and Pasini, 1890).

The other cinchona alkaloids have a similar, but much weaker, action on the protozoa. Quinotinin is practically ineffective (Stephens et al., 1918).

Bass and Johns, 1913, who have cultivated the plasmodia, find that they are readily destroyed by normal serum. They suggest that quinin acts by rendering the red blood corpuscles more permeable to the toxic constituents of the serum; but there is no other evidence for this view.

Actions of Hematin.—W. H. Brown, 1912; and Brown and Loovenhartz, 1913, find that the injection of small doses of hematin into rabbits produces phenomena similar to those of human malaria: A "cold stage" of cutaneous vasocostriction with falling surface temperature and rise of blood pressure; succeeded by cutaneous vasodilatation with hot skin. Larger doses cause splanchic dilation (central) and central vascular stimulation with falling blood pressure. The respiration is depressed, ending in death. Butterfield and Benedict, 1914, failed to confirm these effects, and claim that large doses kill by intravascular precipitation of hematin.

Different Susceptibility.—Quinin is most effective in the tertian less so in the quartan, and least in the pernicious malaria. It does not act on the parasite in all the stages of its development. The sexual forms are more resistant than the usual asexual. Its strongest action is the forms which are just breaking into spores and upon the free.
QUININ

553

running organisms; it is much weaker upon the older segmenting bodies, at least upon the young endoglobular forms.

Immediate Results.—Since the resistant endoglobular forms exist in the blood just before the paroxysm, and their sporulation gives rise to the characteristic chill and fever, and since quinin does not act well upon them, it will not be effectual against the oncoming paroxysm. But if it is given at this time it will be present in the blood when the spores are berated, and as these are most susceptible to its action, it will kill them and thus prevent the development of the new cycle (providing that the dose has been sufficiently large). It should therefore be given several hours before the expected paroxysm so as to allow time for its absorption. The dose should then be quite large: 1 to 2 Gm. given (fasting, if possible) two to three hours before the expected attack (which will in all probability occur), or 0.3 Gm. four to five times a day in the interval; 0.5 Gm. per day should be continued for three months after the last chill.

To be promptly effective, the quinin must be administered in solution: Large doses of quinin sulphate in pills or powder may be largely wasted, if they are not dissolved or absorbed. The sulphate requires 720 parts of water for solution; the hydrochlorid is more soluble (1:8); but the bisulphate (1:8.5) or the dihydrochlorid are the best.

Ehrlich suggested using methylen blue with quinin.

It is not customary to prescribe the bisulphate directly, but to bring the sulphate into solution by the addition of a sufficient quantity of dilute sulphuric acid. The dosage of acid should be rather in excess. If it is only just sufficient, some sulphate will be precipitated on the tongue by the alkaline saliva, and give rise to a very persistent bitter taste. There will be very little of this if an excess of acid is used and the mouth rinsed afterward.

Urgent cases may demand intramuscular injections of quinin dihydrochlorid (1 Gm. in 10 c.c.) or of quinin-urea hydrochlorid (2 Gm. in 1 to 10 c.c.). Intragluteral injections must not be made too near to the sciatic nerve, or they may cause extremely painful and paralytic disturbances of the leg (Sicard, Rimbaud and Roger, 1917).

Intravenous injections of the hydrochlorid have also been used. Concentrations of 1:50 are dangerous (MacGilchrist); and even lower concentrations should be used with caution, for fear of direct cardiac effects. Immediate death has been reported by Thayer, 1914, and James, 1917 cited by Eggleston, 1917). Under proper precautions, however, very strong solution (10 or 10 per cent) may be injected (A.D. McLean, 1917).

Use in Malignant Malaria.—Practically all cases of malignant malaria are due to the.Auto-summer plasmodium (P. falciparium). This spends only a fourth of its life cycle in the circulating blood; the remainder in the capillaries, where it is not easily reached by the quinin. The parasites enter the circulation after they segment. Since this process is continuous, a sufficient concentration of quinin must be maintained in the blood continuously.

The absorption from the intestinal tract is too slow for these severe cases, and epidermic injection may not be any better, since the local irritation often delays absorption. Intravenous injection is therefore preferable in serious cases. Quinin, then administered by vein, appears in the urine in a few minutes; often a half of the dose is eliminated in twelve hours, and practically all in a day.

Reapses.—Unless the quinin treatment is continued for weeks, re-episodes are likely to occur from time to time, for many months or sometimes several years. Some of these are due to reinfections; often from carriers in the family (De Buys, 1920); but there is reason to believe
that they may also be due to the survival of a few of the original plasmodia (Bass, 1919).

After-Treatment.—Quinin, 0.65 Gm., 10 grains, daily, should be continued for at least 8 weeks after the last paroxysm.

This is necessary thoroughly to disinfect the patient, so as to prevent relapse of himself, and contagion of the community, especially those in close association with him. The chief source of malaria transmission consists of carriers that have not been sufficiently disinfected after a malarial attack (Bass, 1930).

Quinin is most readily given to adults as a single daily 10 grain dose for the first three or four days, then a single daily 10 grain dose for 8 weeks.

Side Effects.—Bass advises the quinin in the form of 2 tablets of 5 grains of the sulphate at night. For children under eight, the proportionate dose may be given in 1/2 syrup of yerba santa.

Quinin as Antimalarial Prophylactic.—Opinions differ as to its efficiency; but it is now generally believed to protect if adequate doses are used; at least 0.5 Gm. and better 0.65 Gm. per day; and proportional doses for children.

Prophylactic Administration.—The Italian method of daily administration is now generally preferred to the Koch method, which used somewhat larger doses with longer intervals. The Koch method required less quinin, but is less efficient and more uncomfortable (H. R. Carter, 1914).

Italian Method.—Mariani proposed 0.4 Gm. daily, in divided doses. Bass found that this sometimes failed, and proposed 0.65 Gm. of the sulphate (in tablets) every night. The tannate may be used for children.

Side Effects.—The cinchonism from 0.5 Gm. per day is usually not serious, and those who object to it at first may become accustomed in a week or so. The sulphate seems to be better tolerated than the more soluble forms. No injurious effects have been reported from extensive use of 6 grains daily for 21/2 years (Carter). It does not favor hematuria, and does not render the plasmodia resistant to active quinin treatment, should this become necessary (Carter).

Koch Method.—This consists in 1 Gm. of quinin on each of 2 successive days, with intervals of 1 to 9 days; or 0.5 Gm. twice a week (Carter).

Administration of Small Doses.—Small doses of quinin sulphate or hydrochlorid may be easily administered in the forms of pills or capsules, or in solution, the taste being disguised by glycerrhiza. (No acid must be prescribed with the latter!) The free alkaloid is almost tasteless, and the tannate quite so, because of their slight solubility. Their absorption may not suffice for large, but is probably adequate for small doses. They can be placed dry on the tongue and swallowed with a draught of water.

Antimalarial Efficiency of Cinchona Alkaloids.—MacGillivray states this to be in the order of: Hydroquin > cinchonin, quinin, quinind > ethylhydroxyacridin > cinchonin > quinimoldia; the first being the most, the last the least active. The same order holds for the different forms of the parasites. Confirmation would be desirable.

The efficiency of the cinchona alkaloids has also been compared by Gilman and Wernicke, 1917, and Tanck, 1916, again recommended quinimoldia as a cheap and daily efficient quinin substitute.

Quinin is practically ineffective (Stephens et al, 1918).

Actan, 1910, found levorotary quinin more active against malignant tertiary parasites; and dextro-quinin more efficient against benign tertiary plasmodia.
Laxative Dysentery.—Quinin is used for rectal irrigation. Its administration by enema (4 Gm. per day) is sometimes effective, but less certain than emetin (Brooks, 1916).

Tables.—V. H. Moore, 1913, reported apparently successful results with quinin on 21 cases; in 1915, he reports them only very slightly positive and practically negligible; subsequent observers report negative results (Krauswiede and Mann, 1915; Fielder, 1916).

QUININ DERIVATIVES

The esters of quinin with various acids are insoluble and therefore less effective. They pass the stomach unchanged, but are slowly saponified in the intestines; in this way exhibiting a very gradual and presumably slower action. They are more easily administered, and produce less side effects, but are not always devoid of cinchonism (Schieter, Nebenwirk., 5, pp. 115–119).

They are used in the same doses as quinin, in powder or suspended in liquids. To type belong: triestochin (diquinina carbonic ester); eurquinina (quinin ethyl carbonic ester) and quinina (quinin salicylic ester); the latter may be used for a weak salicylic action; and aphenin (phenetidin quinina carbonic ester) for exhibiting simultaneously the action of benacenin. As to the last two mentioned, there is no advantage in a chemical comparison of these therapeutic agents; on the contrary, it prevents the necessary elasticity of use.

ABSORPTION, FATE AND EXCRETION

Absorption.—Quinin is absorbed mainly from the small intestine (Filchcrist). The absorption is materially hindered by gastrointestinal irritation, vomiting, diarrhoea, etc. (Porak, 1918).

Fate.—The greater part of the administered quinin is destroyed in the body.

The destruction involves usually 60 to 70 per cent. and sometimes to per cent. of the quinin (Merkel, 1902; Biberson, 1916; Schmitz, 1907; ak, 1918; Hartmann and Zilla, 1918). Perfused liver also destroys quinin (Groser, 1908).

Persistence in Blood and Organs.—After intravenous injection, the concentration in blood sinks rapidly at first, then more slowly. With oral administration, the blood concentration remains practically level for 24 hours (Hartmann and Zilla, 1918). It is utilized chiefly in the corpuscles (Baldoni, 1912, 1913).

The brain, liver and spleen generally contain more than the blood (Baur et al., 1918).

Excretion.—Quinin is excreted mainly by the urine, and somewhat by faeces, even after parenteral administration. Traces are also found other secretions.

It is always present in the gastric and intestinal contents after hypodermic injection, or in animals. Its appearance in the bile and saliva is irregular (Hartmann and Zilla, 1918; Baur et al., 1918; Lacage and Valiguric, 1916; Koldewijn, 1916).

Course of Excretion.—The urinary excretion begins within half an hour, and is usually completed in 24 hours (Nich, 1909; Baldoni). Traces may continue for 96 or longer (Lacage and Valiguric, 1916). The faeces do not contain it after 24 hours (Lacage and Valiguric).

The maximum in the urine is reached in 4 to 10 hours, independent of the dose or rate of administration. This would indicate that doses should be repeated every 4 hours. The excretion is delayed in severe nephritis and diminished in cardiac depression (Porak, 1918).

PREPARATIONS—QUININ GROUP

The ordinary salts of quinin are white, odorless, and intensely bitter. They are incompatible with alkalies and other alkaloidal precipitants, and
with salicylates, benzoates, tartrates. Solutions containing free organic acids deteriorate slowly. Average dose of all quinines salts: tonic, 0.1 Gm., 1/4 to 1/2 Gm.; malarial, at least 1 Gm., 15 gr. daily. U.S.P.; ordinary dose, B.P. 0.06 to 0.6 Gm., 1 to 10 gr. The solubilities are shown in the following table,

| QUININA (Quin.), U.S.P.; CuH$_2$N$_2$O$_4$ + 3H$_2$O. | 1.500 | 0.8 | Alk. |
| QUIN. BISULPH., U.S.P.; Qu.1 H$_2$SO$_4$ + 3H$_2$O. | 9 | 23.0 | Acid |
| QUIN. HYDROBROM., U.S.P.; Qu. HBr + H$_2$O. | 40 | 0.9 | Neutr. |
| QUIN. HYDROCHL., U.S.P.; Qu.HCl + 2H$_2$O. | 18 | 0.8 | Neutr. |
| QUIN. DIHYDROCHL., U.S.P.; QUIN. HYDROCHL. ACID, B.P.; Qu.HCl + H$_2$O. | 0.5 | 12.0 | Acid |
| QUIN. SAL. U.S.P.; Qu.C.H$_2$O$_4$ + 2H$_2$O. | slightly | 14.0 | Alk. |
| QUIN. SULPH., U.S.P., B.P.; Qu.H$_2$SO$_4$ + 3H$_2$O. | 725 | 107 | Neutr. |

1 "Qu" stands for CaH$_2$N$_2$O$_4$.

*Quinina Tanna (Quin. Tana.), U.S.P.—A compound of quinin and of tannic acid of somewhat varying composition and containing about 33 per cent. of anthyroid quinin. Pale yellow, amorphous powder; tasteless, or having not more than a slightly bitter and astringent taste. Slightly sol. in water; somewhat more sol. in alc. Dos. up to 3 Gm., 15 gr., U.S.P.

Quinina et Urea Hydrochloricum (Quin. et Urea. Hydroch.), U.S.P.; Qu.HCO.$\cdot$(NH$_2$)$_2$HCl + 2H$_2$O.—Colorless prisms or white granular powder, bitter taste. Very sol. in water (1:00), freely sol. in alc. (1:24). Solutions are strongly acid. Dos. 1 Gm., 15 gr., once daily, hypodermic, U.S.P.

(Ferr. et Quin. Cit.—See Index.)

(P. Ferr. Quin. et Styrch. Phosph.—See Index.)

Pl. Quin. Sulph. B.P.—8 to 12 per cent. Dos., 0.12 to 0.5 Gm., 2 to 8 gr., B.P.

Tr. Quin., B.P.—2 per cent. In tr. of Orange. Dos. 2 to 4 c.c., 1/2 to 1 dram, B.P.

Fr. Quin. Ammon., B.P.—2 per cent. In ammoniated alcohol. Dos. 2 to 4 c.c., 1/2 to 1 dram, B.P.

Vin. Quin., B.P.—0.23 per cent. Dos. 16 to 30 c.c. 1/4 to 1 ounce, B.P.

Tinctura Antiperiodica, N.F. (Warburg's Tincture.—This is used in India for administering quinin against malaria. It contains 5 per cent. of quinin sulphate. 3 Gm. per teaspoonful, with rubarb, aloes, camphor, and aromatic drugs.

Quinina Ethylcarbonas, N.N.R.; Euquinina; CuH$_2$N$_2$O$_4$-O-CO-OH$_2$—Nearly tasteless and insoluble. Dos., as for Quinin.

Arctostachis, N.N.R.; Diuinin carbonic ester; (CuH$_2$N)$_2$O-O-CO-O (CuH$_2$N)$_2$—Nearly tasteless and insoluble. Dos., as for Quinin.

Cinchonellina Sulphas (Cinchon. Sulph.), U.S.P.; (CuH$_2$N)$_2$O$_4$-$\cdot$H$_2$SO$_4$ + 3H$_2$O—White, glistering, silky needles or prisms; odorless and having a very bitter taste. Sol. in water (1:15) or alc. (1:5). Dos. 0.15 Gm., 3/4 gr. U.S.P.

Cinchonina Sulphas (Cinchon. Sulph.), U.S.P.; (CuH$_2$N)$_2$O$_4$-$\cdot$H$_2$SO$_4$ + 3H$_2$O—White, lustrous, prismat crystals; odorless; very bitter taste. Sol. in water (1:10) or alc. (1:25). Dos. 0.15 Gm., 3/4 gr. U.S.P.

Cinchona, U.S.P. (Yellow Cinchona; Callaya Bark; Yellow Peruvian Bark).—The dried bark of Cinchona Ledgeriana, Cinchona Calisaya, and of hybrids of these and other species of Cinchona, yielding not less than 6 per cent. of the total alkaloids. Dos. 1 Gm., 15 gr., U.S.P.

Cinchona Rubra, U.S.P.; Cinch. Rubr. Cor., B.P.; Red Cinchona.—The dried bark of Cinchona succirubra or of its hybrids, yielding not less than 6 per cent. of the total alkaloids of Red Cinchona; 5 to 6 per cent., B.P. Dos. 1 Gm., 15 gr., U.S.P.
**QUININ**

*Inf. Cinch. Acid.*, B.P.—5 per cent. of Cinchona, with 1.25 per cent. of Acid Sulph. um. *Dose*, 15 to 30 c.c., half to 1 ounce, B.P.

*Ferment. Cinch.*, U.S.P.; *Ext. Cinch. Liqu.*, B.P.—1 per cent. of alkaloids. *Dose*, 1 to 1.5 minims, U.S.P.; 0.3 to 1 c.c., 5 to 15 minims, B.P.

*Tinctura Cinchona* (Tr. Cinch.), U.S.P.; B.P.—20 per cent. of Cinchona, with alcohol. *Incompatible* with water, iron and alkaloidal precipitants. *Dose*, 4 c.c., 2 to 4 c.c., 1 to 2 dram, B.P.

*Tr. Cinch. Co.*, U.S.P., B.P.—10 per cent. of Cinchona, with 2.5 per cent. of pterarina, together with Bitter Orange. The B.P. is colored with Cochineal; strongly astringent. *Dose*, 4 c.c., 1 dram, U.S.P.; 2 to 4 c.c., 1/2 to 1 dram, B.P.

*Alstonia*. B.P.—The dried bark of Alstonia scholaris and constrictia. Contains alkaloids and is employed in India against malaria; also as a bitter tonic, anthelmintic and against diarrhea.

*Inf. Alston.*, B.P.—5 per cent. *Dose*, 15 to 30 c.c., 1/2 to 1 ounce, B.P.

*Tr. Alston.,* B.P.—12.5 per cent. *Dose*, 2 to 4 c.c., half to 1 dram, B.P.

---

**HYDROCUPREIN DERIVATIVES**

**General Statement.**—The alcoholic derivatives of hydrocuprein were found by Morgenroth to possess a high bactericidal efficiency; even in the presence of protein; and at the same time a relatively low toxicity to the tissue cells. They were therefore proposed as tissue-antiseptics, both for local and systemic application. The germicidal power varies specifically for different bacteria. Ethylhydrocuprein ("optochin") is especially active to pneumococci; whilst higher homologues, such as "eukupin" and "vuzin" are more efficient against pus organisms.

The practical application of these derivatives is in an experimental stage. Optochin, whilst effective against experimental pneumonia in mice, is not very successful clinically; and on the other hand, is liable to reduce blindness. Eukupin and vuzin, were tried quite extensively by the Germans as wound antiseptics.

**Composition.**—The structure of hydrocuprein may be represented as:

![Linkage structure](image)

The most important Morgenroth substances are derived by substituting alkyl groups for the H in the quinolin. These are:

**Optochin.**—Ethyl hydrocuprein: CH₂CH₂ in place of H

**Eukupin.**—Isomyl hydrocuprein: CH₃CH₂—CHCH₂

**Vuzin.**—Isooctyl hydrocuprein: (CH₃)₇CH

**Salts.**—The bases are but slightly soluble in water. Salts are formed, as with quinin, the addition of acid groups to the N of the quinuclidin group (mono-acid or external salts); or to this and the N of the quinolin group (bi-acid or "acid" salts). The latter are easily soluble in water; forming leebly acid solutions by hydrolytic cleav-
Relative Bactericidal Efficiency.—The hydrocortisone derivatives are highly antiseptic in vitro. Strepto and staphylococcus cultures are killed in 24 hours by the following dilutions (quoted from Brunn, 1919):

<table>
<thead>
<tr>
<th>Compound</th>
<th>Concentration</th>
<th>Efficiency Ratio</th>
</tr>
</thead>
<tbody>
<tr>
<td>Phenol</td>
<td>1:800</td>
<td>1</td>
</tr>
<tr>
<td>Mercuric chloride</td>
<td>2500</td>
<td>3</td>
</tr>
<tr>

<td>60,000</td>
<td>75</td>
</tr>
</tbody>
</table>

The efficiency evidently increases with the size of the alkyl radical. This, however, does not apply to all organisms, for toward pneumococci, optochin is more effective than eukupin or vuzin.

Quinhydrin Derivatives.—Derivatives analogous to quinquin (quinhydrin) may be formed and act similarly. These are more powerfully, and especially more promptly effective. For instance, the eukupin derivative is 7 to 4 times more active, and 48 times more rapid, than eukupin itself. With vuzin, the increase is not quite so great.

ETHYL-HYDROXYCUPRIN (OPTOCIN)

Action of Pneumonia.—This drug has a specific toxicity for pneumococci (Morgenroth and Halberstaedter). It is highly successful against experimental pneumonia in mice; but much less successful in man. Its application is further limited by the fact that efficient doses are liable to produce blindness.

Bactericidal Action on Pneumococci.—In vitro, the drug inhibits the growth of pneumococci with a concentration of 1:800,000 in serum; it kills them with 1:400,000 (Wright, 1912). The action is very slow with low concentrations, and increases in speed with the concentration.

Serum reduces the activity to 1/2 or 1/3 (Cohen, Kolmer and Heist, 1917). Solutions in blood are even less active than those in serum; but the entire blood is more active than the serum separated from it, since the corpuscles take up a higher percentage of the drug (Morgenroth, 1918).

Specificity.—All strains of pneumococci, as also streptococci, are inhibited in vitro by concentrations of 1:100,000; whereas other streptococci, meningococci and gonococci require 1:15,000,000 to 1,000. However, transition races are occasionally found. Quinquin requires much higher concentrations. Optochin also increases greatly (potentiates) the efficiency of anti-pneumococcus serum (Nachtman, 1915; H. F. Moore, 1911).

Phagocytosis.—Optochin (and quinin) accelerate the phagocytosis of pneumococci (Cohen et al.).

Experimental Pneumonia.—Morgenroth, 1911, found optochin more effective than quinin against trypanosome and pneumococcus infections of mice. With these, optochin is effectively prophylactic in 50 per cent, and curative in 50 per cent. of the experimental infections (Morgenroth and Levy; Engwer, 1912). The serum of rabbits is bactericidal after hypodermic doses of 0.1 Gm. per kilogram, which are well tolerated. Larger doses are usually toxic. Oral administration is not as effective (Moore, 1913).

Human Pneumonia (Lobar). —The clinical efficiency is difficult to judge, but it is at best much less successful than in animals. Some clinicians report improvement when it is used in the first two or three days of the disease (Lapinski, 1915; A. Fraenkel, 1915); but the trend of literature is not encouraging (Moore and Chesney, 1917, 1918, Leuck, 1918).

Reasons for Failure in Human Pneumonia.—Really effective doses are too dangerous. Although it is possible to render the blood serum toxic to the pneumococcus in a few hours, by fairly safe dosage (see under administration); the germicidal action is too slow (not acting 20 hours in vitro), to permit new generations of bacteria to come into the blood from the lungs, etc. (R. Cole). Insufficient dosage induces "fastness" in the body and in vitro. It is also very doubtful whether the drug penetrates through the alveolar exudate (Moore and Chesney, 1918).

Further reviews of the clinical results are given by Cohen, Kolmer and Heist, 1915; Moore and Chesney, 1917, 1918.
HYDROCUPREIN DERIVATIVES

Blindness.—This occurs all too frequently even with the ordinary therapeutic doses, such as 1.5 Gm. per day. Fraenkel, 1915, obtained some degree of amblyopia in 10 per cent. of his cases. One case has been reported after 0.5 Gm. Whilst this is usually temporary, the administration of the drug involves serious responsibility.

Course of the Amblyopia.—The disturbance of vision generally starts abruptly and is usually severe, often progressing to complete amaurosis. The pupils are maximally dilated. If the drug is stopped, the vision usually improves, after a few days, but sometimes only after months; and even in the more favorable cases there remains more or less restriction of the visual field, central scotoma, and impaired color vision (literature, A. Adler, 1916).

Pathology.—Optochia produces the same changes as quinin, but with much smaller doses and greater frequency. The eye ground is ischemic, sometimes preceded by venous stasis. The optic disc becomes swollen and the retina edematous. There may be effusion into the lymph-sheath of the optic nerve, resulting in compression of the vessels and nerve fibers. Improved vision may begin whilst the ischemia still persists; on the other hand, the condition may progress to retinal and optic nerve changes (literature, Adler, 1916, experimental, Hirschfelder, 1913). Other Side Actions.—The susceptibility to these varies greatly in different individuals. Temporary cinchonism and vomiting are of frequent occurrence (Seiffert, Neheswirk, 1913).

Administration.—Moore and Chesney find oral administration most satisfactory, and use the hydrochlorid, preferably in capsules. The daily dose should be 0.024 Gm. per Kg. (1.5 Gm. per 60 Kg.), and this should be divided so that a fraction (i.e., 0.15 Gm.) is taken every 2½ hours, to maintain a constant concentration in the blood (on the first day this routine is modified, starting with an initial dose of 0.45 Gm., and following this every 3 hours by 0.15 Gm.). There is a slight accumulation, and the drug should not be continued beyond 3 or 4 days. The vision should be carefully tested throughout.

Pharmacologic Actions.—These correspond qualitatively with quinin, but are more acute. Intravenously, optochin is more depressant to the heart, the blood pressure, however, falls less than with quinin, since there is also vasodilatation. The antipyretic efficiency of optochin is smaller (Smith and Fantus, 1916). It has but little inhibitory action on the emigration of leucocytes (Ikeda, 1916).

Weak concentrations are ineffective; 1 per cent. does not cause permanent damage, but stronger solutions injure the cornea. Subconjunctival injections of 1/5 to 1 per cent. also produce local injury (R. Schneider, 1920).

Perfused Mammalian Heart.—Smith and Fantus observed decrease of both diastole and systole by 17:50,000 in Ringer's.

Blood Pressure.—Intravenous injection produces marked fall (S. and F.; D. and S.), due to cardiac depression. In man, intravenous administration produces cardiac arrest.

Fat.—The alkaloid disappears rapidly from the plasma after intravenous injection, it persists longer and in greater amount in the corpuscles (Boecker, 1917).
EUKUPIN AND VUZIN

General Statement.—These alkyl derivatives of hydrocortisone act similarly to quinin. They were introduced by Morgenroth, 1917, as wound antiseptics, and were used as such by the German Army during the war. They appear to combine a high antiseptic action, even in the presence of proteins, with relatively low toxicity to tissues. Their persistent analgesic action is also a desirable feature. The clinical reports, as usual with new antiseptics, have been almost uniformly laudatory, especially as regards their prophylactic value. However, there does not seem to have been any carefully controlled experimental comparison with other antiseptics, and with simple clean surgery.

The free bases are practically insoluble in water, but dissolve in oils. The bihydrates are used as soluble salts, that of the eukupin dissolving in water to 5 per cent. (stronger solutions are turbid) that of vuizin up to 3% per cent., and above 5 per cent. Serum dissolves E. bi HCl to 1:14,000; V. bi HCl to 1:20,000; the lower solubility being due to the liberation of the base. Solutions should be freshly made, as the antiseptic efficiency diminishes materially even in a few days. Contact with alkalies must be avoided.

Bactericidal Efficiency in Vitro.—This was stated for pus-organisms, in a previous section. Other bacteria are also inhibited by high dilutions; the micrococci tetragenics, for instance, by eukupin 1:150,000; or vuizin 1:50,000. The cholera vibrio is rather resistant (literature in Bruhn, 1919; Bylsma, 1919).

In general, concentrations of 1/4 to 1/3 of the bactericidal suffice to inhibit bacterial growth. The activity is not materially hindered by protein to a per cent., but high protein contents hinder markedly. The bases are not as active as the salts. Surviving bacteria do not acquire fastness (Bruhn).

Tissue Injury.—The "harmlessness" of these drugs holds only for very dilute solutions. For instance, the hypodermic injection of solutions of vuizin 1:100 or eukupin 1:500 produces considerable local edema, associated with some fever, malaise and headache. These, however, all recede rapidly (Ribeigal, 1915). Hypodermic injection of 3 per cent. solutions result in local necrosis (Bylsma). Even the 1:15,000 solutions produce sufficient pain to make the addition of procain advisable. The cornua also responds by local reactions, as described below.

Clinical Application to Wounds.—Vuizin was at first applied as washes to wounds of the soft parts and bones; but resulted only in slight decrease of suppuration. Klapp (1917, 1918) then developed the application by infiltration with 1:10,000 or 1:10,000 solutions, containing 1% per cent. of procain and some epinephrin, in 0.9 per cent. NaCl. The vuizin or eukupin is dissolved by heat; or by dilution of the 10 per cent. alcoholic solutions. The injections are made from the sound tissue toward the wound, impregnating the entire surroundings, below as well as around the wound, using up to 500 c.c. if necessary. The dead tissue is cut away, and the wound sutured. The injections may be repeated daily, if necessary.

This results in less pus, because of the antiseptic action of quinin derivatives. The granulations and the adhesion of the wound edges are delayed, but the total line of healing is not to be shortened, and the scars are more smooth and movable than would otherwise be expected (literature, Bruhn, 1919). Gas gangrene is of rare occurrence, and may also be prevented experimentally. On the other hand, Hanks, 1919 found the success in large wounds from gas edema rather limited. In abdominal wounds, Prahl, 1919, used vuizin, 750 c.c. of 1:15,000.

Superficial Suppurations.—Ribeigal, 1918, injected vuizin biHCl 1:1,000, or eukupin 1:500, with procain, around the wound. He claimed that the suppuration class promptly, but there is considerable local reaction.

Abscesses.—Withdrawal of the pus by puncture, followed by injection with vuizin bihydrochlorid, 1:500, or eukupin 1:200, with 0.5 per cent. procain is said to lead to considerable local and systemic reaction, followed by prompt healing (Ries, 1917, F. Rosenstein, 1918). The analgesia is a very desirable feature. The spreading of boils and carbuncles may be arrested by injecting the surrounding tissue, as for wounds. Repeated injections have also been tried against empyemas and pus-joints (Bruhn-Bier, 1917, attempted to treat pleural empyema by evacuation, rinsing, and filling with 500 c.c. of 0.5 per cent. eukupin bihydrochlorid. The results were not satisfactory. The failure is attributed by Klapp to excessive concentration. The latter claims good
HYDROCUPREIN DERIVATIVES

cess with 200 c.c. of zuvin bihydrochlorid, 1:10,000. Rosenstein also claims good results.

**Diphtheria Carrier**.—Disinfection of these has been attempted by the surface application of 2 per cent. eukupin or eukupinotoxino bihydrochlorid, supplemented by systemic administration. Some observers claim complete success in 1 to 3 weeks, though bad effects. Others were less successful, but may have used it less intensively (Bruhn).

**Diphtheria**.—Sommer claims improvement with local application of 3 per cent. zuvin.

**Meningococcus Carrier**.—Isaac treats these locally with 0.5 per cent. zuvin.

Several observers claim that local or systemic treatment has given decisively favorable results. Bier, 1917, used local injections, and zuvinupin base by mouth, 0.5 Gm., three times per day, for 2 weeks. Lesser, for purulent septicemia injected 1 per cent. zuvin hydrochlorid intravenously; 10 c.c. on the first, 20 c.c. on the second and 50 c.c. on the third day (Bruhn).

**Internal Administration.**—The systemic effects correspond about to those of quinuin.

**Temperature.**—With normal rabbits, the hypodermic injection of zuvin, 20 mg. per g., lowers temperature; the same dose of eukupin has no effect; 100 mg. per Kg. induces a marked pronoctal fall.

With febrile rabbits (calf vaccine fever) 25 mg. per Kg. of either zuvin, eukupin or zuvin lower the temperature (Bylsma).

**Malarias.**—Eukupin basic, 0.5 to 1 Gm. per day, by mouth, causes rapid disappearances of plasmodia from the blood (Baermann, 1914; Blumenthal).

**Influenzal Pneumonia.**—Several observers have reported "excellent results" from zuvin, basic, 0.25 to 0.5 Gm. per dose, to 3 Gm. per day, by mouth. It has no effect on the influenza proper, but is said to prevent pulmonary complications, if used early; if these have started, to cause rapid recovery even in severe cases (Bruhn).

**Erysipelas.**—Zuntz, 1915, claims good results from systemic and local application. Intramuscular injection is required.

**Side Actions.**—Oral doses to 3 Gm. per day are said to produce no bad effects, except occasional nausea and vomiting, which disappear after short omission. Blindness has not been reported thus far (Bruhn).

**Pharmacologic Actions.**—These agree in most respects qualitatively with quinuin (Bylsma, 1920).

**Toxicity.**—By hypodermic injection into mice, zuvin is about 2 to 4 times, eukupin 2 to 3 times as toxic as quinuin, but the ratio varies probably for different animals; and adequate data are available for man. Hoffmann, 1916, injected 2 patients intravenously with 400 mg. of zuvin; and Lesser, 1918, with 300 mg. as 1 per cent. solution. He showed no dangerous effects, only some rigor and pyrexia.

The M.F.D. mg. of bihydrochlorid per Kg., is stated by Bylsma as follows: Hypodermic mouse, zuvin = 200; Eukupin 300; cat, V = 200; Eu = 25 to 50. Vein, cat, zuvin, 1-3 mg. i.e., for either, about 0.2 to 1.100; 10 mg., for 1:1000.

**Toxic Symptoms.**—Cats with either compound show mainly stupor, deepening into death.

**Local Actions.**—The perfused cardiac muscle of mammals (1:15,000) or frogs (1:1500 to 1:150) is depressed by both drugs. The systemic vessels are constricted by zuvin (1:15,000), dilated by eukupin (1:120,000). The pulmonary vessels are generally constricted, the coronary vessels generally dilated, by both drugs. The general blood pressure falls after intravenous injection, but recovers if the dosage was not too high. The pressor response to epinephrin is diminished and finally abolished by zuvin. It also decreases the response of the heart to direct vagus stimulation (Bylsma).

**Renal Effects.**—Sheep's corpuscles are laked by zuvin 1:10,000, or eukupin 1:5000, in Ringer's fluid; or 1 per cent. of either in serum (Bylsma).

**Hemoglobin.**—One per cent. zuvin or eukupin bihydrochlorid convert oxyhemoglobin to a brown derivative, with a spectrum different from that of the known hemoglobin compounds, i.e., not methemoglobin or hematin (Bylsma).

**Spinal Center.**—These are not affected in mammals by the intravenous injection of toxic doses of zuvin or eukupin (Bylsma).

**Vagus Center.**—Zuvin has no effect in cats; eukupin stimulates (Bylsma).

**Respiratory Center.**—Zuvin and eukupin stimulate, in rabbits and cats (Bylsma).

**Bromochi.**—On perfusion of the isolated cat lung, with 1:20,000 solutions, the bronchi constricted by zuvin, dilated by eukupin, quinuin and quinolin (Bylsma).

**Exsanguination Small Intestine.**—For cats or rabbits, zuvin, eukupin and quinuin is almost always inoperative, but do exceptionally stimulate (Bylsma).
Excited Uterus.—For cats or rabbits, quinin, eukupin or quinidin were always inhaible.

Skull Muscle.—On perfusion through frog-legs, small doses of quinin, eukupin an quinidin hasten fatigue; higher doses decrease the excitability, especially of the endings of still larger doses produce rigor. Vuxin is the most, quinin the least toxic (Bylsma).

Corneal Anesthesia.—These ceparin derivatives produce more persistent anesthesia of the cornea than do equal or higher concentrations of cocain. For instance, 3/4 percent cocain produces 10 minute-anesthesia of the rabbit's cornea (Sollmann); but to produce 3/4 to 1/2 hour anesthesia requires 2 per cent. of cocain or 3 per cent. of quinin or 3 per cent. of optochin, but only 3/4 per cent. of quinin or eukupin, or 3/4 per cent. eukupatotin. Only solutions of the bases require higher concentrations. With stronger solutions, for instance 10 per cent. quinin, the anesthesia may last 4 days (Morgenroth and Ginsberg, 1913).

On the other hand, the ceparin derivatives are irritant even with 3/4 or 1/2 per cent solutions (temporary clouding and hemorhous; Bruhn); and 1 per cent. solutions cause severe and fairly lasting injury of the cornea (Bylsma).

Sensory Nerve Fibers.—Direct application of 3/4 per cent. vuxin or eukupin paralyzes in frogs (Bylsma).

Absorption.—This resembles that of quinin. The absorption of hypodermic or Intramuscular injections of vuxin or eukupin hydrochlorid is very slow; a part remaining at the site of injection over 4 days (Bylsma).

Sojourn in Blood.—With intravenous of nearly fatal doses of vuxin, about 3/4 is found in the blood after 35 minutes; the other 3/4 being distributed in the tissues (Bylsma).

Distribution in Blood.—The concentration in the corpuscles is 8 to 17 times that in the serum (Bylsma).

Destruction.—A day after the intravenous injection of nearly fatal doses of vuxin, none was demonstrable in any tissues; nor was any excreted in the urine during the period; i.e., the destruction must have been practically complete (Bylsma).

Excretion.—None could be demonstrated after intravenous or hypodermic injection of vuxin or eukupin into rabbits or cats (Bylsma).

ACETANILID, ACETPHENETIDIN AND ANTIPYRIN

General Statement.—These drugs and their derivatives, the "cold tar antipyretics," lower febrile temperature by dilating the cutaneous vessels through a central action. They are highly effective; but the antipyrctic doses are apt to produce undesirable side actions, and are clinically supposed to be depressant to the circulation. Smaller doses are efficient analgesics in headache, neuralgic conditions, etc. Their use is now without danger from acute collapse. Chronic poisoning, with methemoglobin formation, is also not infrequent. Acetphenetidin (Phenacetin) is somewhat less dangerous, but the difference is merely one of degree. Antipyrin is freely soluble, the others are not.

The former high price of quinin caused chemists and pharmacologists to look about for cheaper efficient substitutes. It was attempted to make quinin or similar substances synthetically, departing from quinin, one of the decomposition products of quinin. Whilst this search did not result in an artificial quinin, nor even of any substance analogous to it in action, it brought to light a very large number of substances, in some respects even more valuable than the alkaloid itself, and served to direct attention to the pharmacologic significance of the derivatives of the aromatic series, or, as they are more commonly called, of cool-tar.

It was found that all the simpler compounds built up from the benzoic nucleus (with a very few exceptions) possess certain physiologic actions in common, as follows:

Common Actions on Benzol Derivatives.—Central Actions: Stimulation, followed by more pronounced depression of the entire central nervous system, but particularly an antipyretic action on the heat-centers, and an analgetic action in neuralgia.

Local Actions: A coagulant, irritant, toxic and antiseptic effect on all forms of protein and protoplasmin—on tissue cells, bacteria, and ferments. A quinin action on all forms of muscle. Local anesthesia. The formation of methemoglobin.

The actions are exerted in a different manner and to a different degree by the seventh members of the series, mainly in two directions, so that these may be classified somewhat arbitrarily as "Antipyretics" and "Antiseptics."
ACETANILID, ACETOPHENETIDIN, ANTIPYRIN

Antipyrhetic group is distinguished by the predominance of the action on the heating center.

Antiseptic group is characterized by a much more marked local action on protoplasm which determines the usefulness of the members as antiseptics. The effect of the thermic centers passes much more readily into general collapse than with the group. Distinction is by no means sharp, and many of the substances—i.e., the salicyl- be classed under either group.

Spect and Antipyrhetic Action.—The large number of antipyrhetic derivatives differ only quantitatively in their actions, these differing definite relations to their chemic structure. Practical exce has shown that acetophenetidin, acetanilid and antipyrin are the useful representatives of the group, and that all the others may well be neglected.

Enterprise of manufacturers of synthetic products has overwhelmed the market almost numberless antipyretics; but it must be confessed at once that the really new and valuable product is comparatively small. The great mass material consists simply of insignificant variations in the established products, ed for the purpose of evading patents; and amounts to little more than do the flavorings in the elixirs of the older materia medica. This multiplication can harm by creating confusion, and should be abolished as speedily as possible.

This multiplication can harm by creating confusion, and should be abolished as speedily as possible.

In this way many new compounds can be t as unworthy of extended trial. A presentation of some of these laws will be of practical value, aside from their scientific interest.

Antipyrhetic action really resides in the benzol ring. Yet benzol itself is not antipyrhetic, because it can not readily enter into reach the body cells; this capacity of reacting may be given to it by sub-g for one of its [H] atoms an [OH] group, as in phenol, C₆H₅OH; more strongly by an NH₂ group, as in anilin, C₆H₅-NH₂ (Phenyl-

We repeat that the power of acting is given to the benzo1 or other chain, by replacing H through OH, or NH₂, or both. The substances so produced are the so-called "mother-substances." They are strongly antipyretic, but they also produce collapse. Before they can be used in practice, this collapse action must be diminished. This may be done by replacing the [H], either of the [OH] or of the [NH₂], by other radicals; the reduction of toxicity being greatest if the substitution is made in the NH₂ group.

These substituted compounds act only after the mother-substance is liberated from them in the body. Their action is therefore more gradual, less violent, and more easy of control.

The influence of the substituted radical is as follows: The reduction of toxicity is greatest if the substituted radical is an alkyl (C₇H₈ + 1 or CO₂.CH₃ + 1); less if it is an acyl (CO₂.CH₃ + 1). If several H atoms are substituted, the toxicity will be less if both an acyl and an alkyl radical are introduced, than if both radicals be of the same kind.

The toxicity and the therapeutic qualities both diminish with the size of the introduced radical. The most useful is the ethyl (C₂H₅) or acetyl (C₅H₁₁O) radical; with the methyl or formyl group, the toxic action is too great; with larger groups, and particularly with aromatic groups, the compound becomes so resistant that the therapeutic action is reduced almost to nothing. This is true of the citrate and salicylate radicals. Such compounds are of course correspondingly harmless.

The above laws must be modified if the compound is decomposed in the stomach with liberation of the mother-substance. It must also be remembered that the radicals must be introduced into the ring by substitution; the mere addition of acid radicals forming salts, does not modify the properties of the original substance. Therefore Anilin Acetate (C₆H₅.NH₂.HC₇H₅.O₂) preserves the original toxic action of anilin; whereas this is greatly weakened in Acetanilid (C₆H₅.NH.C₇H₈.O₂).

The substitution of an H by I, Br, or Cl, does not modify the antipyretic or toxic action of the original substance.

Absorption, Fate and Excretion.—The antipyretics are rapidly absorbed and excreted. Acetanilid, acethoextendin and their derivatives are mainly oxidized to paramidophenol, which is probably the form in which they produce their actions. This is excreted in the urine, chiefly as paired compounds with sulphuric and glucuronic acids. This gives the "indophenol reaction" in the urine. Antipyrin is eliminated largely unchanged by the urine (Jonescu, 1906), traces also by the sweat (Tachas, 1911), and sputum (Hofbauer, 1915). The urine volume is generally decreased. Occasionally the urine is blood red, and green in reflected light (Penzoldt).

The antiseptic action of the antipyretics is not very strong. They are however, sometimes used as antiseptic, astringent, and hemostatic dusting powders (acetanilid or antipyrin in a per cent. sterilized solution). They are less poisonous and less irritating than iodoform; although toxic effects have been reported from the application of acetanilid to wounds.

Leucocytosis.—It has been believed that this is produced by antipyretics; but Gehrig, 1915, found no effect. The migration of leucocytes from the inflamed mesentery of frogs is inhibited by antipyrin (Ikeda, 1916).

Antipyretic Action and Effects on Metabolism.—These were described on page 540.

Antipyretic Dosage.—On account of the possibility of a direct collapse action if the dose is relatively large, the antipyretics must be administered with care.
In general, it may be said that, from the smallest effective dose (0.1 Gm. for acetanilid, 0.3 to 0.5 Gm. for antipyrin or phenacetin), the extent of the antipyretic action increases with the dose of the drug, until the normal temperature has been reached. Beyond this point there is practically no danger of a direct collapse action. But if the dose necessary to secure this result be exceeded, the toxic effects will set in.

The average antipyretic dose may be stated as 0.5 Gm. (7 gr.) of acetanilid; 0.8 Gm. (10 gr.) of phenacetin; 1.2 Gm. (20 gr.) of antipyrin. In beginning the treatment, this dose has to be repeated once or twice, with an hour’s interval, until the desired fall is secured. After this, the single dose is repeated whenever the temperature begins to rise. Four or five doses are required per day to keep the patient practically fever-free. The action does not persist after the drug is excreted. With single doses the antipyretic effect reaches its maximum in about two hours, and then declines gradually, so that the febrile level is practically restored in eight hours (Gottlieb, 1890). Consequently the administration must be continuous, in the manner indicated. Those antipyretics which are rapidly excreted (as is phenocoll) are therefore less useful.

In regard to details, and in determining the choice of the particular substance to be used, experience is the best guide. The same holds here as in other cases: Very much more can be accomplished by any one drug that is thoroughly understood by the user, than can be done with a number of drugs with which he has had only limited experience.

Features Desired in an Antipyretic.—The ideal antipyretic must be reliable in securing a fall of febrile temperature. This fall must be prompt, but not too abrupt; it must be lasting; and when the effect passes off, the temperature must not rise too suddenly. The analgesic effect should be strong. The drug should not be decompensated in the stomach (or by 0.2 per cent. HCl). The toxic dose should be considerably higher than the therapeutic dose. In the latter, the drug must not of itself cause collapse conditions, nor methemoglobinemia, nor profuse sweating, nor skin eruptions. It should not have a bad taste, nor should it irritate the stomach. If it is to be used hypodermically, it must be soluble in water; otherwise great solubility is of no advantage.

Of the compounds which have been proposed so far, Para-acetophenetidin (Phenacetin) seems to fulfill these demands most satisfactorily.

Analgesic Action.—Like quinin and the salicylates, all the antipyretics have an analgesic effect against neuralgic and muscular pains, headaches, migraine, colds, rheumatic conditions, etc.; but are ineffective against other forms of pain, such as trauma. The mechanism of the analgesic action is obscure. It has been suggested that it consists in changes of the meningeal vessels. There is little if any evidence of true narcosis; nor do the antipyretics reinforce the action of the ordinary narcotics to a marked degree (Lomonosoff, 1911).

The analgesic action is extensively used. Small doses (acetanilid, 0.3 Gm., 3 gr.; acetophenetidin, 0.3 Gm., 5 gr.) may be repeated a few times with three-hour intervals, if necessary. If these small doses fail to give relief, larger doses are usually also ineffective.

The analgesia has been investigated in man by Martin, Grace and McGuire, 1915. They found that 0.3 to 1 Gm. of acetophenetidin distinctly raises the threshold of cutaneous sensibility.

Neuro-muscular Coordination.—This, as judged by the “tapping test,” is not altered by non-toxic doses of the antipyretics (Macht, Isacco and Greenberg 1918).

Intracranial Vessels.—The effect of antipyretics and hypnotics on the cerebral and meningeal vessels should be investigated by plethysmograph on trepanned patients. Carrazi, 1918, showed that the cerebral vessels undergo large oscillations with the emotions.
Proprietary Headache Powders.—These usually contain from 50 to 70 per cent. of acetanilid or acetylsalicylic acid (Report C.P.C., J.A.M.A., 1905, 44:1792), generally mixed with caffeine, salicylates, bromids, ammonium carbonate or sodium bicarbonate. The caffeine, salicylate and bromid would reinforce the analgesic action. The alkaloids were supposed to increase the solubility, but do not do so (Puckner, 1906). It was also claimed that all these drugs diminish the toxicity, but this is contradicted by the available evidence (Hale). The indiscriminate use of the powders by the laity has repeatedly produced acute and chronic poisoning. Authoritative statistics of this are presented in the report of Kehler, Morgan and Rupp, 1909.

Chronic Poisoning.—The continued use of acetanilid ("headache-powders") has occasionally caused the development of a drug habit, with craving and withdrawal symptoms. An individual predisposition appears to be necessary, for the condition is relatively rare; but it should be guarded against in the administration of the drug. The symptoms of chronic acetanilid poisoning consist in methemoglobinemia (change in color of the blood) with the histologic blood changes of pernicious anemia; marked leucocyotosis; cyanosis; cardiac weakness; progressive mental and physical debility. Methemoglobin may also appear in the urine. (D. D. Stewart, 1907.)

Diabetes Insipidus.—Beneficial results have been claimed for the antiptyretics, /4, by Hirschfeld, 1904. They require confirmation.

Side Actions.—Undesirable effects are rather common, especially when antiptyretic doses are used. Some of these are the indirect results of the heat regulation—sweating and chills, indirect collapse; some are due to irritation—gastric disturbances, skin eruptions, renal irritation; others to the direct systemic actions of the drugs—chinchonism, cyanosis, true collapse. The susceptibility to them varies greatly in different individuals.

The literature of the side actions is given by Seifert, Nebenwirk., 1915: Acetanilid, page 2; Antipyrin, page 4; Acetphenetidin, page 16.

The sweating is due to the increased circulation through the skin, and is produced in the same manner, and has the same significance, as the critical heat of fever. It must be looked upon as beneficial rather than otherwise, since it adds the reduction of temperature. But should it become too troublesome, it can be suppressed by small doses of atropin.

The cutaneous hyperemia is perhaps also responsible for the skin eruptions. They are particularly frequent after antipyrin.

The tendency to this eruption as also to a stomatitis which is often seen, increases with the repeated use of the drug.

Antipyrin Eruptions.—With susceptible individuals, these occur promptly even after small doses; in the form of round or oval erythematous somewhat pigmented patches, which in some cases may be bullous. When the drug is discontinued, these are replaced by pigmented areas, which become rapidly congested if another dose is taken (H. MacCormac).

Phenylhydrazine produces very similar local actions on the skin (eczema, erythema nodosum and papulom) and on the alimentary canal (gastroenteritis).

The chills occur when the temperature begins to rise again, and are due to a diminished circulation through the skin, just as the chills of malaria. They are therefore not to be attributed to the drugs, but are rather a sign that the action of the antipyretic has worn off.

Gastric symptoms are due to local irritation, but are not frequent. Most of these drugs have a sharp, warm or bitter taste.

Renal irritation, varying from slight diuresis without histologic change, to violet, desquamative, hemorrhagic, parenchymatous nephritis, may be produced by all salutar derivatives. There is not, however, any danger of nephritic lesions from ordinary doses of the antiptyretics. Thallin produces a peculiar papillary nephritis.

Chinchonism symptoms are rare, but have been reported. The cyanosis is due to the methemoglobinemia.

Lactophenin produces icterus in over half of the patients, usually on the ninth to twelfth day of treatment. There is no relation to dose. It appears to be harmless, and is probably of the retention type rather than hemolytic (Hanssen, 1910).

Methemoglobin Cyanosis.—All drugs of the coal-tar series act more or less upon the blood, inside of the body, producing methemoglobin, and
in larger doses causing a disintegration of the corpuscles. This action is much more pronounced in the mother-substances—anilin, phenylhydrazin, etc.—and in the antiseptic group it is stronger with acetanilid than with the other antipyretics. It leads to a peculiar cyanosis, and contributes to the collapse.

The methemoglobin formation proceeds much more weakly in shed blood than it does in the body. The relation of the methemoglobin formation to the chemical constitution of benzol derivatives has been investigated by W. Heusser, 1913.

**Collapse Action.**—Excessive, and sometimes therapeutic doses, produce serious collapse, with weak and irregular pulse, dyspneic or shallow respiration, pale or cyanotic skin, cold sweat, disturbed consciousness, subnormal temperature, and death by circulatory failure. This collapse is sometimes a direct effect of the drugs (cardiac and vasomotor depression); in other cases it is due to the reduction of the febrile temperature, "unmasking" a preexisting febrile collapse: Circulatory failure is a frequent feature of fevers. It may be partly masked by the stimulant effects of high temperature, and will then reveal itself when the normal temperature is restored, whether by antipyretic drugs or by baths. Caution is therefore necessary in the use of all antipyretic measures in asthenic fevers. Menstruation also favors the development of collapse.

Of the more usual antipyretics, acetanilid produces probably the strongest direct collapse effects; then come antipyrin and then phenacetin.

The collapse action is strongest in the mother substances—anilin, quinolin, phenetidine, phenylhydrazine, and carbolic acid, and generally in the members of the antiseptic group; so strong, indeed, that the action of these can not be controlled, and they are hence unfit for internal administration.

**The treatment of poisoning** by overdoses of the antipyretics is the same as for collapse from other causes—stimulants, heat, etc. (see Aconite).

**Circulation.**—The general circulation is but little affected by ordinary doses. Some will slow the heart indirectly by reducing the temperature; this has probably sometimes been misinterpreted as cardiac depression.

The cutaneous vessels are dilated; the intracranial vessels, after a short dilatation, show a more persistent constriction, similar to caffeine or alcohol (E. Weber, 1900). Berezin, 1916, reports dilatation in rabbits and fish. Hirschfelder, 1913, describes dilatation of the pit and retinal vessels, from acetanilid, antipyrin, amyl nitrite, caffeine and alcohol. This tends to raise intracranial pressure, enjoining caution in glaucoma (Wessely, 1913).

With toxic doses, the heart is first accelerated, and later slowed. This is due to direct action upon the heart muscle. Strips of terrapin’s ventricle are slowed and arrested by acetanilid (Carr, 1910).

The urinometer center is not affected by moderate doses (with the exception of the Part controlling the cutaneous vessels). In consequence, the **blood pressure depends solely upon the cardiac action, being at first increased and later diminished. In doses producing collapse there is paralysis of the vasomotor system, and consequent fall of blood pressure.**

**Stripped muscle** shows a somewhat increased efficiency on direct stimulation, and a weak curare action.

**PREPARATIONS—ANTIPYRETIC GROUP**

Only the most important preparations are given; others may be found in N.N.B.

**Acetanilidum (Acetanilid).** U.S.P., B.P. (Antifebrin, Phenylacetamid, etc.), C.H., N.E.-White crystalline powder; odorless; warm taste. Slightly sol. in water (1:18), freely sol. in alc. (1:14), or glycerin (1:5). Liquifies with chloral or antipyrin.

**Dose.** 0.3 Gm., 5 gr., U.S.P.; 0.12 to 0.3 Gm., 2 to 5 gr., B.P.; in powders or capsules.

**Maximum dose.** 0.5 Gm., 8 gr.
**Antiseptic Benzol Derivatives**

**General Statement.**—These differ from the antipyretic derivative mainly by greater toxicity. On local contact they coagulate proteins, thus determining the death of cells, resulting in irritation and inflammatory changes, and in antiseptic effects. After absorption they produce some excitement and more pronounced depression of the central nervous system. Many alter the blood pigment to methemoglobin. Their effects are well known in general, but differ in important details. The high toxicity is due to various side-chains, such as the hydroxyl and carbonyl groups by which they can react with protoplasm.

**Historical.**—In the form of the natural mixtures, the antiseptic properties of this group have long been known empirically, as in the smoking of meat. One of the methods of embalming practised by the Egyptians utilized largely balsams and products rich in essential oils—the latter being very closely related to the aromatic series. The isolated substances, however, belong to the achievements of the nineteenth century. Creosote was first made in 1839, phenol in 1834; but almost thirty years elapsed before they were used in surgery.

**Influence of Structure on Action.**—Benzol, C$_6$H$_5$, the mother substance of the coal-tar series, has a low toxicity, because it can not react with protoplasm. This capacity is given to it by replacing part of the H atoms by other groups, especially by OH (forming phenols) or by CO$_2$H (forming acids); or by both. The OH radical is the most active, the antiseptic and toxic actions increasing with the number of OH groups (i.e., progressively from phenol, C$_6$H$_5$OH, to resorcin, C$_6$H$_4$(OH)$_2$, and pyrogallol, C$_6$H$_4$(OH)$_3$), but it is also influenced by the position; thus, phenol, phenols, and isomers of pyrogallol are not active. The introduction of the CO$_2$H group alone (i.e., benzoic acid; C$_6$H$_5$CO$_2$H) does not render the substance very active. The introduction of both OH and CO$_2$H is the ortho-position (i.e., salicylic acid, C$_6$H$_5$<CO$_2$H) results in a compound which is less toxic and less antiseptic than phenol, but which has peculiar antirheumatic properties. The antiseptic quality may also be brought out by other acyl groups (CO$_2$R, etc.), the activity being proportional to the size of the introduced molecule. Nevertheless, develops the antiseptic action, but adds its own toxicity to that of the phenol. The
substitution or an II of the CH₄ in phenol by alkyls (creosols, C₆H₅<CH₃>OH) leads to an increase of the antiseptic power, and diminishes at the same time the toxicity to tissues. Higher homologues introduce no important modifications. The union of two phenols directly or by CH₃, etc., increases the antiseptic action, but if united by CO or SO₂ it is diminished. The substitution of halogenes increases the antiseptic action, according to the number of atoms. The toxicity is diminished by the lower, increased by the higher numbers (Bachhold and Ehrlich, 1906).

The group which gives the valuable antiseptic, but also the undesirable toxic and caustic qualities to these compounds, is the OH.

The violence of its action may be moderated, as in the salicylic acid, or in the cresols; or it may be masked by replacing its H by other radicals (the "Nencki's salol principle"). These esters (e.g., salol, C₆H₅OH-CO₂-C₆H₅), will develop their action when decomposed into their phenol and combinations which are free to produce this liberation (e.g., the sulfo-carbonates) are neither antiseptic nor toxic; in fact, it is by the formation of such compounds that the organism protects itself against these poisons.

The antiseptic and local actions of the salicylates or other salts are also much less than those of the corresponding acids.

Fate of the Benzol Derivatives in the Body.—The six-carbon ring is relatively resistant to decomposition, and for the most part passes through the body unbroken, although a little is burned. The hydrogen atoms and side-chains undergo more or less oxidation, resulting in new hydroxyl and carboxyl groups (phenols and acids) in considerable variety. These again enter combinations before being excreted by the urine; the phenols forming esters, chiefly with sulphuric acid (Baumann and Herter, 1876; O. Neubauer, 1901); and to a lesser extent with glycuronic acid. The aromatic acids combine with glycocoll to form hippuric acid, etc.

The formation of the esters is generally proportioned to the toxicity of the phenols (S. Fraenkel). Since the esters are much less toxic than the phenols, it constitutes an important protection of the organism against poisoning, especially against the phenols arising in intestinal putrefaction. For instance, the exclusion of the bile from the intestines, by increasing intestinal putrefaction, increases phenol elimination (Dehn, 1917).

The normal phenol excretion (largely paracresol) tends to vary directly with the protein intake (Pollin and Denis, 1913). In phenol poisoning, the urine becomes poor in free and rich in ethereal sulphates, and has a smoky color, especially on standing, from the oxidation of the hydroquinon, pyrocatechin, etc. The glycuronic compounds may be mistaken for sugar, since they reduce copper, although more slowly. Determinations of the phenols of the blood in various conditions do not show distinctive changes (Theis and Benedict, 1918).

The place of formation of the ethereal sulphates is not known, but it has been shown to be independent of the liver (Lade, 1912). Nevertheless, the sulpho-conjugation has been proposed as a test of hepatic function. Thymol, 0.5 Gm., is normally followed by considerable increase of the ethereal sulphates of the urine. This increase is sometimes absent in hepatic disease; but not always (M. Kahn, 1918).

Glycuronic Acid.—This corresponds to dextrose, with the end-chain (CH₂OH) oxidized to (COOH). It is probably an intermediate stage in the oxidation of glucose, for very little can be formed in glycopen-poor animals (Dakin). Glycuronic acid is probably not a normal stage of carbohydrate metabolism; for if it is administered parenterally, it appears almost quantitatively unchanged in the urine (Biberfeld, 1914). It is never excreted free, but always in combination with aromatic alcohols, phenols, ketones and acids. Haemalsalicylic, 1913, supposes that the alcohols first combine with glucose, and that this glucosid is then oxidized to the glycuronate.

The principal drugs which cause the appearance of Glycuronic acid in the urine are: Turpentine, chloroform, chloral, camphor, phenacetin, saccharin, salicylic acid, balsams, morphin; and others are enumerated by S. Fraenkel, 3rd. ed., p. 194.

The Hippuric Acid Formation.—This occurs in some animals exclusively in the kidneys, but it may also be formed in other organs. Dogs, for instance, synthesize hippuric acid even after excision of their kidneys (Kingsbury, 1915).

The liver probably has a share, for the hippuric synthesis is diminished in hydratul poisoning, while increases extensive degeneration of the liver, but is supposed to leave the kidneys unaffected (Lackner et al, 1918).
BENZOL

Benzol, C₆H₅₄, has come into some prominence for the treatment of leukemia. It often causes temporary improvement, but is rather unreliable and sometimes dangerous. Industrial acute and chronic poisoning is also common, from its use in the arts (as solvent for rubber). It is somewhat antiseptic.

Acute Benzol Poisoning.—Fairly large doses of benzol are tolerated by mouth: 9 to 12 Gm. have caused serious collapse (Perrin, 1864; Averill, 1889). The acute symptoms are restlessness, excitement, high rise of temperature, nausea, and death by paralysis of respiration. Subjectual doses are followed by a good recovery. The technical article is somewhat more toxic than the pure (Lehmann, 1911).

Distribution of Benzol after Poisoning.—The brain and spinal cord contain most than other organs (Joachimigii, 1913).

Benzol Vapor.—This causes intoxication by absorption through the lungs. Dilute vapors produce headache, vertigo, ataxia, twitchings, convulsions and coma. Fiehner, 1913, finds benzol about as narcotic as chloroform. Concentrated vapor is markedly toxic, sometimes producing acute death. There are no characteristic anatomic lesions except that the blood remains fluid for a long time; there are often small hemorrhages in various organs. Patients who recover sometimes develop skin changes (Levin, 1927; Wolf, 1913; Heffer, 1915). The entire symptoms are produced, also on animals, by pure as well as impure benzol.

Chronic Poisoning by Vapor.—This causes hemorrhage (purpura), leukopenia, anemia, and finally death under high fever (Santesson, 1897; Selting, 1913). These effects are attributed to destruction of leucocytes in the circulating blood, and to damage of the bone-marrow, lymph glands, spleen, and the whole hematopoetic system. The formation of blood platelets is first stimulated, then depressed (Duke, 1913).

Blood Changes in Animals.—Subcutaneous injections of benzol (2 to 50 c.c.) into rabbits or dogs produce death in three to twenty days, with marked destructive changes in the hematopoetic organs, especially the myeloid tissue. There is a corresponding diminution of the leucocytes and blood platelets. With large doses, the platelets show a preliminary increase in rabbits, not in dogs (Duke, 1913).

Recovery from this fall may be followed by a second fall (Weisckett, et al, 1916). There is little change in the red cells (Neumann, 1915). The prothrombin is also decreased (Hurwitz and Drinker, 1915). The production of antibodies is diminished (Hektoen, 1920). The changes vary quantitatively in different individuals (Neumann, 1915). Use in Leukemia.—The destructive action of benzol on leucocytes led to its introduction by v. Koranyi, 1912. Numerous reporters (Kiraly, 1912; Stein, 1912; Stern, 1913; Billings, 1913; Morawitz, 1914; Hahn, 1914, etc.) have described more or less favorable, but rather inconstant results. The changes are noticed only after continued administration, often requiring some weeks. The leucocyte count falls, more profoundly and persistently than with arsenic, but never to normal, as in X-ray treatment. The general condition is also improved. The best results are obtained when benzol is preceded by or continued with ray-treatment. In a considerable number of cases, especially the advanced, the benzol is unsuccessful. In others, toxic effects supervene.

Mechanism of Action.—Urinary changes indicate metabolic disturbances: increase of neutral sulphur; decrease of Urea + N, slight increase of ammonia, in most cases albuminuria (Sohn, 1913). The uric acid is not increased, and this speaks against destruction of leucocytes. Pappenheim, 1913, believes the decrease to be only apparent, asserting that the leucocytes accumulate in the dilated capillaries of the liver and other internal organs. He found marked hepatic and renal lesions in rabbits after repeated large doses. Duke, 1913, attributes the platelet change to irritant, then toxic action on the bone-marrow.

Toxic Effects.—Ordinary doses cause eruptions, but the appetite is not disturbed. There may be some dizziness, sometimes bronchitis. Occasionally, late symptoms of chronic benzol poisoning develop, which may be fatal (Neumann, 1913; Klemperer and Hirschfeld). It is therefore advised to discontinue the benzol as soon as the leucocytes start to decline (Kiraly, 1912); or at least when they have fallen to 20,000. Liver, kidney and general disturbances are contraindicate benzol (Hahn, 1914).

Administration.—Billings uses the benzol in extemporaneous capsules, 5 minims, increasing to 15 minims, after meals and at bedtime.

Fate.—Benzol is partly oxidized in the body to phenol (15 to 30 per cent.), catechol and quinol and excreted as phenol-sulphates (Baumann and Herter, 1879); a part is
Phenol (carbolic acid, C₆H₅·OH) illustrates the characteristic properties of the series, and is the most widely known and used of these antiseptics. It owes this popularity to its being the pioneer of the group, through its introduction by Lister, 1867. Some of its derivatives are superior, at least for special purposes.

**Antiseptic Action.**—Phenol is a general protoplasmic poison and a fairly active disinfectant, although not nearly as powerful as mercuric chlorid, or even as the cresols. It precipitates proteins, but the combination is so loose that it readily diffuses further, and therefore penetrates more deeply into the tissues than the metallic antiseptics; and its action is not so much hindered by the presence of organic matter. The *disinfectant power* varies greatly for different microorganisms; spores are especially resistant. Tubercle bacilli are killed by exposure to 5 per cent. for twenty-four hours. It is much more effective as an *antiseptic*, i.e., for checking bacterial growth; ½ to 1 per cent. suffices for this purpose. These are the concentrations used on the body, for here it is not necessary to kill the bacteria if only their development is effectively prevented. These solutions do not ordinarily injure the tissues.

**Antiseptic Uses.**—Five per cent. solutions are used for the disinfection of the utensils, instruments, the hands, etc. The penetration and therefore the antiseptic efficiency are increased by the addition of salt. "Crude Carbolic Acid"27 which contains the more active cresols and is cheaper, is preferred for the disinfection of excreta. As antiseptic for wounds and mucous membranes, gargles, lotions or injections ½ to 1 per cent. of phenol are used. A drop of undiluted phenol is useful for disinfecting and cauterizing small wounds, bites, etc. Injections of phenol have been tried against local inflammations, tubercular bones and lymph glands, boils, erysipelas (5 per cent. to scarified surface), etc. Lotions are used as parasiticide in scabies, syphilis, ptyriasis, and against pediculosis capitis. Inhalations have been advocated in fetid bronchitis and pulmonary gangrene.

**Solutions in Pasty Oils.**—In these phenol is not antiseptic (Koch, 1886), because its solubility in fats is so much greater than its solubility in protoplasm that it prevents its transference to the bacteria or tissues. "Carbolated Oil" is merely a mild local anesthetic and dermal irritant, useful for promoting the healing of small wounds. Alcohol and glycerin have a similar restraining action. The solubility in petrolatum is very small, so that ointments made with this base should be very actively antiseptic and irritant.

As intestinal antiseptic, phenol has little value because of its prompt absorption and marked toxicity.
Solubility of Phenol in Mineral Oils.—Pilcher, 1914, found that a part of crystallized phenol dissolves in 8 to 9 parts of petroleum; 20 to 21 of gasoline; 23 to 24 of solid petroleum; 42 to 50 of liquid petroleum.

Phenol Injections in Tetanus.—Those have been introduced by Baccelli. Rather large doses are used, a 2 to 5 per cent. solution being injected intravenously or hypodermically along the spine every two or three hours, the daily dose starting with 0.1 to 0.5 Gm., and increasing rapidly to 0.8 to 1.5 Gm. of absolute phenol in divided doses, according to severity (J.A.M.A., 53:1260, 1900). No bad effects have been reported, and it is said to cause prompt improvement and to lessen the mortality, even in severe cases (Baccelli, 1912; Asscol, 1913), perhaps by its analgesic and antispasmodic action. The treatment has not been tried adequately by independent observers, and final judgment can not be passed on it (Dreyfus, 1914). McClintock and Hutchings, 1913, state that it has only a limited value, as a substitute for the secondary. Joffe, 1914, comments it.

Fielder, 1914, obtained negative results in rabbits.

Pediculosis Capitis.—Whitehead, 1917, advises soaking the scalp in a 2 5 per cent. phenol solution for ten minutes and leaving the solution on the hair for an hour.

Actions on Ferments.—Phenol, salicylic acid, and other coal-tar antiseptics have a retarding effect upon ferment action —especially carabolic and salicylic acid. A 5 per cent. solution of phenol suffices to weaken materially the action of most ferment.

Local Actions.—Concentrated phenol applied to the skin or mucous membranes produces prickling, burning and pain, then numbness and anesthesia, wrinkling and softening of the epidermis, the color of the skin becoming first white, then red, and finally brown. There is no direct corrosion, but a local necrosis. A dry scab forms, which separates without pus. Short applications of weaker solutions determine merely some wrinkling and blanching of the epidermis and the sensory phenomena, but even a 5 per cent. solution of the acid may cause necrosis, especially when applied continuously to the extremities. This enjoys caution in the use of carbolic dressings.

The analgesic effect of dilute phenol solution and ointments is used against itching.

Pirie advocated compresses saturated with phenolated oil (1:6) for burns. It relieves the pain promptly; but when applied to large surfaces, it is probably capable of producing systemic poisoning.

Schleich found that 5 per cent. watery solution applied to an exposed nerve causes anesthesia.

Undiluted phenol may be used for quick local anesthesia of the skin. A scalded spot

with phenol is drawn over the proposed incision, which may be made after a few seconds (Sorens, 1919).

Absorption.—Phenol is absorbed from all mucous membranes and wounds, and even from the intact skin. In the intestinal canal its absorption is at first very rapid, but soon becomes almost arrested, apparently by interference with the local circulation (Sollmann, Hanzik and Pilcher, 1910). It is distributed through all the tissues.

Fate and Excretion.—A part of the phenol (3/4 to 2/5) is completely burned in the body (Tauber, 1898; Schaffer, 1898; Jonge, 1897). The remainder is excreted in the urine, largely as ethereal sulphates and glycuronates of phenol, hydroquinon and pyrocatechin. However, Folin and Denis, 1915, find that 30 to 90 per cent. of the urinary phenol is not conjugated. With a rise of total phenol, a greater proportion is conjugated; except when bile is excluded from the intestines (Dubin, 1918). The oxidation products impart the smoky color to the urine. A trace of phenols is found in the sweat (Tachau).

Central Actions.—Very small doses of phenol, as of all the coal-tar antiseptics, produce at first an analgesic and antispasmodic action. This is so fleeting, and passes so readily into the graver effects, that it can not be
used in therapeutics. This preliminary stage is followed by more pronounced symptoms resembling the "toxic" effects of salicylates. Dangerous doses produce prompt collapse and coma. Frogs and mammals exhibit characteristic muscular tremors, twitchings and convulsions, persisting until the blood pressure falls very low. These are absent, or at most very faint in man (Husemann, 1871).

Phenol Convulsions.—Salkowski, 1872, showed that these are located in the spinal cord (division of sciatic; decapitation). Morita, 1915, also found that the convulsions occur in rabbits after ablation of the hemispheres. Baglioni, 1900 and 1909, by the methods explained under strychnia, concluded that the convulsions depend on increased excitability of the spinal motor cells. Direct application of dilute phenol solutions to the exposed spinal cord produces anesthesia. The excitability of the motor cortex is lowered by its local application (Baglioni and Magnini, 1910), without convulsions (Amantea, 1913). Muscle and nerve fibers are also paralyzed by local contact with strong solutions, but do not seem to suffer if the drug acts systemically. Phenol does not awaken animals from chloral sleep (Ariola, 1911).

Symptoms in Frogs.—Phenol produces successively local reflex irritation, short stupor, a medullary cry, then gradually the twitchings and irregular and incoordinated contractions. The reflexes are preserved, but naturally ineffective because of the interference and interruptions of the convulsions (Baglioni).

Circulation.—Intravenous injections of phenol, even with small doses, cause marked fall of blood pressure, usually with rapid recovery until a certain dosage is exceeded. The fall appears to be both cardiac and vasomotor. When phenol is given by stomach, the blood pressure remains low because of the continuous absorption (Sollmann and Brown, 1906).

Vasomotor Center.—This is usually depressed, probably directly. This may, however, be modified by indirect stimulation through the convulsions or ischemia. The center may therefore be stimulated; or a period of stimulation may precede or follow the depression period (Pilcher and Sollmann, 1915).

Respiration, Temperature and Collapse.—The respiration becomes slow and shallow, and finally stops. The temperature falls. Since the collapse affects all the medullary centers, and the cardiac muscle as well, it can not, of course, be removed by artificial respiration.

This constitutes an important difference from the collapse produced by the drugs of the alcohol series. Another difference consists in the fact that with the antiseptic group the sensibility to pain is often preserved far into the collapse. The local effects of the phenol play no important part in the production of the collapse (Sollmann and Brown, 1906).

Phenol causes an increase of secretions, especially of saliva, sweat, and tears, not yet accounted for.

TOXICOLOGY

Suicidal poisoning by carbolic acid is very common, particularly in the United States. Accidental poisoning is also common; it may result even when the phenol is applied to the intact skin; its liberal application to open surfaces has frequently led to toxic symptoms. The fatal dose, by mouth, varies between 8.5 and 60 Gm. (Lewin); 0.8 Gm. has been given therapeutically without bad effects. The toxicity is about the same by mouth and hypodermically (Hale, 1913).

The course of carbolic acid poisoning is very rapid. In almost all fatal cases death ensues inside of twenty-four hours.

Symptoms.—The local symptoms consist in burning of the mouth and throat, nausea and vomiting, abdominal pain. The carbolic burns generally heal promptly, with small tendency to scar formation.
The systemic symptoms are those of a very speedy collapse, starting in a few minutes, even when the drug is taken by mouth. It is manifested by faintness and muscular weakness; rarely twitching and convulsions; pulse small, weak, and slow; face livid; cold sweat; respiration slow and shallow; unconsciousness; coma; death by stoppage of respiration.

The urine is scanty and often contains albumin and casts, sometimes hemoglobin or bile pigments. It has a dark smoky color, due to phenol compounds, and gives little or no sulphate-precipitate with barium chloride. These points are of diagnostic importance. The urine rarely contains traces of uncombined phenol.

Chronic Phenol-poisoning.—In the days of the Lister spray, chronic phenol poisoning was not at all uncommon amongst surgeons. It presented the general symptoms of marasmus. The quantity of the acid entering the system under these circumstances is quite phenomenal: a Gm. of phenol were recovered from the urine of a surgeon who had assisted for two and a half hours at an operation under a 2 per cent. spray. Minor grades may occur from carbolic applications. They often show skin eruptions (Leone) and renal irritation (kidney changes, Uyeno, 1909).

Treatment of the Local Effects.—These are removed by promptly washing with alcohol (or whiskey) and applying an oil dressing. Alcohol, fats, glycérin, turpentine and ether act simply by their solvent-affinity for phenol, preventing its penetration into the tissues or dissolving it from them (Sollmann, 1906).

Treatment of Internal Poisoning.—The best success is obtained by lassage of the stomach with warm water, or first with 10 per cent. alcohol taking care that the fluid does not enter the trachea. The washing must be continued till the phenol odor disappears. It should be attempted even if an hour or more has elapsed since the poison was swallowed (D’Hotel, 1907), because a large part of the phenol remains for a long time unabsorbed in the stomach (Sollmann, Hanflik, and Pflüger, 1907). Chemic antidotes are of less service. Syrup of lime or potassium permanganate are the most promising. Alcohol and sulphates are practically useless. Intravenous saline infusions have some value against the circulatory depression; and heat against the collapse.

Lime forms an insoluble compound and is fairly effective (Husemann and Unmethen, 1870). Syrup of lime may be given freely; lime-water is too weak. Permanganate destroys phenol, but it has not been demonstrated whether the ordinary doses are efficient. Tincture of iodin was suggested by Maberly, 1909. Scoville, 1913, claims that charcoal is useful. Alcohol was formerly considered a chemic antidote, supposedly effective even when left in the stomach. Both the clinical and the experimental evidence disprove this view (Clarke and Brown, 1906). Its solvent action is useless if it is left in the stomach to be absorbed. Macht, 1915, asserts that alcohol given after phenol increases its toxicity; but that it is protective when taken before the phenol.

Sulphates have been given with the object of forming the non-toxic phenol sulphonates. This combination does not occur in the alimentary canal, and the sulphates are very slowly absorbed, so that the oral administration is useless except in chronic poisoning. The combination is so slow, that it is practically not available in acute poisoning, even if the sulphate is injected intravenously (Brown and Sollmann, 1906). The antidote-failures are reviewed by Wilbert, 1916.

PREPARATIONS—PHENOL

*Phenol, U.S.P.; Acidum Carboxilicum (Acid. Carbol.), B.P., C,H,OH.—Should contain not less than 96 per cent. of hydroxybenzene, C,H,OH, obtained either from guttar by fractional distillation and subsequent purification, or prepared synthetically. Occurs as needle-shaped crystals, colorless but acquiring a reddish tinge by oxidation of the air. Soluble in alcohol and ether, soluble in water. Odorless and sweetish caustic taste. Melts about 38°C; sol. in water (1:15); miscible in
PHENOL

Il proportions with alcohol, glycerin and fats; dissolved by alkalis. The solubility of a water diminishes with the temperature, and can be increased by the addition of alcohol or glycerin. Phenol is sometimes very faintly acid to litmus, but this is due to impurities (E. Schmidt, 1911). It is not a true acid, either chemically or physiologically. It is incompatible with iron and colloidion. *Dose*, 0.06 Gm., 3 gr., U.S.P.; 0.06 to 0.2 Gm., 1 to 3 gr., B.P.; diluted. *Maximum dose*, 0.2 Gm., 3 gr.

*Phenol Liquefacitum* (Phenol.Liq.), U.S.P.; *Acid Carbolic Liquef.*. B.P.—This is obtained by liqurifying phenol with 10 per cent. U.S.P., 15 per cent. B.P., of water. It is more convenient for dispensing. When it is diluted with an equal volume of glycerin, the mixture is miscible with water. *Dose*, 0.05 c.c., 1 minum, U.S.P.; 0.06 to 0.18 c.c., to 3 minims, B.P.; diluted.

*Susp. Acid. Carb., B.P.—0.05 Gm., 1 gr.*

Carbolized oil is usually made of 5 per cent. strength.

*Track. Acid Carb., B.P.—0.09 Gm., 1/4 gr.*

*Ly Sol. Ben. Corp., N.F.* (Dobell’s Solution)—This is often used on mucous membranes (nose, etc.). It contains 0.5 per cent. phenol, 1.5 per cent. each of sodium bicarbonate and borate, with glycerin and water.

**PHENOL-CAMPHOR**

When camphor and phenol are rubbed together they liquefy. Mixtures of this kind (phenol 50, camphor 50, alcohol 10) have been employed on suppurating wounds and abscesses, with the claim that the caustic action is diminished and the antiseptic efficiency increased. The latter is doubtful; but the decrease of irritation agrees with the effects of all good phenol solvents. There is no chemic combination (Yvon, 1876; Lemberger, 1906; Chlumsky, 1905 and 1913, recommended phenol-camphor in superficial inflammatory conditions, especially erysipelas; painting it on and around the affected area.

F. Pohl, 1913; and Schieff, 1914, injected 2 to 5 c.c. into diseased joints, without bad effects.

**PHENOLSULPHONATES OR SULPHOCARBOLATES**

These are less toxic and irritant, but also much less antiseptic than phenol. They have little value.

*Sod. Phenolsulphonate* (Sod. Phenolsulph.), U.S.P.; *Sodium Phenolsulphonate* (Sulphocarbulate), C6H5(OH)SO4Na + 2H2O. Colorless, transparent prisms or crystalline granules, odorless, cooling, saline, bitter taste. Sol. in water (1:4.2). *Dose*, 0.03 Gm., 4 gr., U.S.P.; as intestinal antiseptic, but inefficient. *(Acet. Phenolsulph.*—See Index.)

**CRESOLS**

The introduction of alkyl groups into phenol greatly increases the permiscidial efficiency. The most important of these derivatives are the cresols, C6H4(OH)CH3 obtained from “crude carbolic acid.” Attention was directed to their valuable properties by Franke, 1889. The three somers, ortho-, para-, and metacresol, differ somewhat quantitatively, the meta being the most antiseptic and least toxic, and para being the most toxic; but they are all contained in variable proportions in the commercial products usually employed.

The *permiscidial power* averages three or more times that of phenol; preparations containing higher homologues (N.N.R.) may be 15 times more active than phenol.

The *toxicity* of the cresols averages somewhat less than phenol (Tolliens, 1905; Hale, 1913; toxicity and fate, Jonescu and Bukarest, 1900), but they produce identical effects and lesions (Wandel, 1906; Hale, 1913). They are excreted for the most part “combined,” but otherwise unchanged. The *treatment* would be similar. In practice, they are less toxic than phenol, because they are used more diluted; but they are far
from being "non-poisonous." Another advantage over phenol is their lower cost. Their disadvantages are the disagreeable odor, which depends mainly on impurities; their limited solubility in water; and their variable composition and activity. Organic matter slows their action rather more than with phenol. Acid and hard and salty water hinder them by precipitating the soap by which they are usually dissolved (Hamilton, 1914).

Solutions and Application.—The cresols may be rendered soluble by the addition of soap, as in the official Compound Cresol Solution; and in several other ways. The soap-mixtures partake of the slippery nature of soap and are therefore less useful in operating; but they are well adapted to cleansing the hands (brushing for two or three minutes with 1/2 to 1 per cent. solution) and for other purposes. A dusting powder containing 3 per cent. of tricresol has been recommended for pediculosis (Herzheinzer and Nathan, 1915).

Serum Preservatives.—Tricresol, 0.25 per cent., is often added to secure the preservation of serums. This is harmless with the usual hypodermic injections but was suspected of being a factor in the collapse that sometimes follows intravenous injection, especially of the antineuritic serum. Some basis for this existed in the results of Voeglin, 1914, on dogs; but those of Auer, 1914, on monkeys, render it very improbable that the ordinary concentrations can do any harm. Clinically, it has marked advantage. Being more bactericidal than chloroform, and markedly analgesic. Without it, the pain of the injections is often so great as to interfere with efficient use (J. B. Neal and Abramson, 1917).

With anti-pneumococcic serum, a further danger might arise from the intravenous injection of relatively large doses. However, Voeglin, 1915, found that there is no danger of toxicity if the concentration does not exceed 0.5 per cent. and if the injection are made very slowly. With higher concentrations, the collapse is serious. Phenol acts similarly. Chloroform, even in saturated solution, is harmless. Auer, 1917, found monkeys much more resistant to cresol than the dogs used by Voeglin. He considers the ordinary concentration quite harmless, and that other antiseptics have no advantage.

Arterial Changes.—Paracresol, in common with many other substances, is said to produce thrombotic lesions in rabbits (Denny and Frothingham, 1914).

Phenol Coefficient.—The variability of the cresols is best determined by the determination of the "phenol coefficient," i.e., the ratio of the germicidal power of the disinfectant to the germicidal power of phenol, both being tested under identical conditions. A disinfectant three times as active as phenol would have the coefficient 3, etc.

The phenol-coefficient is valuable only for the disinfectants related to phenol; not for metals, iodin, chlorin, etc.

Most disinfectants are now sold with the statement of their coefficient, generally determined either by the "Kedel-Walker" (1904) or preferably by the "Hygienic Laboratory" method (Anderson and McClintie, Hyg. Lab. Bull., 72, 1912) with or without the presence of organic matter (2 per cent. peptone and 1 per cent. gelatin). The degree of dilution for disinfection is obtained simply by multiplying by 50 the phenol-coefficient (with or without organic matter, according to the material to be disinfected). For a disinfectant having the coefficient 1 would be diluted 3 X 50 = 150 times.

Benzene Derivatives on Insects.—W. Moore, 1917, tested the vapors of a series of house-flies. He found that all the benzol derivatives tested had a higher molecular toxicity than carbon disulphid; the physical characters being more important than the chemical composition.

PREPARATIONS—CRESOLS

*Cresol, U.S.P.; B.P., Cresol (Tricresol, Cresylic Acid), C,H,CH,OH.—A mixture of the three isomeric cresols obtained from coal-tar, and freed from phenol, hydrocarbon and water. Straw-colored refractive liquid, of phenol-like odor, darkening on exposure to air. Sol. in water (1:50), usually forming a cloudy solution; miscible in all propor-
PHENOL DERIVATIVES

1. with alcohol, ether or glycerin, and dissolving in alkanes. **Dose, 0.05 c.c., 1 in. U.S.P.; 0.05 to 0.18 c.c., 1 to 3 minims, B.P.; diluted.** for local use, the following concentrations are employed:

- in surgery, 1% to 10% per cent.; gurgles or clysels, 1/2 per cent.; cuspiders (tubercle B) or stools, 1 to 1½ per cent.; for sponging rooms or soaking clothes, 1/2 to 1 cent. To make a 1 per cent. solution, add 2 teaspoonsfuls to a quart of water.

Cresol is generally used in the form of:

- *Liquor Cresolis Compositus, U.S.P.—50 per cent. of cresol, brought into clear solution by a potash-lined soap. It has a phenol coefficient of about 5, and is in every respect equal to most of the proprietary solutions, with the advantage that it is not irritating under exaggerated and dangerous claims, such as being "non-poisonous."

Proprietary preparations may be found in N.N.R.

Metsucresyl acetate is very little soluble in water, and therefore less toxic (Greenwald, 1). It was tried as a mild antiseptic for mucous membranes.

Commercial Cresol Preparations—Those containing cresol up to 50 per cent. of ol. They may be grouped according to the dissolving agent:

1. Emulsions: turbid, brownish liquids, yielding turbid suspensions with water.

- Resin-soap: *Cresitn-Pearson; Izol; Cresolin.*
- Petroleum Oils (the mixture lowering the specific gravity to that of water):

- Coal-tar Products (Carbolic Acid, Naphthalin, Pyridin).

II. Solutions: brownish liquids, yielding clear solutions with sufficient water:

- Potash Soaps and Alcohol: *Lysol, Lysitol; Lucozolol; Sapokresol, Phenolin.* or water will precipitate the soap, and cause a turbid solution.)

- Cresocate of Sodium: *Solvole, Solosul (Sodium salts of sodium may also be used);* nassoyacetate of sodium: *Kresin.*

- Sulfo-acids (Made by heating crude carbolic with equal parts of concentrated HCl); *Sanitol; Cresolin-Arima (sulfo-acids of resin and mineral oils may be played).*

- Ethyl en-diamin: *Kresamin.*

- Phenoloid Disinfectants.—Cresol mixtures containing the higher homologs are tribed in N.N.R.

PARADICHLOORBENZENE

This is a by-product of the manufacture of picric acid. It resembles naphthalen in its properties, and is chemically very indifferently. It is a powerful insecticide (Konanta, 1918). It is also toxic to worms. Oral irritation to dogs produces no apparent deleterious effect, even in the dosage (cm. per Kg. (Sollmann, 1919)).

POLYATOMIC PHENOLS

The introduction of further OH groups tends to raise the antiseptic, but also the irritant effects; however, the modifications depend largely on the position of the OHs. Of the three isomers with two OH groups, *Resorc in, 1:3, is perhaps somewhat more antiseptic than phenol, and rather less toxic and irritant. Hydroquinone, 1:4, is more toxic; and Pyrocatechin, 1:2, is much more so. They act as reducing agents, esp. in alkaline solutions. Pyrocatechin is not used in medicine. Hydroquinone is used directly, but is formed from arbutin, contained in Uva ursi. Pyrogallol, containing three OH groups, is highly toxic, whilst its isomer, *florogallin,* is practically inactive.

RESORCINOL

Resorcin coagulates albumin. Strong solutions soften and slowly itterize the skin; weak solutions are merely antiseptic. It is employed various skin diseases. Internally, it is used to check gastric fermenta-

- tion, and in diarrhea. After absorption, it produces the same effects as phenol, but with more prominent convulsions, occurring even in man; bm. have caused severe poisoning but with recovery (Murrel, 1881). Also, doses are antipyretic, but the action is too short to be useful, they produce "toxic" effects resembling those of salicylates. The fate of excretion are similar to phenol.
PREPARATIONS—RESORCIN

Resorcinol (Resorcin), U.S.P.; Resorcinum, B.P.; (meta-dihydroxy-benzene), C₆H₄(OH)₂—Colorless needle-shaped crystals; of peculiar faint odor, and sweetish, then bitter taste. Acquires pinkish tint on exposure to light and air. Very sol. in water (1:60) or alc. (1:50), freely sol. in glye; or eth. Dose, 0.125 Grm., 2 Grm., U.S.P.; 0.00 to 0.3 Grm., 1 to 5 Grm., B.P. Maximum dose, 1 Grm.; 15 Grm. On the skin, 5 to 10 per cent. ointment, or 10 to 20 per cent. solution in glycerin. For urethral or vesical irritation, 5% to 2 per cent. In alopecia, 1 to 5 per cent. (but discolors hair).

Resorcin stains may be removed from the skin by citric acid (Mankiewicz, 1916).

UVA URSI

This plant has been used for its diuretic and antiseptic effects in vesical catarrh. It contains arbutin, tannin and other constituents.

Arbutin is a crystalline glucoside, yielding glucose and hydroquinone on decomposition. It is decomposed completely in the body (Lewin, 1883; Grisson, 1888); with large doses the hydroquinone appears in the urine (Bass, 1912) and is supposed to be the active agent. Lewin and others found it beneficial in cystitis, etc.; Paschikis and Felbes, 188, doubted its efficiency; Bass found no action on healthy men, even with 20 Grm. The usual dose is 1 Grm., 3 to 6 times daily.

PREPARATIONS—UVA URSI

Fustex. Uva Ursi, U.S.P. Dose, 2 c.c., 30 minims, U.S.P.

Inf. Us. Ursi, B.P.—Per cent. Dose, 15 to 30 c.c., 54 to 1 ounce, B.P.

PYROGALLOL

The powerful reducing action overshadows the phenol effect. Locally, it is a mild caustic for wounds and mucous membranes; it produces but slight irritation of the intact skin, passing into erythemas on continued use. Absorbed into the blood it forms methemoglobin, disrupts the corpuscles and leads to intense acute nephritis. Concentrated solutions acting on blood in vivo (not in the body) produce a peculiar insalubrable, hemoglobin. Fatal poisoning may occur even when the drug is applied in the intact skin; and may set in suddenly after it has been used for some time without effects. The symptoms consist in diarrhea, vomiting, chills, prostration, hectic pulse; nephritis with scant dark urine containing blood or hemoglobin derivatives (Neisser, 1881); sometimes icterus and glycosuria. The rapid cases show cyanosis, dyspnea, convulsions and collapse. The treatment would be symptomatic.

Uses.—The danger of poisoning and the black staining limit its employment. It is used similarly to chrysarobin in poriasis, lupos, ringworm and other parasitic skin diseases; and in hair dyes.

PREPARATIONS—PYROGALLOL

Pyrogallol (Pyrogall), U.S.P.; (Pyrogallic Acid; Tri-hydroxy-benzene), C₆H₄(OH)₃—Freely sol. in water (1:1:7), alc. (1:3), or eth. Solutions turn brown, especially in the light; very rapidly if alkaline. Used externally (but dangerous) as 1 to 10 per cent. ointment in skin diseases; and as 1 to 3 per cent. solution to deodorize ozena and discharging wounds.

PICRIC ACID

The saturated aqueous solution is used as a dressing for burns and superficial wounds, weeping eczemas, etc.; irritating anesthetic, antiseptic, astrignent and protective actions, and stimulating the reproduction of epithelium, in contrast to most other antiseptics (Ehrenfried, 1911). Stronger alcoholic solutions are irritant; and being absorbed, become toxic. By mouth, 1 to 2 Grm. produce severe poisoning, generally with recovery under treatment (Lewin). It stains the skin, conjunctiva and tissues yellow, even on systemic administration, simulating icterus. This may persist for two weeks after taking 1 Grm. The urine is colored a peculiar red (Walko, 1901).
Pieric acid is trinitrophenol, $C_6H_5(NO_2)_3\cdot\text{OH}$. Its toxic effects were investigated on dogs by Rapp and Forch, 1827. Racoonet, 1836, introduced it against intermittent fever; it was also used as an anthelminthic; but its internal administration was soon considered too dangerous. It was employed in surgery by Cheron, 1876.

**Application.**—Pieric acid is soluble to 10 per cent. in alcohol, to 22 per cent. in ether, to 1.2 per cent. in water. In burns, etc., it is used as a saturated aqueous solution, whose antiseptic efficiency is about seven times that of 1 per cent. phenol. (Pieric acid has a phenol coefficient $\approx 6$; so that $0.195$ per cent. pieric acid would equal $1$ per cent. phenol; Tidy, 1915.) Stronger alcoholic solutions should not be used. An ointment would be illogical. The watery solution is said to be free from danger, but should not be applied over large surfaces. It is prepared by dissolving $17.5$ g in a pint of hot water and filtering when cold. Clothes saturated with this solution are applied, covered with dry cotton, and left in place for several days.

**Pieric State.**—These may be removed from the skin by applying powdered potassium sulphate for a minute, then washing with soap; or by a paste of magnesium carbonate (Maksiewicz, 1916).

**Toxicology.**—This is practically important, especially in munition factories (Alice Hamilton, 1917). The common belief of its use in beers seems to be unfounded (Gadon, 1874).

Locally, the handling of the dry powder produces eczematous dermatitis, "pieric itch." A macule rash also occurs sometimes in poisoning. Systemically, toxic does destroy the red corpuscles and produce gastro-enteritis, hemorrhagic nephritis and acute hepatitis. There may thus be a true icterus, although the yellow coloration is mainly due to piecic staining (Malmejac, 1917).

The toxic effect on rabbits and dogs is described by Kozumi, 1914. *Fate.*—A part of the pieric acid may be excreted unchanged by the urine, but most is transformed by the liver into picric acid. This confers the diazo-reaction on the urine (Pecker, 1916).

**PREPARATIONS—Pieric Acid**

*Trinitrophenol* (Trinitrophenol), U.S.P.; *Acidum Piericum* (Acid. Pier.), B.P.; Pieric Acid, $C_6H_5(NO_2)_3\cdot\text{OH}$.—Yellow crystalline powder, odorless, of very bitter taste and intense staining power. *Sol. in water (1:78) or alc. (1:12).* *Dose. 0.025 Gm., 5G gr., U.S.P.*

**DINITROPHENOL**

This produces toxic hepatitis and jaundice, similar to pieric acid or trinitrotoluol. It is one of the dangerous occupational poisons (Warthin, 1918).

**TRINITROTOLUENE**

This is important as an explosive ("T.N.T."). It is $C_6H_4(NO_2)_3\cdot\text{CH}_3$. Other nitro- and amino-derivatives of benzene which are also used as explosives, produce similar effects with differences in detail (Alice Hamilton, 1917). Poisoning arises by the inhalation of the dust; in a proportion of the munition workers, generally between the 5th and 6th week of the employment; young and old subjects being more susceptible than vigorous adults (Marland, 1917).

The poison is absorbed mainly through the skin, (Moore, 1918).

The symptoms take two directions: local irritation of the skin and mucous membranes; and degenerative hepatitis similar to phosphorus poisoning. (Livingstone, Lamsouth and Cunningham, 1916).

Minor ailments (digestive disturbances, etc.) are much more frequent than toxic jaundice; but the latter may develop after a long interval; for instance in one extreme case, seven months after stopping work on the poison (J.A.M.A. 7:678, 1918).

The local irritations affect the eyes and nose; then produce cough, bitter taste, pruritus, eruptions, colic, and vomiting. At first there is obstinate constipation, later diarrhea and tenesmus. The skin is eczematous.

The systemic effects consist of nausea, vomiting anorexia, jaundice, mental depression, blurred vision, transitory peripheral neuritis. The condition may terminate in delirium, coma and convulsions.

*Toxic Jaundice, anemia, purpura.*—The T.N.T. jaundice is of hepatic origin, and leaves the liver tissue so severely damaged that recovery is very exceptional in patients who have reached this stage. There is also destruction of the red marrow, resulting in aplastic anemia; and purpura (Panton, 1917; B. Moore, 1917).

The blood of T.N.T. workers who do not exhibit symptoms, does not show any characteristic changes (L.H. Smith, 1918).
Cyanosis.—Moore describes the immediate effect of the absorption of T.N.T. as a change in the hemoglobin, with diminished oxygen capacity, leading to cyanosis, air hunger on exertion, etc. This is generally easily recovered from, and its intensity bears no relation to that of the jaundice.

Toxic Effect on Animals.—Rabbits appear to be rather insusceptible (Panton, 1917). Dogs respond by a train of chronic digestive and cachectic symptoms ending in death. These resemble the human symptoms, except that the liver is relatively little affected (Kramer and Meierholz, 1918).

Treatment.—Little can be done for the fully developed disease. The workers should be withdrawn from exposure with the first appearance of any symptoms.

Protection.—This offers the only satisfactory solution of the problem. It involves proper ventilation, cleanliness, etc. The subject is discussed by Scherenscheidg, 1917.

"Tetryl" (Trinitro-phenyl-methyl-nitratin). This is another explosive. It often produces dermatitis; also abdominal symptoms, asthmatic attacks, hemorrhages from mucous; headaches and giddiness (Cups & Ruston, 1917).

NITROBENZOL

Nitrobenzol, C₆H₅NO₂, is used extensively in the manufacture of anilin. It has been tried as an insecticide. Its odor resembles that of hydrocyanic acid, and it is therefore been used in cheap perfumery and soaps, under the name of Artificial Oil of Almonds or Oil of Mirbane; but it is highly toxic; a 1 gm. may be fatal.

Toxic Symptoms.—These are usually rather delayed, sometimes for hours. They resemble anilin poisoning; and consist in nausea and prostration, burning, headache, intense cyanosis, vomiting with characteristic odor, convulsions, and coma, ending in death after a few hours. The mortality is high, but 30 c.c. with prompt treatment were survived, (Zuccola, 1918). In protracted cases, temporary improvement and relapses occur.

The cyanosis is a very striking feature, the face turning almost black; the blood, when withdrawn, is also very dark, due to the formation of methemoglobin. The blood corpuscles undergo rapid and intensive destruction. In case of recovery, this is followed by active regeneration, with marked hyperactivity of the bone-marrow (Zuccola).

The other symptoms result largely from the asphyxia; but the motor centers are probably affected directly. The respiration and circulation undergo relatively little disturbance.

Nitrobenzol has been taken to produce abortion, but even large doses are ineffective (Spoder, 1917).

Subacute and chronic poisoning show icterus and cyanosis, the clinical picture resembling pernicious anemia.

The reported cases of nitro-benzol poisoning are reviewed by S. S. Adams, 1912.

Shoe-Dye Poisoning.—The use of shoe-dyes flavored with nitrobenzol resulted in numerous cases of temporary cyanosis in the Army; fortunately all recovered (Slichter, 1919). It is not certain, however, whether the effects were due to nitrobenzol per se, or to anilin or some other nitration product (Jour. Amer. Med. Assoc. 1919, v. 71, p. 593).

Treatment.—This consists in evacuation and stimulation. No fat should be given. Transfusion of blood results in marked improvement (Zuccola).

Inhalation of Nitrobenzol Vapor.—The symptoms differ in detail with the species of animals. They generally begin 3 or 4 days after exposure, with vomiting and marked digestive disturbance; then loss of muscular coordination, generally starting with the hind-legs; forced movements or extensor rigidity. Consciousness is preserved. Death occurs through respiratory failure (Dresbach and Chandler, 1917).

The motor symptoms are of cerebellar type; and histologic examination shows changes in the cerebellar Purkinje cells, whilst other nerve cells are unaffected (Dresbach and Chandler, 1918).

ANILIN

Anilin, C₆H₅NH₂, is used extensively in the arts and therefore gives rise to industrial poisoning, with methemoglobin formation, headache, weakness, dyspnea, cyanosis; convulsions, and psychic disturbances. Its excretion has been studied by Ramsdell, 1913.

Bibliography and history of industrial anilin poisoning, Alice Hamilton, 1913; Lutz and Hamilton, 1916.

It has been suggested that impurities may play a large share in industrial poisoning.

Unusual frequency of bladder papillomas and cancer has been recorded repeatedly amongst workers in anilin dye (Hoff Schloeth, 1927; Edit., J.A.M.A., 1927, vol. 89, page 284).
CREOSOTE AND GUIACOL

Composition.—The empyreumatic products of the distillation of wood—the smoke, and the creosote and tar which may be condensed from it—posses very considerable antiseptic power. They consist indeed of a mixture of coal-tar derivatives. The most important of these products from a therapeutic standpoint is creosote, the variety which is obtained from beech-wood (first by Reichenbach, 1830) being particularly valued. Its principal constituents are

\[
\text{guaiacol, C}_9\text{H}_{10}\text{OCH}_3; \text{and creosol, C}_9\text{H}_{10}\text{CH}_3.\]

The action of these compounds could be largely deduced from their composition, which is similar to the cresols. They are more strongly antiseptic and antipyretic, and rather less irritant and toxic, than is phenol. Creosol should be superior theoretically, but practically does not differ sufficiently from guaiacol, to offset its higher cost. Guaiacol constitutes from 60 to 90 per cent. of the creosote, and shares all its properties, with the advantage of constant composition.

Uses.—Creosote and guaiacol are employed mainly in tuberculosus, having been introduced especially by Sommerbrodt, 1887. Clinical opinions are divided as to their value. They are generally believed to increase the appetite, nutrition and weight, and to lessen the cough, the fever and the night-sweats. The benefits are seen only in early cases, if the use is long-continued, and if it does not cause gastro-intestinal disturbances. This explains the difficulty of arriving at a fair judgment. It would be still more difficult to explain the effects. The tubercle bacilli are certainly not killed in their foci; it is even doubtful whether their growth is restrained. Possibly the benefits may be referred to the local effect on the alimentary canal and on the bronchitis; and to the antipyretic action. Guaiacol is considered an intestinal antiseptic, although its action is difficult to demonstrate (Harris, 1912). Creosote-wafer is sometimes given to check gastric fermentation.

Other Pulmonary Diseases.—These (bronchitis, pneumonia) are also benefited, especially by inhalation, where the local antiseptic and stimulant action can come into play. Absolutely none is excreted by the lungs (Bufalini, 1904). When guaiacol is injected hypodermically, the major part is contained in the blood, liver and spleen, much less in the lungs and kidneys (Hofbauer, 1912). It is therefore difficult to conceive of an antiseptic action in the lungs. However, it has been proven that creosote increases the secretion of mucus even when taken by the mouth. In pleuritic effusions, it hastens the absorption of the exudate when it is rubbed into the chest.

As an antipyretic guaiacol (10 to 30 drops, dissolved in an equal volume of oil or corn oil) may be rubbed into the clean and dry skin of the abdomen for ten to fifteen minutes, thus avoiding intestinal irritation. It causes considerable diaphoresis, and has no advantage over other antipyretics.

The local anesthetic action is utilized especially in dentistry.

Administration.—In tuberculosis, creosote or guaiacol is given in the largest doses which can be tolerated without too much gastro-intestinal irritation; beginning with 1 drop and increasing to 5 or 10 drops, in extraperitoneous capsules, three times daily after meals. If they are not tolerated, guaiacol carbonate should be substituted.

Poisoning by Creosote.—This resembles that by phenol, but the effects are less convulsive. The local actions are also similar. The side actions of therapeutic doses are detailed by Seifert, N ebenw. , 1915, p. 196. Death has occurred after 7 Gm.
Guaicol Carbonate.—The undesirable local effects of guaicol, the taste and the toxicity, are largely reduced by converting it into esters, on the "salol-principle," i.e., by replacing the H of the OH group by acyl groups. These esters are insoluble and inactive; but in the intestine they are decomposed (saponified), into their constituents, and the OH is thus regenerated. In this way the antiseptic is liberated but slowly; its action extends over the entire intestine; but the amount which can be liberated crystalline powder is too small to be either irritating or toxic. The creosote esters are decomposed even more slowly than salol, perhaps only through putrefactive bacteria. An excess will pass the intestine unabsorbed. As much as 6 Gm. of Guaicol carbonate has been given to phthisical patients, as much as 75 Gm. (2½ oz.) to dogs, without producing toxic symptoms. With these large doses, a great deal of the substance is passed in the feces, without having undergone decomposition.

Other Guaicol Compounds.—Since the liberated creosote or guaicol is the active portion of these compounds, the acid with which they are combined is absolutely immaterial. The carbonic acid esters are the cheapest and contain the largest percentage of active principles, and therefore deserve the preference which has been universally accorded to them. Similar compounds have been prepared from all other phenols—from thymol, menthol, etc.

As there are no good reasons for the use of these other guaicol compounds, they need only be mentioned. They are more fully described in N.N.R. Compounds formed by replacing the OH by acyl groups (analogous to the carbonate: Benzate (Benzoic); Cinnamate (Styracol); Salicylate (Guaicol-salicylic); Methylure (Monotal).)

Replacement of the OH by alkyl groups: The methyl derivative, Veratrol, is practically inactive, and the hydroxylic chain is not regenerated. The glycerin derivative, Guaicol-glycerate, insoluble and active, but has a bitter taste. Guaianosol is the chlorid of diethyl-glycocoll-guaicol.

Thiocole is potassium guaicolusulfonate, analogous to sodium phenoilsulfonate. Like the latter, it has very little effect.

PREPARATIONS—CREOSOTE

*Creosotum (Creosotum), U.S.P., B.P.—A mixture of phenols and phenol derivatives chiefly guaicol and cresol, obtained during the distillation of wood tar, preferably that derived from beech. Almost colorless or yellowish, highly refractive, oily liquid, having a penetrating, smoky odor; burning, caustic taste. Slightly sol. in water. Mixable with alc. and fixed volatile oils. *Dose, 0.05 c.c., 4 minims, U.S.P.; 0.06 to 0.3 c.c., 1 to 5 minims, B.P. *Maximum dose, 0.5 c.c., 8 minims.

Ag. Creosotum, U.S.P.—A saturated watery solution, recently prepared, containing about 1 per cent. *Dose, 10 c.c., 25 to 50 minims, U.S.P.

Ung. Creosotum, B.P.—10 per cent.

Creosot Carbamin (Creosot Carbamin), U.S.P.—A mixture of the carbonates of various constituents of creosote, chiefly guaicol and cresol. A clear, colorless or yellowish, viscous liquid, odorless and tasteless, or having a slight odor and taste of creosote. Mix. in water, freely sol. in alc. or fixed oils. *Dose, 1 Gm., 15 gr., U.S.P.

Guaicol, U.S.P., B.P., C₆H₅(OH)(OH₃).—Nearly colorless refractive liquid, crystalline at low temperatures. Odor aromatic; sharp taste. Sol. in water (1:10): freely miscible with glyc., alc., or oils. *Dose, 0.5 c.c., 8 minims, U.S.P.; 0.06 to 0.3 c.c., 1 to 5 minims, B.P. *Maximum dose, 0.5 c.c., 8 minims.

Guaicol Carbonate (Guicol Carb., U.S.P., B.P.; (Duotol), C₆H₅(OH)(OH₃)(O)O₃.—Powder, almost without odor or taste. Preparatory in water, sol. in alc. (1:60). *Dose, 1 Gm., 15 gr., U.S.P.; 0.5 to 1 Gm., 5 to 15 gr., B.P.; in powder or capsules. *Maximum dose, 1 Gm., 15 gr.
Tar

his is a complex product obtained by the destructive distillation of woods, especially Pinus palustris. It contains phenols and other aromatic derivatives, resin acids, acetic acid, etc. Tar is strongly irritant to skin; it is used in scabies and other parasitic skin diseases, chronic eczema, itching, etc.; but has now been displaced largely by the less reeable naphthal and resorcin. Internally, it has been employed in the treatment of chronic bronchitis and cystitis, acting similarly to turpentine and copaiba. Official syrup is little more than a flavoring vehicle. Toxic doses of reduce effects similar to phenol: vomiting, colic, diarrhea and collapse.

1 of Tar.—When tar is subjected to redistillation, it can be separated into a fixed or pitch—consisting mainly of resin; and a volatile portion which separates into Oleum Picis Liquidae, U.S.P. and pyrogenous (crude acetic) acid. The oil consists of various coal-tar derivatives, mainly Cresols, Guaiacol Phenol, Xylenol, and Pyrocatechin. It also contains methyl alcohol and acetone.

PREPARATIONS—TAR

is Liquefier (Pic. Liq.), U.S.P., B.P.; Pine Tar.—A viscous blackish-brown sub- obtained by the destructive distillation of Pine wood. Empyema, odorous odor and taste. Miscible with alcohol or volatile oils, only partly soluble in water.

0.5 Gm., 8 dr., U.S.P.

Pic. Liq., U.S.P.; Oil Tar.—A volatile oil distilled from Tar. An almost colorless when freshly distilled, but soon acquires a dark reddish-brown color, and has a pungent odor and taste. Dose, 0.2 c.c., 3 minims, U.S.P.

Pic. Liq., U.S.P.—0.5 per cent. Dose, 4 c.c., 1 dram, U.S.P. Used as flavor for mixtures.

Pyrogenous Picis Liquidae (Ung. Pic. Liq.), U.S.P., B.P.; Tar Ointment.—50 per cent., U.S.P.; 70 per cent., B.P.

um Cadmium (Oil. Cadin.), U.S.P., B.P.; Oil of Cade (Oil of Juniper Tar; Oil Empyema,).—An empyema oil obtained by the dry distillation of the juniperus oxycedrus. A dark brown, clear, thick liquid, having a pungent odor and a warm, faintly aromatic, and bitter taste. Used externally, for producing a less unpleasant odor.

Carbonis Preparata (Pic Carbon, Prep.), B.P.—Prepared Coal-tar.—Commercial tar is heated for an hour at 20° C. to expel ammonia. It is employed as antiseptic and antipruritic in the form of Liquefier Carb. Crema. B.P.—20 cent. in alcoholic solution of Quillaja.

Eczema and Cancer.—Workers with coal-tar often develop eczema, which may state in epithelium. “Gas-works tar” is especially liable to produce these effects. The constituents responsible for its “acutic” action are not yet identified; a threecent fraction is the most active (Norris, 1914). It stimulates cell division a vire (Ross, Cropper and Ross, 1911). Yamagawa and Ichikawa, 1917, claims re produced typical epithelium, with metasases, by painting tar on the inner rabbits ear.

Dermatitis and Cancer.—Workers in crude paraffin are also very often of the same manner. Pure paraffin, however, is harmless.

effects were first described by Volkmann, 1805. The acute stage begins with rash and abscesses, “ wax boils.” These last several months, and then pass into a dermatis, with seborrhea resembling psoriasis, pigmentation, dry fissures, thickening, resembling ichthyosis, etc. In the terminal stage, multiple warts or masses develop, turning finally to true epithelium (Davis, 1915).

THYMOL

is contained in a number of aromatic oils, for instance Thyme. Terpenic structure, C_H_2_H_2 OH-C_H_2, 1:3:4, is allied to that of the ole constituents. Its actions are also similar to those of phenol. Its septic efficiency is higher, restraining the growth of pus organisms 

3,000; it is not a very active germicide. The local effects and the toxicity are relatively slight, because of its slight solubility and slow ab-
sorption. The absorption from the alimentary canal is, however, prac-
tically complete (Seidel, 1915). The solution and absorbability are favored by alcohol or oil (Schultz, 1915); these must be avoided in the therapeutic use. Even after absorption its toxicity is but a fourth of that of phenol. About half of the thymol is completely destroyed in the body (Seidel, 1915). The remainder is excreted paired with sulphuric and glycuronic acid (Blum). The symptoms are similar to phenol (W. H. Schultz, 1911), except that there are no convulsions, the central nervous system being primarily depressed. It is rapidly absorbed from hypodermic injections of oily solutions (Schultz and Seidel, 1912).

Uses.—Thymol has a rather pleasant clean taste; and a saturated watery solution makes a rather agreeable and fairly efficient antiseptic and deodorant mouth wash or gargle; lotion for discharging wounds, etc. Internally, it is occasionally employed as antipyretic and intestinal anti-
septic. Its main use is as an anthelmintic in the treatment of hook-worm disease (Bozzolo, 1885).

Administration in Uncinaria.—It is given fasting, in the total dose of 2 Gm. for adults, and the usual modifications for age, divided into three portions, taken as far apart, best as fine powder in 5-gr. capsules. The efficiency is increased by mixing the powdered thymol with equal parts of lactose or, better, sodium bicarbonate (Wab-burn, 1917).

The thymol is preceded and followed by a saline cathartic (not by castor oil). A rather detailed technique, established by Stiles (described in J.A.M.A. 60: 1544, 1910) should be used to insure success. The treatment is repeated at weekly intervals until successful.

Although highly effective against hook-worm disease, thymol is not ideal. It some-
times fails; produces some disagreeable after-effects in nearly half the patients; in a few.

It causes severe poisoning; and its cost is high (Levy, 1914).

Thymol in Trichinosis.—When the parasites are still in the intestines, thymol may be given by the uncinaria technic. B. A. Booth, Goebbing and Kahn, 1910, etc. report good results in one patient after the parasites had lodged in the muscles by intramuscular injection of an oily solution (2 to 3 c.c. of 6 per cent., daily for 7 days. Internit and repeat). No toxic symptoms occurred.

Thymol Tast of Hepatic Function.—Administration of 0.5 grams of thymol may usually result in considerable increase of the ethereal sulphate of the urine. The response is sometimes absent in hepatic disease; but it is not distinctive (M. Kahn, 1915).

PREPARATIONS—THYMOL

*Thymol, U.S.P. B.P., C6H5(CH3)(OH)(OH);—Occurs in the volatile oil of Thymus vulgaris and in some other volatile oils. Large, colorless prisms; aromatic thyme-like odor; pungent, aromatic taste. Very slightly sol. in water (1:1,000); freely sol. in alc. (1:4) or olive oil (1:1,7); sol. in other fixed oils and in vol. oils. Liquefied when triturated with camphor, menthol or chloral. Dose, 0.125 Gm., 2 gr. B.S.P.; 0.05 to 0.1 Gm. ¼ to 2 gr. B.P., as antiseptic; 1 Gm., 15 gr. (caution!) per day, as anthelmintic, U.S.P.; 1 to 2 Gm., 15 to 30 gr. B.P.

The saturated watery solution furnishes an efficient mouth-wash (H. P. Goodrich, 1917).

NAPHTHALIN

This represents the union of two benzo rings. It is practically insoluble in water, and is employed mainly as insecticide (moth-balls); as antiseptic dusting powder in skin diseases and as intestinal antiseptic and anthelmintic, especially against eggs.
Fumigations have also been tried against pertussis. It has usually a relatively low toxicity for mammals because but little is absorbed, the greater part being eliminated unchanged by the feces. That absorbed is excreted as naphthol, naphthaquinon, etc., and produces renal and vesical irritation and hemorrhage. However, the absorption is sometimes greater, especially in the presence of oil; 2 Gm., administered in the course of two days, has proven fatal to a six year old child (Tschuckw, 1912). Heine, 1913, reports poisoning in a woman after 2.8 Gm., distributed over three days. Retinal changes may occur, similar to those produced by naphthalin (Takamura, 1912). Further references to the side actions are given by Seifert. Nebenwirk., 1915, p. 140.

PREPARATIONS—NAPHTHALEN

*Naphthalenum, C16H14.—Colorless, crystalline powder; coal-tar odor; hot taste. Insol. in water; sol. in alc. (1:12). Dose, 0.1 to 0.5 Gm. (2 to 8 gr.). For children, 0.05 Gm., 1 gr., at 1½ years; to 0.2 Gm., 3 gr., at twelve years, three times daily.

NAPHTHOL

The naphthols are compounds analogous to phenol, formed by the introduction of an OH group into naphthalin. Alpha-naphthol is the more toxic of the isomers and is not employed in medicine. Beta-naphthol acts similarly to phenol, but is more germicidal. It has a special irritant action on the kidneys, and severe nephritis has been caused by its absorption from the intact skin in the therapeutic use (Koposi, 1881; Baatz, 1894). It is therefore especially contraindicated in the presence of renal disease. Changes in the retina and opacity of the lens have also been described after its use (e.g., Howe, 1913). Further references to the side actions are given by Seifert, Nebenwirk., 1915, p. 186.

It is almost insoluble, and is employed as an ointment in psoriasis, acne, parasitic skin diseases, pruritus; and to decolorize oxena. Internally, it is used as an intestinal antiseptic and anthelmintic. It is effective in hook-worm disease but inferior to thymol (Freeman, 1908). The local irritation and toxicity may be lessened on the salol-principle, by transforming it into esters. The benzene, salicylate (Betol) and oxytoluate (E-panicin) are described in N.N.R.

PREPARATIONS—NAPHTHOL

*Betanaphthol, U.S.P.; *Naphthol, B.P., C16H12O.—Colorless or buff-colored, crystalline lamina or powder; faint phenol odor; pungent taste. Very slightly sol. in water (1:2000); very sol. in alc. (1:0.1) and in oils, glycerin and alkalis. Dose, 0.25 Gm., 4 gr. U.S.P.; 0.2 to 0.6 Gm., 3 to 10 gr., B.P.; against hook-worm, 1 to 4 Gm., by special technique (Freeman, 1908). Externally, 1 to 10 per cent. ointment or 2 to 5 per cent. solution in oil or alcohol; in alopecia, 1 to 2 per cent.

QUINOLIN

Quinolin, C17H14N, is derived from naphthalin by the substitution of a N for a CH group. It is highly toxic and strongly antiseptic, but does not inhibit the growth of yeast (Donath, 1881). In rabbits, the hypodermic or intravenous injection of 0.2 Gm. per kilogram produces retinitis, similar to naphthalin; the lens, however, remaining clear (Jess, 1916).
Oxquinolin Sulphate (C₇H₄O₂S₃N₄) is a very strongly antiseptic, but feebly gaseous. It appears to be very effective and has been used as an antiseptic on mucous membranes, etc., under the name of chinonol (N.N.K.). Its fate was studied by Brahm, 1890.

**BENZOIC ACID AND BENZOATES**

Benzoic acid, C₆H₅-CO₂H, occurs in the balsams (Benzoin, Tolu, etc.), in cranberries and in other vegetables; and in the decomposed urine of herbivora. It is now prepared synthetically. It is a fairly strong antiseptic of about the same rank as phenol; the salts are somewhat less efficient. The free acid in concentrations above 0.1 per cent. produces moderate local irritation; the salts are not irritant. The systemic toxicity is very low, even large doses producing mainly digestive derangement, sometimes with further effects, resembling those of salicylates. There is also a similar, but weaker therapeutic action in rheumatic fever. Fatalities are unknown. Benzoic acid combines in the kidneys with glycocoll to form the inactive hippuric acid.

**Use as Food Preservative.**—The low toxicity and the absence of odor or marked taste has led to the use of benzoates for the preservation of foods, especially fruits and vegetable products. Sodium benzoate is generally employed for this purpose in the concentration of 0.1 per cent.; in acid foods, especially fruits, most of the benzoic acid would be liberated. This concentration suffices to restrain bacterial growth considerably, but may not prevent it completely.

**Antiseptic Efficiency.**—Buchholz, 1875, found the free acid to be germicidal in 0.4 per cent., and antiseptic in 0.1 per cent. Balkowski, 1890, found that 0.25 per cent. kept meat sterile for five months; with 0.1 per cent. there were only a few coloids. Sodium benzoate in neutral media inhibits growth in 0.3 to 0.5 per cent. (Th. Smith). Action on Digestive Ferments.—In test tubes, benzoic acid up to 0.25 per cent. does not interfere markedly; but higher concentrations are detrimental, especially to pepsa (Leffmann, 1890). However, peptic digestion proceeds fairly rapidly, even in a saturated solution (Dakin). These actions have no practical importance (Lang, 1923).

**Actions of Moderate Doses.**—These are especially important in view of the use of benzoates for the preservation of food. In a very careful investigation, Chittenden, Long and Herter, 1911 (Report 88, U. S. Dept. Agr.), could not demonstrate any effects on healthy individuals, if large quantities than are likely to be used in foods, 0.5 Gm. per day, were continued for weeks. Even still larger doses, to 4 Gm., were not generally injurious. They were sometimes followed by indications of slight digestive disturbance (Herter); but it is doubtful whether these had any significance. Excessive concentrations (above 0.1 per cent.) of the free acid, consumed too freely (as in cider or fruit juices) probably cause more pronounced gastro-intestinal irritation (Lucas, 1910) but not albuminuria (Herter, 1910; Gerlach, 1909). These concentrations have a noticeable taste which might serve as a warning. There is no reason to assume that the benzoate has a cumulative action, since it is promptly excreted as hippuric acid; nor is there any evidence that the formation of this acid is in any way detrimental.

**Investigations of the Referee Board.**—Chittenden, Long and Herter each experimented on four to six healthy young men, administering sodium benzoate, dissolved in food or drink, 0.3 Gm. per day for two months, then 0.6 to 1 Gm. for one to two weeks, and 4 to 6 Gm. for shorter periods. Clinical observations and extensive analyses of food and excreta were made. Chittenden and Long observed no effects whatever on the general...
feeling of the subjects; on pulse or blood pressure; red or white blood corpuscles or hemoglobin; no loss of appetite, nausea, headache, intestinal disturbance and no change in the intestinal flora. The body-weight did not diminish; the digestion, assimilation and utilization of fat or protein food; the composition of the feces; the N-balance; the quantitative composition of the urine; and the distribution of nitrogen, remained absolutely normal. There was no indication of damage to the kidneys.

Herter agreed with these negative results; but with doses above 1 Gm., he observed a slight increase of indican, of cecal bacteria and of free gastric hydrochloric acid. These effects could mean a slight irritant action from the use of these doses, which, however, are larger than would ordinarily be experienced with food.

The Prussian Scientific Deputation of Medical Affairs, 1911, accepted the conclusion that 0.5 Gm. distributed in small doses during the day, are innocuous; but they do not consider the experiments with doses of several grams as affording proof of absolute harmlessness.

The conclusions of Wiley and his collaborators (Bull. 84, 908), were less favorable. Their experiments were also made on healthy young men with doses of 1 to 2.5 Gm.; but these were given dry in capsules, offering opportunity for more violent local actions than when the benzoate is dissolved, as in food. This may in part explain the claimed deleterious results (gastric pain, vomiting, digestive and metabolic disturbances, reduction of body-weight, etc.). However, these results were not very striking, nor their causal connection with the benzoate administration at all conclusive (K. B. Lehmann, 1911).

Effects of Large Doses.—Sodium benzoate is tolerated without serious symptoms even in much larger doses, at least up to 60 Gm. per day (J. J., Jaksch, 1897). Such doses were formerly used in therapeutics. There are generally symptoms resembling those of salicylates (Lewinski, 1902; Kost, Franz and Heitzel, 1913); as with the latter, the dose required to elicit these symptoms varies greatly. Nausea and vomiting were obtained in some cases with 6 to 8 Gm. (Meissner and Shepard, 1860); whilst in others, 25 Gm. had no effect. The urine sometimes contains reducing substances, presumably glucuronic acid, especially if very large doses (25 Gm.) are taken (Lewinski).

Toxic Effects on Animals.—These are analogous to phenol, gastric irritation, vomiting, dyspepsia, decrease of reflexes, narcosis, sometimes convulsions (Kobert and Schulz, 1880). Dogs tolerate 1.7 Gm. per kilogram by vein without danger. This produces short vagus stimulation and prolonged rise of blood pressure (Naumann, 1879).

Permissibility of Benzoated Foods.—These investigations justify the conclusion that healthy individuals may safely consume reasonable quantities of benzoated foods (0.5 Gm. of benzoate per day, in concentration of 0.1 per cent.), if these foods are not otherwise spoiled or unhealthy; but that patients with gastro-intestinal or renal diseases would do better to avoid them. Benzoate is probably the least harmful of food preservatives, and where these are needed, its use appears permissible; provided that its presence is stated so that it may be avoided by patients to whom it could be harmful. However, it is very difficult to pass a final judgment on such questions.

Possible Objections.—The evidence in favor of benzoates is really negative, viz., that no deleterious effects have been proven. Such negative evidence is always open to the objection that our methods of investigation are not sufficiently delicate or comprehensive, or otherwise not adapted to reveal the possible deleterious effects. More serious probably is the objection that the investigations have so far been confined almost exclusively to healthy individuals. It is quite conceivable that irritant actions which would be too feeble to influence normal organs, might become deleterious to these organs, especially the gastro-intestinal tract or kidneys, if these are already diseased,
or when the general resistance is lowered. Herter, 1910, advises against the free use of benzoates. Le dyspepsie. The evidence that the formation of hippuric acid, which is probably in part responsible for the harmlessness of benzoic acid, is interfered with in at least some types of kidney diseases.

**Hippuric Acid Synthesis**—Benzoic acid and its homologs (cinnamic acid, quinic acid, etc.) combine in the body with glycocollic to form hippuric acid, which is excreted in the urine. The normal hippuric acid (averaging 0.7 gm. per day in man) arises in this manner from the benzoic acid occurring naturally in vegetable foods; and from its homologs which are formed in protein putrefaction in the intestines (Salkowski, 1885; Baumann, 1886). The synthesis of hippuric acid was discovered by Woehler. Meiser and Shepard, 1866, showed that this occurs in the kidneys. Bunhe and Schmiedberg, 1877, demonstrated the process in excised kidneys, and believed that this is the only organ concerned in dogs. However, considerable hippuric acid is formed in nephrectomized dogs (Kingsbury and Bell, 1894). In herbivorous animals, the synthesis also takes place partly in other organs (Salomon, 1877), in the small intestines and liver (Jaarsveld and Stokvis, 1879).

The liver also participates in dogs; for the hippuric acid is diminished by the injec- tion of hydrazin, which induces fatty degeneration of the liver, but is supposed to leave the kidneys untouched (Lackner, Levinson and Morse, 1918). Chickens do not form hippuric acid (Yoshikawa, 1911). In man, benzoic acid up to 10 gm. per day is excreted almost quantitatively as hippuric acid (Dakin, 1910) (85 to 90 per cent. with five or six hours; H. B. Lewis, 1912). With very large doses (5 gm., Levin) a part escapes synthesis. After the administration of benzoic acid, a fifth of the total nitrogen of the urine may be in the form of hippuric acid. Injected hippuric acid is excreted rapidly, i.e., within nine hours (Rainizs, Rainizs and Ringer, 1914).

In parenchymatous nephritis, even smaller quantities are excreted in part as benzoic acid (Jaarsveld and Stokvis, 1879; Kromecker, 1883).

**Uric Acid.**—Large doses of benzoates (5 gm. per day, in man) increase the elimination of urates in the urine, and decrease the urate content of the blood. The effect is therefore similar to salicylic. The creatin of the blood is not lowered (Denis, 1905, H. B. Lewis, 1912; Karr, 1912). Ross and O'Meara marked a marked decrease in uric acid during the period of maximal hippurate excretion, after 7 to 8 gm. of benzoate. The effect is not produced by administering hippuric acid directly. Creatinin excretion was not affected by the benzoate.

**Therapeutic Uses.**—The slightly irritant and stimulant action of free benzoic acid is sometimes used to promote expectoration in bronchitis with abundant thin secretion; and in the form of benzoic, to promote the healing of small wounds, chapped hands, etc.

Benzoates were formerly employed in uric acid diseases (Ure, 1841); in arthritis, with a tendency to salicylates, but weaker; in tuberculosis; and as a diuretic and antiseptic in cystitis. It is not diuretic, and its antiseptic action on the urine is even weaker than that of the salicylates (Sollmann, 1908).

**PREPARATIONS—BENZOATE**

*Acidum Benzeniicum (Acid. Benz.), U.S.P., B.P., C.H., COOH.—Obtained from benzoic acid by sublimation, or prepared synthetically. Colorless, lustrous scales or needles, odor resembling benzoic acid, pungent taste. Slightly sol. in water (1:275), freely sol. in alc. (1:73). *Dosage.* 0.5 gm., 5 gr., U.S.P.; 0.2 to 1 gm., 5 to 15 gr., B.P.

*Trich Acid. Benz., B.P.—0.01 gm., 1/4 gr.*

*Ammon. Benz., U.S.P., B.P., NH₄·C₆H₅.O—White, laminar crystalline powder; odorless, or a slight odor of benzoic acid, saline, bitter, afterward slightly acid taste; gradually losing ammonia on exposure to air. Sol. in water (1:10) to alc. (1:35); freely sol. in glye. (1/8). *Dosage.* 1 gm., 15 gr., U.S.P.; 0.2 to 1 gm., 5 to 15 gr., B.P.

*Lippeutin, N.F.—A mildly antiseptic alkaline and demulcent mouth wash, containing about 25 per cent. of glycine; 1 per cent. each of sodium benzate and potas. bichromate; 0.8 per cent. of sodium borate; flavored with thymol and aromatic ingredients, and colored purplish red with persimmon. Applied with 4 to 5 volumes of warm water.*
CINNAMIC ACID

Cinnamic acid, \( \text{CaH}_7\text{CH:CH COOH} \); its soluble sodium salt and Balsam of Peru

contains large quantities of cinnamic-benzy1 ester and free cinnamic acid) protofluorocytosis. They were administered intravenously by Landcrer against tubercu-

osis, with the idea of setting up a localized inflammatory reaction about the tubercular

leading to cicatrisation. The results have been disappointing and the treatment gone out of fashion. Sodium Cinnamate (Hetol) and its administration are de-

Not much is known about the pharmacologic actions of cinnamic acid. Erdmann

Marschand, 1843, showed that it is largely converted into benzoic and hippuric

acid. It has no effect on urate metabolism (Denis, 1913). Cinnamic acid has been

used as a food preservative; but the German commission decided that whilst its

city is low, its harmfulness has not yet been sufficiently demonstrated to make it permissible (Heff ter and Rubner, 1914).

SALICYLIC COMPOUNDS

Salicylic acid (ortho-oxybenzoic acid, \( \text{C}_8\text{H}_7\text{OH:COOH} \), 1:2) and its

aounds are less antisepctic and much less toxic than phenol; but they

duce marked antipyretic and analgesic effects and a practically specific ef

of the phenomena of acute articular rheumatism. Large therapeu-
doses produce the so-called “toxic” symptoms resembling cinchonism.

different compounds act qualitatively similar but present quantitative

cences. The salicylates are excreted by the urine, partly free and

ty combined.

Historical.—An excellent review of the introduction of salicylic acid is furnished by

O. Moore, 1879. The entire literature to date is presented by Hanlik, 1914,
cenic acid was first prepared in 1838 by Pira from salicin, which had been discovered

by Leroux. Cabourns, in 1844, and Procter, prepared the acid from guaiacothia

Kolbe and Lautemann produced salicylic acid synthetically from phenol in 1860;

Kolbe devised a commercially practical synthetic process in 1874. He also investi-
gated its antifertmentative action. It soon became thoroughly established as a surgical

tptic (Thieresch, 1873); antipyretic (Buesen, 1873); and anti-rheumatic (Strickler, 3).

Antiseptic Action.—Free salicylic acid is about equivalent to phenol

benzoic acid; its salts, however, are scarcely antiseptic (Kolbe, 1874).

The irritant effects disqualify salicylic acid as a surgical antiseptic. It

been used as a food preservative, but it is doubtful whether this

could be permitted. Salicylates have a moderate antiseptic effect on

urine (Sollmann, 1908; Jordan, 1911), and may be used for this

pose.

Action on Leucocytes.—Binz, 1875, found that these are paralyzed and killed,

in to quinin and many other aromatic derivatives. Ikeda, 1916, observed no effect

emigration of white cells from inflamed mesentery. In mammals, the leucocytes

blood are said to be doubled an hour after the administration, but return to normal
n hours but Gehrig, 1915, finds that salicylate and other antipyretics do not

leucocytosis, as was commonly believed.

Local Actions on Skin.—The application of salicylic acid in substance

strong solution, produces a slow and painless destruction of the epithete.

It is used as ointment, 2 to 10 per cent., in itching skin diseases (psoriasis) and against pityriasis versicolor; as lotion, 1 to 2 per cent.,

opia; as powder, 3 per cent. in tate, against sweating feet; and in

ion, 10 to 20 per cent. and plasters to soften corns and warts.

Qerkenbusch, 1915, recommends a 10 per cent. ointment (spread thickly) against

mentation, boils and eczema.

Hypersensitiveness of Skin to Salicylates.—Sauerland, 1912, found that external

ications (not the systemic administration) of salicyl preparations cause a gradual
development of persistent sensitiveness, leading to eruptions after an incubation period. This involved all parts of the skin, not only that to which the salicylate had been applied. The skin was not hypersensitive to other irritants.

Local Actions on Mucous Membranes.—Strong solutions cause considerable irritation and superficial corrosion. The salts are free from this objection, and the free acid is therefore little employed internally. It also softens the enamel of the teeth and should not be used in mouth washes.

Salicylates have practically no effect on muscle or nerve.

Absorption, Fate and Excretion.—The salicyl compounds are rapidly absorbed from mucous membranes and even from the intact skin. The insoluble esters are saponified and absorbed in the intestines; a part is generally absorbed without decomposition. In the tissues and blood the salicyl exists probably as sodium salicylate; high tensions of CO₂ may liberate free salicylic acid. It is excreted to some extent in all the secretions (sweat, Tachau; only traces in the feces, Hanzlík); but by far the larger part appears in the urine; partly free and partly conjugated. The excretion begins within fifteen minutes, and is practically completed in six to forty-eight hours. The rapid excretion explains the need of large and frequent doses. Larger doses may color the urine green.

Conjugated Salicylic Acids and Salicyluric Acid.—The forms in which salicylates are excreted by the urine are still in question. A part of the salicyl is excreted conjugated with sulphuric and glucuronic acids, also as oxsalicylic acid (C. Neuber, 1911), and perhaps in other forms. U. Mosso, 1890, estimates that more than half is conjugated; but his methods are open to doubt. It is generally stated that the greater part combines with glycoroll, forming a compound analogous to hippuric acid and named salicyluric acid (Bertagnini, 1876). This is supposed to be inactive in rheumatism (Stockmann, 1906). However, Hanzlík, 1910, failed to find such a compound in human salicyl urines and believes that the older workers dealt merely with impure salicylic acid.

Absorption from the Alimentary Canal.—Sodium salicylate remains in part for a considerable time in the stomach. The insoluble esters pass the stomach rapidly without absorption and are slowly decomposed and absorbed in the intestines (Buon, 1907; dogs with duodenal fistula). Sodium salicylate is also absorbed from the rectum (Ziensen; Massol and Minet, 1908); although not quite as rapidly as by mouth (Fiedler, 1905).

Absorption from the Skin.—Free salicylic acid, sodium salicylate, methyl salicylate and some of the other esters, in ointments or alcoholic solutions, are absorbed by the skin but less rapidly than by mouth (Francescini, 1906; Schmatner, 1908; Seeslitz, 1913).

Sodium salicylate is absorbed from the skin much less than free salicylic acid (Lentowicz, 1914).

The absorption by various channels has been studied by Levin, 1912.

Diffusion through Colloid Membranes.—This is hastened by salicylic acid or sodium salicylate (Oswald, 1907; Hanzlík, 1912). Salicylic acid also enters living cells which are generally impermeable to other acids (Harvey, 1914).

Distribution in Organs.—Blanchard, 1879, investigated this in dogs and found the salicyl in the saliva, bile, cerebro-spinal fluid, articulations, etc. Nencik, 1895, found it in the bile but not in the gastric juice. Filippi, 1900, demonstrated it in the synovia, in the brain and in the spinal cord. Vinci, 1905, again confirmed its presence in all organs and secretions, but found more in the secreting organs (kidney, liver, gastric mucosa) and in blood than in other organs (spleen and muscles). The nervous system showed the salicyl reaction only after large doses. Olmer and Totin, 1910, confirmed its presence in cerebro-spinal fluid and found its quantity there independent of the dose. Stockman, 1906, found none in the saliva, traces in sweat, and considerable in the joint fluid, blisters, bronchial, mucus and pleural effusions. Scott, Thoburn and Hanžka, 1916, found the percentage in joint fluids of rheumatic patients a trifle smaller than in the blood. Hofbauer, 1905, concludes that it appears in the sputum only under certain conditions.
Distribution in Normal and Infected Animals.—Bondi and Jacoby, 1906, found the concentration of the salicyl highest in the serum, and relatively high in the joints, especially in rabbits infected with staphylococcus, so that infected joints would appear to have a higher elective affinity for salicylates. However, the evidence is not altogether convincing, as the data were obtained with very rough methods and the authorities point out that the apparently larger quantity might be due simply to the serous effusion.

Liberalization of Salicylic Acid in the Tissues.—It is generally assumed, but without convincing proof, that the salicyl exists in the blood and tissues as sodium salicylate. In 1875 and 1879, showed that free carbonic acid, if in sufficient concentration liberates salicylic acid. The CO₂ tension of normal blood (about 6 per cent.) is too low for this; but when it rises, as in asphyxia, free salicylic acid can be demonstrated. Hanflik, 1916, failed to confirm this liberation. In inflamed tissues the CO₂ tension may be even higher locally, to 17.5 per cent. Other acids are also produced in cells and would aid the liberation. Since free salicylic acid is more active than its salts, at least as an antiseptic, its liberation could explain the greater efficiency of salicyl treat

Time of Excretion in Different Conditions.—This varies with the preparation, the dose, and also in different patients. It is possible that these differences may partly explain the variations in the efficiency and toxicity (Fraser, 1883).

Normal Time of Excretion.—Blanchier, 1879, investigated this on sodium salicylate, administered by mouth. It appeared in the urine in fifteen to eighteen minutes; with doses of 1 to 2 Gm. the excretion was completed in twenty-two hours; with 4 to 5 Gm. in forty-four hours. After continued administration, the excretion persisted from three to eight days. In dogs, the excretion was relatively slow; in heribvora, somewhat quicker than in man. Ehrmann, 1907, found the excretion in man completed in three to five days. He believes that the excretion is hastened by alkalies. Guiller, 1915, reports the excretion as completed in eighteen to twenty-six hours. Although the excretion was not influenced by giving sodium bicarbonate. It was not parallel to the excretion of potassium and phosphates. After administration of milk the excretion was delayed, lasting two days (Schumacher, 1909).

The elimination after intravenous injection has been studied by F. Mandel, 1908.

Excretion in Rheumatism.—It is generally agreed that the excretion is slow in rheumatism, and is an average amount, or even smaller. This is in contrast with normal individuals; the deficit being greatest in the first ten to twenty hours of administration. It is not due to retention, or to differences of diuresis, but partly to excretion in the sweat, and chiefly to increased destruction. The percentage of salicyl in the blood and urine at this time is little more than half of that in normal subjects (Scott, Thoburn and Hanflik, 1916). Ehrmann, 1907, claimed no difference between the normal and rheumatic.

Excretion in Other Pathological Conditions.—The excretion is also diminished in chronic alcoholism and morphinism; tuberculosis; and diminished renal efficiency (H. A. Scott, and Thoburn, 1917).

Purpur and Chelchowski report delayed excretion in renal and circulatory diseases.

Time of Excretion of Salicyl Esters.—The excretion of Aspirin, Novaspirin and Aquapen is about as rapid as that of sodium salicylate, beginning in one-half hour and being completed in two or three days; Salol and Salipyrin are-excreted more slowly (Hock, 1900; Finscher, 1902).

Quantity of Salicyl Recovered.—This was investigated for sodium salicylate by U. Mose, 1880, and for ethyl salicylate by Bondzynski, 1907. In each case over 90 per cent. of the salicyl was recovered from the urine. However, the methods give high results. More recent investigations indicate that about 20 per cent. is not excreted, but destroyed (Hanflik).

In rheumatic fever, and in some other pathologic conditions, the destruction is more extensive (30 to 55 per cent.; R. W. Scott, Thoburn and Hanflik, 1917).

Metabolism.—Salicylates increase the elimination of nitrogen (Laqueur, Bruenecke and Crampé, 1912), especially in the form of uric acid; the latter is followed by a compensatory decrease (Kumagawa, 1898; Urici, 1907; Schreiber and Zandy, 1899). The increase of uric acid is probably due partly to lessened destruction, but the uric acid concentra-
tion in the blood is also decreased, in the same way as with atophan (Denis, 1915).

The normal non-protein nitrogen of the blood is not lowered; but when abnormally high it may be decreased. The creatin of the blood is not affected (Denis, 1915). Gaulier, 1913, claims that the chlorid excretion is diminished. Phosphate excretion is slightly increased (Denis and Means, 1916). There are few definite data on the respiratory metabolism (review, S. Weber, 1904). Denis and Means found uncertain changes in the basal metabolism in man.

The gastric secretion is somewhat decreased (Klocman, 1912); but the absorption of food is not materially affected. The secretion and flow of bile are somewhat increased.

Uric Acid.—The increased elimination is due (as with atophan) to increased permeability of the kidneys to uric acid; for the uric acid content of the blood falls during salicyl administration, to resume its original level when the salicyl is discontinued. In man, 5 Gm. of sodium salicylate may reduce the blood uric acid to one-half or one-third. The efficiency may be greater even than with atophan (Fine and Chace, 1911; Frank and Pietrulla, 1914; Denis, 1915). The increase of urate excretion may reach 50 per cent. (Denis and Means).

By less direct methods, Hall, 1904; and Rockwood, 1909, also reached the conclusion that the increased excretion of uric acid is not due to increased production; but they could not exclude diminished destruction of uric acid as a factor. Excised organs indeed destroy uric acid more rapidly in the presence of salicylic acid (Stooley and Morris, 1907). Wacoumont, 1911, concluded that salicylates decrease the uric and purine excretion in experimental gout.

The para- and meta-isomers do not affect the uric acid excretion (Denis, 1915).

Postmortem Autolysis of the Liver is increased by small, and decreased by large concentrations (Lagueur, 1915).

Cholagogue Action.—Salicylates are among the few drugs which cause a genuine increase of the secretion of bile (Pfaff and Balch, 1897; Okada, 1913). Other aromatic products which conjugate with sulphuric acid act similarly (Petrowa, 1915). Salicylates have been used in obstructive jaundice and biliary colic, but it is doubtful whether they are of value.

Diabetes Mellitus.—Salicylates have been credited with decreasing the output of sugar and the consumption of water (Einstein and Mueller, 1875; von Noorden, 1921); but their efficiency is at best inconstant (Kaufmann, 1903).

Continued Administration.—The effects of continued moderate doses are important because of the use of salicylate as food preservative. They have been investigated by Wiley, 1906, on healthy individuals. The drugs were administered in capsules of tablet of 0.2 to 2 Gm. per day. The appetite, digestion and utilization of food was at first increased. This effect became less apparent after a time, but the food consumption generally remained above normal. Notwithstanding this increased intake, there was a slight loss in body-weight and of nitrogen. The excretion of phosphates was diminished. The quantity of urine was not affected; there was some tendency to albuminuria.

Antipyretic Action.—Salicylates lower febrile temperature energetically and promptly. The mechanism is probably similar to that of acetanilid, i.e., increased heat dissipation by cutaneous dilatation, aided by perspiration. In healthy individuals this is compensated by increased heat production so that the normal temperature is not easily affected. Salicylates may take the place of other antipyretics, but their side actions are more disagreeable.

Kidneys.—Salicylates may have a slight and inconstant diuretic effect (Blanchier, 1879). Full doses, however, decrease the output of urine partly by diaphoresis, partly by water retention. This is accompanied by evidences of renal irritation (slight albumin and casts) and diminished renal permeability (pethaline test and non-protein nitrogen of blood). With the ordinary doses, these changes disappear rapidly, and apparently without permanent damage, on discontinuing the administration (Scott,
Thoburn and Hanzlik, 1916; Luethje, 1902; Knecht, 1904; Questedt, 1905; Ehrmann, 1907).

The albuminuria, etc. occurs in normal individuals, and is therefore due to the drug, not to the rheumatic fever (Hanzlik, et al). It is also produced in animals, by doses corresponding to the therapeutic. Their kidneys show histologically various grades of nephritis, especially cloudy swelling (Hanzlik and Karner, 1917).

Highly toxic doses produce anatomic parenchymatous lesions (Vinci, 1905). The albuminuria, edema, etc. are not modified by the administration of bicarbonate (Hanzlik, et al., Ehrmann, 1907) contrary to the earlier claims (E. Frey, 1905; Ghesquiere, 1913).

Salicyl Edema.—Full therapeutic doses of salicyl diminish markedly the quantity of urine, with an almost corresponding increase of body weight. This is demonstrable about 20 hours after the start of the salicyl administration (about 80 hours). There is no dilution of the blood hemoglobin, so that the fluid must be mainly in the tissues; i.e., this is essentially an edemic condition, although the edema is not visible (Hanzlik, Scott and Reynard, 1917).

Therapeutic “Toxic” Actions.—When the dosage of salicylates is raised to the full therapeutic effect, there occur usually a series of side actions resembling cinchonism. They consist in nausea and vomiting, ringing in the ears and deafness, vertigo and headache, mental dulness and confusion, diaphoresis, quickened pulse and deepened respiration; rarely skin eruptions, albuminuria, impaired vision (de Schweinitz, 1805; Claiborne, 1906), and delirium, the latter especially in alcoholic patients. All these effects are usually without danger, disappearing promptly when the drug is discontinued. Abortion has sometimes occurred, but it is doubtful whether this was due to the drug or to the disease. Mattos, 1909, claims it to be meningeal action.

The nausea and vomiting are not due to local irritation, except if free salicylic acid is given. The salicylates and esters are not especially irri-
tant; and if fractional doses are given, the gastric phenomena set in only after some hours, about the same time as the ear and other systemic effects. They are therefore probably central. This has been confirmed by the direct method of Eggleson and Hatcher, 1915. To guard against the liberation of salicylic acid, it is advisable to neutralize the gastric acidity by giving one to two grams of sodium bicarbonate with the salicylate.

The ear symptoms are perhaps connected with congestion of the auditory apparatus (Kirchner, 1881; but Haake, 1904, believes these lesions to be asphyxial artefacts). The brain vessels are dilated (Berezin, 1916). Toxic Dose.—This has been investigated by Hanzlik, 1915, in over 300 administrations. If the salicylates are administered in repeated doses of about 1 Gm., one or two hours apart, the “toxic” effects appear usually when the total dose of sodium salicylate attains between 7 and 13 Gm., 100 to 300 gr.; the mean being about 12 Gm., 180 gr. Women require about four-fifths of this dose. There are no differences between sixteen and seventy-five years of age. Children have a relatively high tolerance, i.e., the toxic dose is much higher than would be calculated from their age (Archambault, 1878). The dose is the same for the white and the colored race. It is not affected by the presence or nature of disease. Occasionally there are unexplained idiosyncrasies or tolerance (toxic doses as low as 20 and as high as 1,300 gr.). These are usually only temporary. The toxic dose of acetylsalicylic acid and methyl salicylate is about two-thirds, that of salicyl-salicylic acid (MacLachlan, 1913) about one-half that of...
sodium salicylate. The toxic dose and effects of strontium salicylate are the same as for the sodium salt (Blankenhorn, 1920).

**Dangerous poisoning by sodium salicylate** is rare; and it is often difficult to judge whether the effects attributed to the salicylate were not really due to the disease.

The symptoms are described as vomiting, unconsciousness, delirium, dyspnea and deepened respiration (Quincke, 1888), fall of temperature, arhythmia, albuminura, parestis, collapse, asphyhial convulsions (Peterson, 1877; Weckerling, 1877; Allaire, 1879; Vinc, 1905). Sicard and Meary, 1915, attribute a case of sino-aorticul block, with standstill of the entire heart, to salicylate. The fatal dose is stated as 5 to 10 Gm.; but must be very variable, even severe cases ending generally in recovery. The autopsy in Quincke's case showed hyperemia of the brain and its membranes, of the kidneys and lungs, and pericardial echymoses.

**Acidosis.**—Vulpian called attention to the resemblance of serious salicylate poisoning to diabetic coma. Langmead, 1906, and Lees, 1908, emphasize this resemblance in children, and describe the occurrence of acetone even after relatively small doses of salicylates. The acidemia is probably often due to the associated conditions of the disease rather than to the salicylate; but it is advisable to follow their suggestion to administer sodium bicarbonate for prophylaxis and treatment of any acidosis.

**Toxic Effects in Animals.**—These are similar to those in man. The respiration is deepened and labored, first quickened, then slowed to final asphyxia with convulsions. The blood pressure rises at first, then falls severely; the pulse is inconstant. The intracranial vessels are constricted (Wichowski, 1902). There is general collapse and sometimes paralyses. The heart stops with the respiration. The autopsy shows the same congestions as in man (Kocher, 1876; Deselle, 1879; Blancher, 1879; Quincke, 1882). The toxicity is low, the fatal dose per vein for dogs being about 1 Gm. per kilogram. Methyl and ethyl salicylates intravenously produce pulmonary edema by injuring the capillary walls.

**Therapeutic Effects in Rheumatic Fever and Rheumatic Tonsillitis.**—The proper administration of salicylates controls the manifestations of this disease in a most remarkable manner in nearly all typical cases—so uniformly that failure throws suspicion on the diagnosis: the pain and fever disappear; the local inflammation, the immobility, swelling and redness subside; the general condition of the patient is vastly improved, and the disease is under complete control in one to at most five days. These benefits last only so long as the patient is kept salicylated and relapses occur when this is discontinued. According to statistics, the total duration of the disease, as judged by the stay in the hospital, is not affected (J. L. Miller, 1914).

The rheumatic cardiac lesions are not relieved directly (Vulpian, 1880). Indirectly the salicylate treatment doubtless has an important tendency in this direction by favoring rest and avoiding the extra tax of fever, pain and insomnia.

**Efficiency in Related Conditions.**—Salicylates are much more certain in atypical, subacute, chronic, and muscular rheumatism, lumbago, etc., although they usually have some analgesic effect. In acute gout they are often quite effective (Vulpian, 1880). They are notably ineffective in scarlatinal and gonorrheal arthritis (G. See, 1877; Stockman, 1906). They are also used in headache, neuralgia, sciatica, tubas and other similar pains, but with inconstant results. In chorea it is difficult to prove any benefits.

**Response in Different Affections.**—In the routine statistics of Hanell, 1913, in 132 cases of rheumatic fever, salicylates gave complete relief in 82 per cent, partial relief in 16.9 per cent, and failed in only 1.5 per cent. In subacute rheumatoid, thirty cases, it gave complete relief in 55 per cent; partial in 30 per cent; failures in 15 per cent. In sciatica, eleven cases, it did not give complete relief in any, failed completely in 27 per cent., and afforded partial relief in 73 per cent.
Mechanism of Action.—This has been attributed to the general analgesic effect; and to a specific germicidal action on the hypothetic organisms of rheumatic fever. The present data do not suffice to establish either of these views.

The enormous doses which are required; the small efficiency of other antipyretics and analgesics; the relative inefficiency of the salicylates in other forms of arthritis—all these facts point to a specific action on the infecting agent.

Against this view speak the prompt recurrence of the symptoms if the salicylate is discontinued and the failure to prevent the cardiac infection. In rabbits, the prophylactic use of salicyl does not prevent or even influence arthritis from intravenous injection of rheumatic hemolytic streptococci (Miller, 1914; Davis, 1915); but this is not conclusive since the etiology has not been established, and the administration is very different. The analgesic explanation is based on the limited efficiency of salicylates in other painful conditions (Laborde, 1877; Vulpin, 1880); and on the effect of other analgesics in rheumatic fever.

Hanzlík et al., 1918, found that combination of other analgesics (for instance, morphin) and antipyretics (for instance, quinin) also relieve the symptoms of acute rheumatic fever promptly and effectively, and sometimes permanently. Quantitatively, however, salicylates are superior.

Administration.—For internal use, the free salicylic acid is too irritant. The sodium salicylate is the most commonly used, notwithstanding its mawkish, nauseant taste. This may be partly disguised by giving the salt in carbonated water, or flavoring with peppermint or wintergreen water. The direct gastric irritation is avoided by adding an equal or double quantity of sodium bicarbonate.

To be effective in acute rheumatism, large doses must be administered: 1 to 1.5 Gm. (15 to 20 gr.) should be given every hour until “toxic” symptoms (tinnitus, nausea, etc.) set in. The administration should then be stopped for twelve hours. After this, 1 Gm. (15 gr.) should be given every four hours for several weeks, keeping the patient in bed as long as possible. If the sodium salicylate is not tolerated, oil of gaultheria or aspirin may be substituted. Oil of gaultheria also gives some relief when applied externally to the affected joints.

Hypodermic injections are used by Selbert, 1911, 10 c.c. of 20 per cent. sodium salicylate per 100 pounds of body-weight, every twelve hours; to avoid pain, cocain may be injected before. R. T. Williams, 1913, uses it intramuscularly, 8 per cent., with but little pain. Considering the prompt absorption, these special methods are superfluous.

Rectal Administration.—This is preferred by Heyn, 1914, as being more prompt and less disagreeable. He gives a cleansing soap sud enema. When it has taken effect, it is followed by the salicylate through a rectal tube, inserted 6 to 8 inches. The first dose is of 8 to 11 Gm. for men, 6 Gm. for women, in 150 c.c. of water or thin starch, with 1 c.c. of Tr. Opill. It may be repeated in twelve hours, but usually one enema per day suffices. Salicyl appears in the urine within fifteen to thirty minutes.

In very severe cases, the intravenous injection of sodium salicylate may be justified (Mendel, 1905, 1906). Conner, 1914, uses it, with a small needle to avoid thrombosis, in doses of 1 to 2 Gm., every eight to twelve hours. Cernadas, 1915, advises a solution containing 20 per cent. of sodium salicylate and 1 per cent. caffein; injecting this daily, at first 0.5 c.c., increasing to 10 c.c. The relief is more prompt, and no bad effects have been reported; but it would not be justifiable as a routine measure.

“Natural” and Synthetic Salicylates.—It is often stated that the synthetic sodium salicylate, owing to the presence of supposed impurities, is more toxic and less efficient than that prepared from oil of wintergreen
or birch. The evidence for this view, which has been fostered mainly by interested manufacturers, can not stand critical examination. There need be no hesitation in employing the much more economical synthetic product (Rep. Councl. Pharm. Chem., 1913; J. A.M.A., 61:797).

The literature of the subject and its uncritical status have been fully discussed by Eggleston, 1921. Various impurities have been announced in synthetic salicylates, especially cresotic acids, phenol, para-hydroxybenzoic acid, and hydroxy-isophthalic acid; but the evidence for their presence is not convincing. However this may be, Hilpert, 1910, showed that at the present time even the cheapest commercial samples are quite as pure as the most expensive. Waddell, 1921, proved that the effects of natural and synthetic salicylates on animals are quantitatively alike; and the cooperative clinical tests, conducted by the Council on Pharm. and Chem., arranged so as to exclude all bias, showed that their effects on patients are indistinguishable (Hewlett, 1911). In practice, it is almost impossible to be certain of their source, since the oils of wintergreen or birch are very often adulterated, beginning at the still.

**Relation of Constitution to Specific Anti-Rheumatic Action.**—Phenol, C₆H₅·OH, is quite inactive. Benzoic acid, C₆H₅·CO₂H, has a limited efficiency. The OH and CO₂H groups are both necessary, and must be in the ortho position to obtain the full efficiency. Derivatives which can be converted into salicylic acid in the organism are effective, in proportion to the ease of their conversion; but if the H of either group is firmly combined (as in methyl salicylic acid, C₆H₅·CO·H·OCH₃, and in salicylic acid), they are inactive. The introduction of additional groups into the benzol nucleus, as in the cresotic acids, does not disturb the action (May, 1900; Stockman, 1912).

**Cresotinic Acids.**—These were at one time blamed for the reputed higher toxicity of synthetic salicylates. In fact, however, they act very similarly and have about the same toxicity as salicylic acid (R. May, 1905; Stockman, 1890, 1909 and 1912; Waddell, 1921). They have a similar specific effect in rheumatic fever, although they are somewhat inferior. They have even been used therapeutically in doses up to 8 Gm. (Bus, 1876; Gatlib, 1879; Demme, 1888). The resemblance is explained by their chemical structure, C₆H₅·OH·CO₂H·CH₃ with the OH and CO₂H in ortho position.

**Isomers of Salicylic Acid.**—Meta- and para-hydroxybenzoic acids, which differ from salicylic acid only in the position of the side-chains, are practically inactive and nontoxic. The efficiency therefore depends on the adjacent position of the OH and CO₂H groups. The cause of this has not been explained. Another difference is that these isomers are not precipitated in combination with sulphuric acid instead of glycerol.

P-hydroxybenzoic acid, when given to monkeys, does not pair with glycerol (Sherwin, 1918).

**PREPARATIONS—SALICYLATES**

\[ \text{Acidum Salicylicum (Acid. Salicyl.), U.S.P., B.P.} \]
\[ \text{Salicylic Acid (Ortho-hydroxybenzoic acid), C₆H₅·CO₂H COOH. Prepared synthetically from phenol; or by saponification of methyl salicylate (oil of birch). White, light crystalline powder or needle-like odorless or with faint odor of wintergreen, of sweetish, then acid taste. Slightly soluble in water (1:460); freely sol. in alc. (1:2 or 1:4) or eth. Dose, 0.25 Gm., 12 gr., U.S.P., 0.3 to 1.2 Gm. to 20 gr. B.P.} \]

\[ \text{Ung. Acid. Salicyl., B.P.,—2 per cent. in Paraffin Ointment.} \]

\[ \text{Ammon. Salicyl., U.S.P., NH₃·C₆H₅·CO₂H—Resembles Solid Salicyl. Free sol. in water (1:1) or alc. (1:2). Dose, 0.5 Gm., 8 gr., U.S.P.} \]

\[ \text{Sod. Salicylatus (Sod. Salicyl.), U.S.P., B.P.; Sodium Salicylate, NaC₆H₅·CO₂H. White amorphous or crystalline powder or scales, or not more than faint pink tinge, odorless, or disagreeably sweetish saline taste. Very sol. in water (1:1.9), freely sol. in alc. (1:2.5). Incompatible with acids, iron salts, iodides, spirit of nitrous ether and quinins. Dose, 1 Gm., 15 gr., U.S.P., 0.5 to 2 Gm., to 30 gr. B.P.} \]

\[ \text{Syrup. Salicyl., U.S.P., Sr(C₆H₅·CO₂H)₂ + H₂O—Resembles Solid Salicyl. Sol. in water (1:19) or alc. (1:6). Dose, 1 Gm., 15 gr., U.S.P.} \]

**SALICYL DERIVATIVES**

To avoid the disagreeable taste and gastric symptoms of salicylates, esters and similar compounds have been introduced, which are more or less insoluble, and in which the salicyl radical is bound so as to be liberated only in the intestine or after absorption. These compounds have little or no direct action on the stomach, but they do not avoid the nausea and
vomiting (Hanzlik, 1913; MacLachlan, 1913), since these are probably central. In this respect they are therefore not superior to sodium salicylate, which also does not produce direct gastric irritation, if properly guarded by bicarbonate. The taste is materially improved, but this advantage scarcely balances their high cost. The alkyl esters (methyl salicylate) are more efficiently absorbed from the skin and are therefore better for external use. The acyl derivatives (acetyl salicylic acid) possess a higher analgesic and antipyretic action and have therefore a special field. The salols contain active phenols which adapt them to intestinal antisepsis. These compounds may be arranged under three types:

1. Replacement of the H of the Hydroxy by Acyl Radicals.—To this type belong: Acetyl salicylic acid (aspirin), C₆H₅-C(OC₂H₅)-COOH, and the corresponding compounds of salicylic acid with methylene-citric acid (Novaspirin); with salicylic acid (Niprosalin); and with sucinic acid (Dispirin).

2. Replacement of the H of the Carboxyl by Alkyl Radicals.—Methyl salicylate, C₆H₅-OH.CO.CH₃, and the corresponding salicyl esters of ethyl (Sal Ethyl); of methoxyethyl (mesetan); and of monoglycol (triprosal).

3. Replacement of the H of the Carboxyl by Phenyl Radicals.—Phenyl salicylate (tosal), C₆H₅-OH.CO(C₆H₅), and the corresponding salicyl esters of naphtol (totol); of guaiacol; and of acetamidophenol (salophen).

To these may be added salcin, from which salicylic acid is formed in the organism. Only a few of these derivatives need be considered in any detail; the others which are acceptable are described in N.N.R. Percentage of Salicyl in Various Derivatives.

PREPARATIONS—SALICIN

Salicinum (Salcin.), U.S.P., B.P., C₆H₅.H₂O.—Colorless, silky, shining, crystalline needles or a white, crystalline powder; odorless, and having a very bitter taste. Sol. in water (1:25.3) or alc. (1:98.5). Dose, 1 Gm., 15 gr.; U.S.P.; 0.3 to 1.2 Gm.; 5 to 30 gr., B.P., in solution or wafers.

Salicin occurs in willow bark, which was used as antipyretic in antiquity. It also occurs in poplar bark. It was introduced against rheumatic fever by Maciagán, 1867, on the basis of the fancied resemblance to malaria. It is inferior to the salicylates, because its conversion is often incomplete. Salicin is a glucosid, yielding on hydrolysis saligenin, C₆H₅(OH).CH₂OH; this in turn is oxidized to salicylic acid (Neeck, 1870), but a part is excreted unchanged. Salicin yields 45 per cent. of salicylic acid, and is therefore at most half as effective.

ACETYSALICYLIC ACID (ASPIRIN)

This was introduced by Dreser, 1899. It was supposed that it would pass unchanged through the stomach, thus avoiding gastric irritation; and that the salicylic acid would be liberated in the intestine. In fact, however, it produces some gastric irritation (Roch) and the intestinal decomposition is slow and incomplete, a part being absorbed unchanged; but the salicylic acid is completely liberated before excretion (Bondi and Katz, 1911). Acetyl salicylic acid is about one and one-half times as toxic as sodium salicylate in man (Hanzlik, 1913); about twice as toxic.

1 Krammerfeld, 1914, considers the correct formula of acetosalicylic acid as:

\[ \text{C}_6\text{H}_5\text{O} \quad \text{OH} \quad \text{CO} \quad \text{H} \]
in animals (Chistoni and Lapresca). In man even small doses (0.3 to 0.65 Gm., 5 to 10 gr.) occasionally produce alarming symptoms, especially acute local or general edema of the skin and mucous membranes, urticaria, erythema, pruritus, etc. (Graham, Morgan, Gilbert, 1912; Krause, 1914; literature of side actions, Seifert, Nebenwirk., 1915, p. 12). The effects of poisonous doses in animals are similar to other salicylates (Block, 1900). These side effects make this drug inferior to sodium salicylate in rheumatic fever. It has, however, stronger analgesic and antipyretic actions, even in non-rheumatic affections, perhaps because the undecomposed acetyl compound enters the nerve cells more readily. It is used extensively in colds, influenza and other fevers; and in neuralgias, headaches, tubes, and other pains, in tablets or capsules of 0.3 Gm., 5 gr.

Antipyretic Effect.—Yamamoto, 1916, finds acetyl-salicylic acid more efficient than simple salicylate.

Differences in Health and Fever.—The heat-regulation apparently is affected quite differently. With normal men, at absolute muscular rest, a gram does not lower the temperature, but increases the heat production (CO₂ excretion), with the heat dissipation practically unaffected.

With febrile patients, even with very mild fever or when the temperature is merely unstable, the same dosage lowers the temperature to 0.8° C. below normal; and produces a great increase (58 per cent.) of heat dissipation, and a slight decrease of heat production. When the effect passes off, there is a compensatory decrease of heat dissipation to half the normal level (Barbour).

Chronic Poisoning.—Symptoms of conjunctival catarrh and urticaria have occurred after six years of the continued use of 20 grains daily (Stiel, 1917).

PREPARATIONS—ACETYL SALICYLIC ACID

"Acidum Acetylsalicylicum" (Aker. Acetylnal.), B.P., N.N.R.; Aspirin; CalO-(CH₂-CO)-COOH.—White, crystalline, odorless powder of sour taste. Slightly sol. in water (1:1000), freely sol. in alc. (1:5). Incompatible with moisture and alkalies, Drug, 0.3 to 0.6 Gm., 5 to 10 gr., B.P., in powder, tablets or capsules. Maximum dose 1 Gm., 15 gr. It forms soluble salts with calcium (Berke, 1917; Lewis, 1917) and with hexamethylenamin (Puckner, 1915); but these are unstable.

Practically all American brands are of the pharmacopeial standard (Leech, 1918). Diplocaul, N.N.R., is tasteless and yields one-half more salicylic acid than aspirin and one-fourth more than sodium salicylate—a matter which is easily compensated by the dose. Its toxicity in man is twice that of sodium salicylate (MacLachlan, 1918).

It is very resistant to gastric juice, but is rapidly saponified by the duodenal secretion (Toennies, 1915).

Neospirin, N.N.R. is but slowly absorbed, and therefore, is said to be less powerful than aspirin, and less liable to produce unpleasant side effects (Koerner, 1916), perhaps because it has not been used as extensively. The literature of its side actions is given by Seifert, Nebenwirk., 1915, p. 25.

METHYL SALICYLATE

This acts somewhat more slowly, but otherwise as efficiently as sodium salicylate; the "toxic" dose being about two-thirds of that of the sodium salt. It is for the most part saponified in the intestine, but some may be absorbed unchanged (Baas). It avoids the disagreeable taste, but is more irritant to the stomach. The synthetic ester is said to cause less irritation than the natural oils. It may be given internally in temperate, capsules, in the same way as sodium salicylate; or externally, generally diluted with 1 or 2 parts of olive oil and painted over the affected region. This is sometimes more effective than the internal use, especially in muscular rheumatism. Fatal poisoning by methyl salicylate is rare, but has been reported (Nerthney, 1903), especially from its use as abortifacient. An ounce is usually fatal, with convulsions, coma, gastritis and congestion of the kidneys (Pinkham, 1887).
SALICYL COMPOUNDS

599

Rosenbloom and Johnston, 1919, report severe poisoning, after one ounce, but with
immediate recovery. There was immediate emesis; later, severe salicylatism and albumi-
naria, both persisting about a week. They cite the bibliography.

Ethyl salicylate is less irritant and half as toxic (Houghton, 1905). Spirosal is
used externally being non-irritant and easily absorbed (Immer, 1907; literature,
affurt, Nebenhir., 1915, p. 13).

Mesotan was introduced by Floret, 1902. It is decomposed by water into salicylic
acid, formaldehyde and methyl alcohol. It is used externally, but has caused dermatis.

PREPARATIONS—METHYL SALICYLATE

*Methyl Salicylat (Methyl Salicyl), U.S.P.; R.P.; Oleum Rutulae (Ole. Betula),
U.S.P.; Oleum Gaultheria (Ole. Gault.). U.S.P., B.P.; Methyl Salicylate; Ole of Sweet
Birch; Oil of Gaultheria (Wintergreen), CH4.C6.H4.O.—Produced synthetically or
Kained by distillation from Gaultheria procumbens or from Betula Lenta. A color-
less, yellowish or reddish liquid; characteristic odor and taste of gaultheria. It is
sparingly sol. in water; sol. in all proportions in alc.

Dose, 0.75 c.c., 12 minims, U.S.P.;
1 to 1 c.c., 5 to 15 minims, B.P. Maximum dose, 2 c.c., 30 minims.

PHENYL SALICYLATE

Salol was introduced by Nencki, 1886. Being insoluble, it passes
be stomach practically unchanged, but is gradually decomposed into its
components, 40 per cent. of phenol and 60 per cent. of salicylic acid, in
the intestine, by the saponifying action of the alkali, pancreatic lipase
and putrefactive bacteria. This avoids the taste of the components and
the local gastric action; and since the decomposition is gradual, the local
intestinal action is less violent but more prolonged, and the toxicity is
materially lessened. This “Nencki’s salol principle” has been extensively
applied in the form of other phenolic esters, f., guaiacol carbonate, to
mitigate the taste, local actions and toxicity of other active phenols or
acids.

Therapeutic Uses.—Salol proper has not fulfilled the original expec-
tations. The toxicity of the phenol limits the dosage, and its absorption
is so slow that it is practically inferior to the other salicyl compounds
in rheumatism or as urinary antiseptic (Sollmann, 1908). The phenol
component was thought to be valuable as intestinal antiseptic, especially
in infantile diarrhea; but the decomposition is so slow and the absorption
of the phenol so rapid that effective quantities could scarcely come into
action. The clinical and experimental evidence is not conclusive (Harris,
1912). As a wound antiseptic it would be useless because it is not
decomposed by wound secretions and only very slowly by bacteria. Its
use in tooth powders has caused eczema of the lips (Hugenschmidt,
1907). Perhaps its main value is as a coating for “enteric pills,” i.e.,
pills masses which are intended to pass the stomach unchanged (f.,
“secac in dysentery”). It must be remembered that a coating sufficiently
heavy to be effective introduces large doses of salol.

Decomposition and Antiseptic Action.—Salol is also decomposed to a slight extent
in the mouth and stomach by bacteria (Lesniki, 1888). It is split by human milk, so
that its administration to nursing infants may cause gastric irritation (Usener,
1912). Its saponification by pancreatic ferments and alkalies is very slow and incomplete,
insufficient to prevent putrefaction even in test-tube experiments; it is inferior to
salolin salicylate or bromath substrate (Sollmann, 1908). Its antiseptic action on the
blood is also slight. A part escapes decomposition in the intestines and passes un-
decomposed into the feces—5 to 8 per cent. In the experiments of Bondzynski and Hum-
nicki, 1909; but doubtless often much more. If given in capsules, it may be found in
the feces as crystals, “salol calculi” (Brossard, 1897), formed by the partial fusion
and recrystallization of the salol (C. R. Marshall, 1897). It should therefore be
ministered subdivided as emulsion or with indifferend powders.
**Preparations—Salol**

*Phenyl Salicylas* (Phenyl, Sal.), U.S.P.; *Salol*, B.P., C,H,H(OH),COOH.H.,—White crystalline powder, of faint aromatic odor and taste. Very slightly sol. in water (1:6,500); freely sol. in alcohol (1:6); very slightly sol. in fixed or united oils. Dose, 0.3 Gm., 5 gr., U.S.P.; 0.3 to 1.2 Gm., 5 to 20 gr., B.P., in powders, generally with bismuth. Externally, as 5 per cent. ointment. Maximum dose, 2 Gm., 30 gr.

**Phenyl-Quinolin-Carboxyl or Phenyl-Cinchonic Acid (Cinchophen; Atophan)**

The formula of this substance (C,H,N-C,H,COOH, 2:4) shows its relation to quinolin and salicylic acid. It has the antipyrletic virtues of quinolin, and like salicylic acid it is analgesic, antirheumatic, and increases the excretion of uric acid. It was prepared by Doebner and Giesecke, 1887; and introduced by Nicolaier and Dohrn, 1908, for the treatment of gout.

**Effect on Uric Acid Elimination.**—The excretion of uric acid is greatly increased; sometimes more than doubled by therapeutic doses, even on a purin-free diet. The increased excretion begins within an hour (maximum in three hours) and lasts only so long as the drug is continued; and is followed by a compensatory decrease (Haskins, 1913). With continued administration, the uric acid returns to normal after one or two days, unless the diet contains purins. The mechanism of this action is probably renal. The increase of uric acid is often so great that it precipitates in the urine before it is passed. Indeed, cinchophen apparently interferes with the urate-solvent action of the urine (Haskins, 1916). The urine is of a dark color, due to urochroom (Skorczewski, 1912).

In other respects, its composition and quantity are not notably changed. The leucocytes of the blood are also unaltered. The uric acid of the blood is diminished by the increased excretion (Folin and Lyman, 1913; Mc Lester, 1913), but soon reaches an irreducible minimum; there being no further lowering even if the administration is continued forty-five days. When the administration is stopped, the initial concentration is restored within two to four days (Fine and Chace, 1914; Frank and Pietrulla, 1914). The effects on the blood were also studied by Buse, 1914.

**Other Changes in the Urine.**—Skorczewski and Sohn, 1912, found an increase of purin bases and of neutral sulphur (parallel to the urochroom; Skorczewski, 1912); retention of chlorids and the diazo-reaction. Frommherz, 1912, did not find the uric acid increased in dogs; but Starkenstein, 1911, reports increase in rabbits and dogs with diminished allantoin. Schittenhelm and Ullmann, 1913, found no increase of allantoin, but higher total N excretion in dogs. Biberfeld, 1913, found no increase in purin bases, but increase of phosphates in dogs. Mc Lester, 1913, finds an increase in the quantity of urine and of total nitrogen. Eiser, 1913, reports the excretion of chlorid and total nitrogen as often diminished. Renal-function tests gave inconsistent results.

The creatin content of the blood is not decreased (Denis, 1915). In birds, the uric acid is decreased. The atophan itself is oxidised in the benzo nucleus (Dohn, 1912).

**Allantoin Excretion.**—The effects of a variety of drugs were studied by Puhl, 1918; Mechanism of Action.—This has been attributed to increased destruction of nucleic proteins (Starkenstein, 1911; Schittenhelm and Ullmann; Retalaff, 1913); to increase eliminative activity of the kidneys for uric acid (Weintraub; Buse, 1911; Chace and Lyman, 1913; Fine and Chace, 1914); to conversion of absorbed into filtrable uric acid (Frank and Pietrulla, 1914); to an intestinal action (Abl); and to increased formation of uric acid by lessened oxidation of its purin and nuclein precursors; perhaps the result of its more rapid elimination (Dohn; Frank and Procedoborski; Skorczewski, 1912).

The curve of excretion—temporary increase followed by compensatory...
crease—and the lowering of the uric acid concentration of the blood indicate increased elimination of uric acid already present in the body. Weintraub, and Frank and Pit-tralla, 1914, find that uric acid injected into the blood is excreted more rapidly. The urate excretion is not increased by cinchophen in kidney disease (Fine and Chace, 1915). The absence of increased phosphate elimination speaks against destruction of nucleoproteins. The decrease of allantoin indicates diminished destruction of uric acid in animals, but this might be different in man. In surviving organs, cinchophen does not lessen the destruction of uric acid (Starkestein).

Other Actions.—Large doses produce convulsions, paralysis and coma. Intravenous injection, in rabbits, is followed by stimulation of the vagus and vasomotor centers; these, as also the respiratory center, are finally depressed. The pupils are constricted, even after atropin. Cinchophen also prevents anaphylaxis and puncture gout and diminishes mustard chemonia. It lowers temperature, even in normal rabbits. These actions resemble calcium (Starkestein and Wiechowski, 1914).

Cinchophen inhibits completely the emigration of leucocytes in the inflamed frog’s esery, and exhibits in this respect a potentiated synergism with quinin (Ikeda, 1916).

Therapeutic Uses.—The mobilization of uric acid was supposed to be useful in gout by removing it from the blood and by dissolving the tophi. The uric acid and the non-protein nitrogen of the blood are in fact lowered by it (Folin and Lyman, 1913). Zueker, 1911, states that the increase of urate excretion in gout is more marked and prolonged than in health. Feulgen, 1912, claims that the tophi are actually decreased, at least in some cases. Clinically, however, cinchophen is much less efficient in chronic gout than in the acute attacks and in non-uratic joint affections. This throws some doubt on the uric acid explanation, and makes it probable that cinchophen acts similarly to salicyl, perhaps as a specific analgesic. In agreement with this, Klemperer, 1913, found derivatives, which lack the uratic action, equally efficient clinically. In acute gout, it causes prompt subsidence of the pain and swelling. In rheumatic fever it also acts promptly, similar but somewhat inferior to salicyl; but it is sometimes effective when salicylates fail (Oeller, 1912). The same applies to other joint affections.

Side Actions.—The precipitation of uric acid contraindicates its use in urate calculus. It is generally free from other unpleasant effects, even in large doses; but occasionally it produces vertigo, digestive disturbances, complete anorexia, cardiac distress (Loening, 1913) and purpural, uraliciar and scarlatiniform skin eruptions and fevers (Mueller; Phillips; Herrick, 1913; Maranon, 1914).

Administration.—The dosage of cinchophen is from 0.5 to 1 Gm., 8 to 15 gr., three or four times a day; or 0.5 Gm. every hour for six doses; suspended in large quantities of water. To prevent the precipitation of cinchophen in the urine, Weintraub advises the administration of 15 Gm., 1/2 ounce, of sodium bicarbonate (or its equivalent of acetate or citrate) on the first day, and 5 to 10 Gm. on the succeeding days. In gout, the diet should be purin-free.

PREPARATIONS—CINCHOPHEN

*Acidum Phenylcinchoneniicum (Acid. Phenylcinch.), U.S.P. (Cinchophen; Atofalan, Phenylequinolin carboxylic acid), C₉H₁₇N(COOH).—Small colorless needles or white powder; odorless; bitter taste. Almost insol. in water; slightly sol. in alc. (1:125); sol. in alkalis. Dose, 0.5 Gm., 8 gr., U.S.P.

Nerscinchophen (Tolyract), Nematophex).—This is an ethyl-methyl ester of atophan. It has the advantage of being practically tasteless, (Haskins, 1913). Other related compounds have been investigated by Impens, 1912.
QUINIC ACID

This is hexahydro-tetraxy-benzoic acid. It occurs in cinchona bark, coffee and many other plants. In man (also in rabbits, not in dogs; Studelmann, 1879) it is largely transformed into benzoic acid and excreted as hippuric acid (Lauteumann, 1891). Weiss, 1890, claimed that it lessened the formation of uric acid and that it had a beneficial effect upon gout. Decreased urate elimination was also claimed by Fawcett, 1900. Several observers reported clinical benefits, and various compounds were placed on the market (aconin, sidonial, chloroptin, etc.). Further observations, however, showed the effects to be inconstant (Delacamp, 1921) or rather negative (Hupfer, 1903; Fatavall and Gies, 1921; Watromont, 1917). Denis, 1914, found neither increase of urate elimination nor decrease of the urate content of the blood.

SACCHARIN, BENZOSULPHONH OR GLUSDIS

General Statement.—This substance, also sold under many other trade names, has the formula, C₉H₉SO₄.CO-NH, and is the anhydride of ortho-sulphamido-benzoic acid (the para-isomer is not sweet). In common with a number of other benzol derivatives, it has an intensely sweet taste, even in very dilute solutions. It passes through the body almost quantitatively unchanged, 75 to 90 per cent. being excreted by the urine within twenty-four hours, and the remainder in the feces. Consequently it has a very low toxicity. Small doses, up to 0.3 Gm. per day, continued for months, produced no deleterious effects, so far as ascertainable by available methods of investigation. Large doses, 0.75 to 1.5 Gm. per day, are also practically harmless, except for occasional minor disturbances of digestion (Herter and Folin, 1914). Single doses of 5 Gm. have been given without much effect (Aducco and Mosso, 1887).

Uses.—Sacharin is used as a substitute for sugar in diabetes (tablet of 0.03 Gm., 36 gr. = an ordinary lump of sugar); as flavoring agent and adulterant of sweet foods; and as a mild antiseptic in fermentative dyspepsia (0.2 Gm., 3 gr., several times daily). Sacharin itself is but little soluble in water, but its sodium salt, "soluble saccharin," dissolves readily. It may be prepared by adding 12 parts of sodium bicarbonate.

Sweetening Power.—This is about 500 times as great as that of cane sugar. It is perceptible in dilutions of 1:20,000; 1:10,000 is agreeably sweet; with 1:2,000 it becomes bitter and disagreeable. Even with the more dilute solutions the quality of the taste is somewhat different from sugar and on continued use the persistent aftertaste becomes very objectionable.

Effects of Continued Use.—Long-continued and detailed investigations were made for the Referee Board by Herter and Folin, 1911; Herter administered the sodium salt, Folin the free saccharin, in "small" doses to 0.3 Gm. per day, and "large" doses of 0.75 to 1.5 Gm., corresponding in sweetening power to 130 Gm. and to 475 to 750 Gm. of cane sugar respectively. The small doses produced no discoverable effects whatever. The large doses were also negative as to metabolism (total nitrogen, ammonia, uric acid, creatinin, sulphur—except that of the saccharin—chlorides, acidity and phosphates). The kidney was not affected (no diuretic or sediments). There were no general symptoms or blood changes, etc. The digestive functions were also generally unaffected (motor and secretory functions of the stomach, bulk of feces, etc.) even in patients with hyper- or hypo-chlorhydria; but occasionally there was slight hyperacidity and indications of slight increase of intestinal putrefaction (urinary oxy-acids, indican, fecal H₂S, methanal and acetic acid). The fecal gas flora remained unchanged. In mice, the efficiency of all the digestive fermentations was not altered by the concentrations which might occur in the body (except by the acidity of free saccharin, a factor which had been neglected in some of the earlier investigations; Riegler, 1893; Matthews and McGeigan, 1920). The antiseptic action was very slight.

The older literature contains reports of digestive and other disorders (Bornstein, 1900), especially after continued use (v. Jakob); but these observations were not made with the same degree of accuracy.

1 Quinic acid = C₆H₇(OH)₆COOH + H₂O.
The toxicity for animals is very low (Adduco and Mosso, 1887). Matthews and Sigan observed depression, stupor, convulsions and nephritis. Herter, administer-
olulose saccharin to rabbits by stomach, found no effects with 4 to 5 Gm. per kilo-
t; double this dose was fatal in two hours, the autopsy showing violent re-
testinal irritation.

Use of Saccharin in Foods.—The preceding investigations show that serious damage need be apprehended from the quantities of saccharin ch would ordinarily be used. Larger quantities, however, tend to duce minor derangements, which could perhaps become more accen-
ted in pathologic conditions. For this reason, and because saccharin is not a food, its indiscriminate use as a mere sweetening agent aluld be condemned, except in cases in which sugar is inadmissible.

Voschert, Robin and Hayem, 1917, claim to have observed digestive disturbances, from the excessive use of saccharin. This was endorsed by the French Acad. de
Reynier, on the other hand, observed no bad effects in animal or human

PREPARATIONS—Saccharin

Benzenesulphamide (Benzenesulphanilid.,) U.S.P.; Glutaidum, R.P. (Saccharin),
-SO₂-NH, the anhydride of orthosulphanilido-benzoic acid.—White, crystalline
fer; odorless, or having a faint, aromatic odor, and intensely sweet taste is dilute
ion. Slightly sol. in water (1:255); sol. in alc. (1:25); easily sol. in alkalies. Diss.
.5 gr., 3 gr. U.S.P.

Sodium Benzenesulphonamide (Sod. Benzenesulphon.,) U.S.P. (Sodium-Saccharin), NaC₆H₄-
H₂O.—Colorless prisms, or white, crystalline powder; odorless; intensely

METHYLTHION IN HYDROCHLORIDE OR METHYLENE BLUE

This dye (tetramethyl-thionin hydrochlorid) was introduced on the
of its selective coloring power, under the belief that this implied
ally selective actions. The expectations were disappointing. It is
ather doubtful value as an analgesic in neuralgia, neuritis, sciatica;
antizymotic and antipyretic in malaria; as antiseptic in cystitis, hritis, conjunctivitis and skin diseases; and as a test for kidney func-
. It colors the urine green or blue (also the sweat; Tachau, 1911).

Triary Antiseptic.—Methylene blue (1:120,000) is antiseptic for pure cultures;
it is a slow and weak germicide and practically inactiv in the leucoform, in which
creted in the urine. In doses of 0.4 to 0.6 Gm., four times daily for several days,
ape is of some use in staphylococcus cystitis; but useless in urethritis (Hinman,

Acetic Actions.—Therapeutic doses sometimes cause slight vesical or gastro-intes-
iritation (Seifert, Nenewirk., 1915, p. 24); but its toxicity is very low, the fatal
for dogs exceeding 1 Gm. per kilogram. Its continued use is also harmless (Tan-
1907). Hypodermically, it may produce ulcers and abscesses. Intravenously,
the blood pressure by a cardiac action (Garfounkel and Gauvret, 1932).

Methylene blue is distributed through all the tissues (localization in kidneys,
Safer, 1908), but it is rapidly reduced to colorless leuco-compounds. These
ized when the tissues are exposed to air (Herter, 1904) or in contact with hydro-
ized, thus restoring the blue color. It is excreted in the urine and feces (traces
and spumum), partly unchanged and partly as "methylene azure." The
is also present in medicinal methylene blue, being formed from it by alkalies.
exist in a colored and colorless (reduced) form in the urine (Underhill and Closson,

This is therefore rendered more blue by oxidizing agents, especially in acid
and paler by reducing agents (dextrose, etc.).

Kidney Function.—0.02 to 0.5 Gm. are injected hypodermically. The
on begins normally between fifteen to twenty-five minutes. Indigo Carmine (4
per cent., hydrometrically) has also been used; as well as chlorhidric. The use-
se of these tests is much more limited than that of the phenolsulphonphthalein
PREPARATIONS—METHYLENE BLUE

Methyliodonina Chloridum (Methylthionin Chlor.), U.S.P. (Methylene Blue; Tetramethylthionin Chlorid).—Not to be confused with methyl blue! A dark green, crystalline powder, or prismatic crystals having a bronze-like luster. Freely sol. in water and alc. Dose, 0.15 Gm., 2 to 5 gr., U.S.P. Externally, 0.5 per cent. solution on mucous membranes, 2 per cent. on skin.

Sodii Indigoindisulfonas (Sod. Indigozin.), U.S.P. (Indigo carmin).—Blue powder or paste, sparingly sol. in water; insol. in alc. Used for coloring Bichlorid Poison Tablets.

FLAVINS (ACRIDIN DYES)

Derivations.—Certain derivatives of acridin, a coal tar base, were suggested by Ehrlich as trypanocides. His "trypafavin" is now known as "Acrifolin," or simply as "flavin," but the latter term is likely to confuse.

Bibliography.—A review of the literature is given by the Council on Pharmacy and Chemistry in the Journal of the American Medical Association, 1919.

Structure.—Acrifolin is diaminomethylacridin chloride.

H₂N

N

CH₃

Cl

H₂N + H₂O

Proflavin is diamin-acridin sulphate. It differs only by the absence of the methy group, and is used as the sulphate. N It is also used as proflavin base.

H

HSO₄

Many other acridin dyes have been studied, but are not bactericidal. The preparation and properties of acri- and proflavin were described by Benda, 1912.

Actions.—Acrifolin and the closely related proflavin are highly active antiseptics and have the distinction of being apparently more germicidal in serum than in water. They are also relatively non-toxic for plas- cyttes and epithelium (Browning et al., 1917, 1919). However, Dakin and Dunham, 1917, consider the bactericidal claims as misleading.

Acrifolin is more antiseptic and more toxic than proflavin, but acts more slowly.

Systemic Toxicity.—Tubby et al., 1919, found that rapid intravenous injection kills cats by paralysis of respiration. For rabbits, 10 to 20 mg. of acridin by vein are non- fatal; proflavin is half as toxic.

Clinical Uses.—The clinical absence of tissue injury led to the extensive trial of the flavins in infected wounds during the war; and also against gonorrheal infections. The clinical publications are conflicting, but the results very evidently did not meet the expectations. The germicidal action is incomplete; and the irritation and interference with wound healing is much greater than was anticipated. On the other hand, the flavins seem to have a distinct field for temporarily checking bacterial growth whilst a wound is awaiting operation; as in transportation with war-wounds; or in the interval of two-stage operations. They are not advisable for long continued treatment (Crlle).

The reports on gonorrhea are contradictory.
FLAVINS

cation to Wounds.—After trimming the wound, it is washed and flooded with 11:1000 in normal saline. As much as possible of the solution (up to 100 cc.) is used at each dressing, to check evaporation. Profavin may be used as a 1 per cent.

tion of Generhes.—The concentration for injections is 1:10,000 for irrigation, 8000. There is a slight burning sensation in the urethra.
ry Antiseptic.—Davis and White, 1919, found the flavins efficient in both acid and alkaline urine. With some organisms, the efficiency was much better in alkaline than in acid urine. In animal experiments was inconstant; perhaps because of differ-
ent.
ul Properties.—Both flavin salts occur as reddish-brown, odorous powders, of
ting, fluorescent solutions in water. These are not injured by boiling, but soluble in alcohol, but insoluble in fat solvents. Profavin base is soluble

OTHER COAL-TAR DYES

share the general properties of the aromatic group. A number are discussed connections, e.g., fuchsin, scarlet red, trypan red, etc. Basic dyestuffs may be
able urinary antiseptics, but have not been sufficiently worked out (Himan, Ichthy violet (Pyrrothallamine Coeruleum) is used as an antiseptic (Stilling, 1890) 10,000 solution or 2 per cent. ointment.
of the dyes are bactericidal, and often with specific predilections. Reeser,
Lachlein, 1924, have worked out the efficiency of a series of dyes in eye infec-
therapy.—The specificity of dyes make them favorite objects for chem-
osed tissues and their products generally have a marked tendency to take up
eger concentration than do normal tissues (Cecil and Well, 1917). In
er. The caseous masses are penetrated in vivo by certain dyes (trypan red), in
centration. Quite a number of dyes, especially the safranin and
rise, inhibit tubercle bacilli much more effectively than tryphoid; but their
iquence does not appear sufficiently high (P. A. Lewis, 1917). Ac-
also, the necrotic areas accumulate diazo-dyes, but no therapeutic effects
attained (R. Weil, 1920).

ty.—Marsius yellow resembles cocain in toxicity and in some of its actions
ths and Longellon, 1910). Acid dyes are generally much less toxic than
urious effect in human subjection followed the intravenous injection (as 0.2
olution) of 1 gm. of cong-red or trypan-red. The toxicity of diazo dyes varies
second days, with relatively slight discolored in their chemical structure (Cecil and Well, 1917). The penetration of dyes
resents very interesting problems (A. P. Mathews, 1910). Basic dyes dimin-
tively increase the inhibition of gelatin. This may be a factor in the penetra-
not a complete explanation (Traube and Koehler, 1915). The vital staining
icity of acid and basic dyes are not parallel (Hoecher, 1914). The addition
other poisons often modifies their toxicity (Selle, 1914).

er generally are excreted more rapidly by the bile than by the urine, no matter
istered (Salant and Bengis, 1916). Acid dyes are generally much less toxic than

Formulation.—Basic dyes (methylene blue) stimulate in dilute solutions and
ome moderate concentrations. Acid dyes have little effect (Somogyi, 1916).

sein, N.N.R. (Resorcinolphthalie), the anhydride of fluorescenic acid, in
he solution dropped eye does not stain normal tissues, but produces beautiful yellow and green
ny abraded parts or ulcerations about foreign bodies, etc. Given by mouth, the
body becomes of a jaundice color, which disappears in twenty-four hours.
The normal eye is not colored, the dye being retained in the posterior chamber; the presence of intraocular disease, glaucoma, iritis, etc., the aqueous humor is light green in about twenty minutes, thus differentiating these diseases from vities in which there is no coloration. The dose by mouth for adults is 1/2 to 1 gm., in water. This presents no danger.

Function Test.—This is described by Strauss, 1913. Std. Fluorescein, 1 Gm.
d tea, is given on an empty stomach. Normally, it appears in the urine (best
seen when alkaline) in ten to twenty minutes, and lasts thirty-five to forty hours. In renal disease, it appears later and lasts longer. The skin may be stained slightly yellow, but there are no other side effects.

Eosin.—Rost, 1915, found its oral administration harmless in man and animals. On intravenous injection, the toxic effects of eosin and erythrosin are much higher than those of fluorescein, of which they are bromin and iodin derivatives (Salant and Bengts, 1917).

Basic Fuchsin (Grußbler), para-rosanilin acetate, was advised by May, 1912, and Donnelly, 1914, as a lotion or ointment (1 per cent.) for ulcers and burns. It is antiseptic, non-irritant, non-toxic and seems to encourage epithelial growth and granulation. The color may be removed from the skin by alcohol.

Gentian Violet.—This combines a relatively high toxicity to bacteria with a low toxicity to higher tissues. Rüssel, 1914, for instance, found that tissue cultures are not injured by concentrations which kill bacteria. It is practically ineffective against tetanus, however (Hall and Tabor, 1914); rabbies, etc., also showed poor success (Churchman, 1914).

Fluorescent Substances.—V. Tappeiner and Raab (1905) found that fluorescent substances are very destructive to all forms of life, and also to fermentations; but that the effects appear only in the presence of the specific light rays which induce the fluorescence (Review, Tappeiner, 1906). Toxins are very susceptible to fluorescence (Noguchi, 1906).

**MISCELLANEOUS ANTISEPTICS**

**FORMALDEHYD**

**General Statement.**—The aldehydes react chemically with an exceptionally large number and variety of organic substances, amongst other with proteins. This probably explains their actions (Liebreich, 1865). Formaldehyde, HCHO, especially is very strongly germicidal and is largely used as a disinfectant. It hardens the tissues on local contact and thus produces irritation, especially of mucous membranes. Its systemic toxicity is relatively low.

**Formaldehyde** is a colorless, irritant gas, prepared by the oxidation of methyl alcohol. It is freely soluble in water, and is found on the market in the form of a 40 per cent. solution (Formalin). The solutions tend gradually to become inactive by the formation of the insoluble, polymer, trioxymethylen or paraform, (HCHO) especially on heating, but some, what also on standing. The latter may be prevented by chemical means (calcium salts, methyl alcohol). Trioxymethylen again yields formaldehyde by dry heat.

Formaldehyde is converted into hexamethylenamin by ammonia or ammonium salts.

**Other Aldehydes.**—Aldehydes contain the CHO group linked with organic radicals. Acetaldehyde and paralleldehyde are somewhat antiseptic, but more markedly narcotic. This narcotic action is especially prominent in thychloraldehyde (chloral).

Aerolein, CH·CH·CHO, resulting from the decomposition of glycercin by excessive heat, is highly irritating and but little antiseptic (Fraselkel, Arzneimittel-synth., p. 625).

**Historical.**—Formaldehyde was discovered by von Hoffmann, 1867; its antiseptic action by Loew and Fischer, 1886. Aronson, 1894, showed that it also destroys toxins. Reaction of Formaldehyde with Proteins.—Formaldehyde enters into rather peculiar compounds, which are precipitated under suitable conditions, from which the formaldehyde and the original proteins may be completely regenerated under other conditions. The literature to 1897 is given by Benedict. With albumoses (Sollmann, 1902) and presumably with other proteins the compound contains definite proportions of formaldehyde, albumose and alkali. It is precipitated in weakly alkaline solution.
dissolved without decomposition by stronger alkalies, and is decomposed, or its formation is prevented, by weak acids and by excess of neutral salts. Even under the most favorable conditions the combination is completed slowly. It is hastened by increased concentration of formaldehyde, protein or alkalinity, and by heat. (This combination has also been investigated by Schryver, 1911.) The precipitate also contains a further quantity of formaldehyde mechanically:

Other Chemical Actions.—Formaldehyde retards or prevents the coagulation and spontaneous taking of salt blood, when added in the proportion of 1:500 to 400. Uric acid and urates are dissolved, or their precipitation is prevented, by the formation of soluble compounds. Urea, on the other hand, forms an insoluble compound with formaldehyde.

Protective Fermants.—The digestibility of fibers and the coagulability of casein are diminished. Formaldehyde also lessens the activity of certain fermenta, namely, papain, trypsin, ptyalin, and amylopectin; whilst papain, rennin, and malt diastase are but little altered.

Antiseptic Action.—Formaldehyde is one of the most powerful disinfectants, of relatively high penetrating power, harmless to metals, fabrics and colors and of relatively low toxicity. On account of its irritant effects, its use on the body is inadvisable. It is employed particularly for the disinfection of rooms and excreta.

Antiseptic Efficiency.—Formaldehyde is very much more effective as an antiseptic than as a germicide. Its activity varies for different organisms. Typhoid bacilli, with exposure of twenty-four hours, are killed by 1:5000, completely restrained by 1:10,000; partly restrained by 1:30,000. 1:40,000 is practically ineffective (Hyman, 1914); all the concentrations refer to absolute HCHO. Solutions of 1½ to 3½ per cent. destroy all bacteria, spores and toxins, in six to twenty-four hours. The gas is similarly antiseptic, especially when it is moist. The activity is increased by acids, presumably by preventing combination with the proteins of the medium. (Further details, J. F. Anderson, 1895, Hyg. Bull., 30, Himman, 1914.)

The germicidal efficiency against spirochetes is low (1:8000, absolute; Akatsu, 1907).

Practical Application.—Feces are mixed with 10 per cent. of the commercial solution. This destroys the odor almost immediately, but to insure complete disinfection, they should be left in contact for an hour. Tubercular sputum should be disinfected with 5 per cent. of the commercial solution for an hour. Instruments and other articles may be placed in 1½ to 5 per cent. solutions of formalin.

Fumigation of Rooms.—No method of fumigation is absolutely reliable. Mercapt formaldehyde vapor is the most efficient fumigant against bacterial diseases, but has little penetrative power. It does not destroy mosquitoes or other insects, and is therefore inferior to sulphur dioxide against malaria or yellow fever (McClimont, etc., 1911).

Formaldehyde vapor is usually generated by the heat evolved by the interaction of formaldehyde solution with permanganate or cheaper oxidizing agents. This is somewhat wasteful, but convenient.

It may also be formed by special apparatus involving the incomplete combustion of mercuric alcohol or the vaporization of trioxymethylene.

Simple spraying with formaldehyde solution (8 c.c. per cubic meter) is also used. Exposure of formaldehyde solution by heat is wasteful, but may be employed (150 c.c. for 1000 cubic feet).

A 1:20 dilution, allowed to stand about a room in saucers, is said to kill flies.

Formamide Method.—This was introduced by Evans and Russell, 1915. For a room of 2000 cubic feet, 2 pounds of potassium permanganate are placed in a 3-gallon pail and this is set in a large tin containing water. When everything is ready, 2 parts of 40 per cent. formaldehyde are poured on the permanganate, the room is vacated immediately and left closed for at least twelve hours, then thoroughly aired (Hoxie).

With this and the following methods, about 40 to 80 per cent. of the formaldehyde is effectively volatilized (Bower, 1916; Hamilton, 1917; Storm, 1918).

Chromate Method.—This was introduced by S. G. Dixon, 1914, at the suggestion of Ewing. A solution of 1½ fluidounces of concentrated sulphuric acid and 1 pint of water is added to the formaldehyde Sol. is prepared in advance and kept perfectly. When needed, it is poured on 10 ounces of sod. dichromate crystals, which have been spread
in a thin layer in a vessel of ten times the capacity of the ingredients. The gas is liberated more rapidly than with permanganate; the operator must therefore withdraw promptly.

**Chlorate Method.**—Sturm, 1918, suggests a mixture of 1 part sodium chloride and 4 parts of formaldehyde solution. The reaction starts only at 65°C.

**Applications to the Body.**—This is not recommended as account of the local irritant action. It has been employed, however, for the disinfection of hands (1 per cent.); as a mouth wash and gargle (2/3 per cent.); in skin diseases and hyperkeratosis (2.5 per cent.); for painting the throat in *diphtheria* or tonsillitis (2% to 2 per cent.). The evaporation of a small amount of the solution in the room has also been used in *tetanocedus*. Maguire, 1900, suggested intravenous injections of 1-20,000. They were quickly abandoned.

**Formaldehyde as Food Preservative.**—Concentrations of 1:25,000 to 1:10,000 have been used, especially for milk. It is both ineffective and dangerous, and is therefore properly prohibited. The ordinary concentration for milk (1:10,000) checks lactic fermentation, but does not kill the tubercle bacilli and is therefore of questionable utility. Whilst it may not interfere with digestion in *vivo* (Price, 1904), in life it may produce intestinal ulcers (Schap, 1905). It probably causes cumulative effects.

Even the local application is said to lead to inflammatory changes in the liver and kidneys (Fischer, 1905). The effects on digestion and general health are described by Wiley, 1908.

Salwowski, 1915, states that formaldehyde, 0.6 to 1.0 gm. per day, added to the food of a 12 kilogram dog, was well tolerated and did not impair the utilization of protein.

**Local Actions.**—Formaldehyde solutions or vapor, even when very dilute, produce very strong irritation of all mucous membranes. The susceptibility to this irritation is diminished by habituation. Applied to the unbroken skin, it hardens the epidermis, renders it rough and whitish and produces anesthesia. Repeated application of strong solutions leads to superficial necrosis of the skin and nails and to persistent eczema (Galewsky, 1905). Its application to broken surfaces is very painful. Isolated tissues are promptly hardened. Formaldehyde is therefore used in histologic technic in strengths of 1/2 to 10 per cent. These effects are produced by the coagulation of proteins. They are influenced by the concentration and by the time of contact (Meneguzzi, 1915).

**Urticaria.**—The endemic application of formaldehyde (2 per cent.) produces skin rash (Sollmann, 1917). General urticaria is also sometimes seen from the systemic use of formaldehyde, in mouthwash (Heidingsfeld, 1916) or formamid tablets (Glasier-Lichten).

**Use on Perspiring Fest.**—Althof, 1914, claims relief by painting the skin with 20 per cent. formaldehyde, daily for 5 days. The effect is said to persist 4 to 6 weeks, when the treatment is repeated. It is doubtful whether the method is harmless.

**Red Corpuscles.**—These are fixed by dilute solutions similarly to other tissues; strong solutions of commercial (not of pure) formaldehyde may produce laking by their formic acid (Franchi, 1913).

**Systemic Actions.**—The inhalation of formaldehyde vapors, even for a long time, produces but small effects, beyond the local actions, causing bronchitis and pneumonia. The intravenous injection of solutions in normal saline of a strength of 1:500 also produce no immediate effects, even in man. The fatal dose for mammals intravenously, is about 0.07 to 0.09 gm. per kilogram; the hypodermic dose is approximately ten times as much.

When applied directly to the mucosa of the upper intestine (not the lower), the irritation of the formaldehyde produces an increased flow of pancreatic juice. The most favorable concentration is 1 to 2 per cent., 8 to 10 per cent. being ineffective (Delezenne and Pozerski, 1912).

**Poisoning by Swallowing Formaldehyde.**—A number of such cases have been reported. As summarized by MacLachlan, 1909, the symptoms consist of immediate and severe abdominal pain; often sudden and prolonged loss of consciousness, and collapse. Death occurs in twenty-four to forty-eight hours. The autopsy shows severe gastritis with erosions. In non-fatal cases, the urine is suppressed for twelve to twenty-four hours, and then generally contains blood and casts. There is often diarrhea and tenesmus, sore mouth and dysphagia. The recovery is usually rapid, the patient being well within a week. The fatal cases all took over 3 ounces of the commercial solution. The largest quantity from which recovery is reported is 60 c.c.
The treatment should consist in the administration of dilute ammonia and ammonium salts, and in lavage.

Fate of the Formaldehyde.—Formaldehyde is absorbed from all parts of the alimentary tract and lungs (McGuigan, 1914). It is not excreted as such (Burm; Pohl, 1853), even with intravenous injection; unless very large doses are given (McGuigan, 1911; Impens and Rosenberg; Salkowski, 1915). It is mainly oxidized in the tissues, especially the liver (Pohl), to formic acid. The oxidation of aldehydes is not direct, but through the "Camilozzaro reaction," commonly observed in vitro when aldehydes are treated with alkalies, 2HCHO + H₂O = CH₂OH + HCOOH. A part of the formic acid may appear in the urine (Pohl; Klüeber and Gerlasch); but small quantities of formic acid are also completely destroyed (Sollmann, 1908). Some of the formaldehyde may be transformed into hexamethylenamin (McGuigan).

PREPARATIONS—FORMALDEHYD

*Liquor Formaldehydi (Liq. Formaldehydi, U.S.P., B.P.; Solution of Formaldehyde (Formalin).—A watery solution containing about 37 per cent. of HCOH. Clear, colorless liquid; pungent odor and caustic taste. Miscible with water and alcohol. A tablespoon in a quart of water makes about 1 per cent. of absolute formaldehyde.

Liquor Formaldehydi Sap. HCOO (Liq. Formaldehydi Sap.), B.P.—20 per cent. of Liqu. Formaldehydi, 40 per cent. of Soft Soap; 30 per cent. of Alcohol.

Paraformaldehyde (Paraform.), U.S.P. (Paraform, Trioxymethylene), (HCOH).—White friable masses, or as a powder, having a slight odor of formaldehyde. Slowly sol. in cold water; insol. in alc. or eth. Dose, 0.5 Grm., 8 gr., U.S.P.

It sublimes slowly at 100°C. and melts at 175°C. Heated under proper conditions, it is decomposed into formaldehyde and is used for the disinfection of rooms. Two Gm. of paraform are required per cubic meter (35 cubic feet of space). Formaldehyde is also slowly liberated at body temperature; paraform has therefore been suggested as an intestinal antiseptic (0.05 to 0.1 Gm. every two hours, for children), but its irritant actions renders it objectionable. Larger doses (5 to 4 Gm.) are cathartic, small doses are rather constipating. It will not cause serious poisoning even in large doses.

FORMALDEHYD COMPOUNDS

These are generally inactive and non-irritant in themselves, but regenerate formaldehyde under suitable conditions. It was therefore thought that they would prove valuable antiseptics. However, most of them liberate it either too slowly or too readily. Hexamethylenamin alone has proved really valuable.

Gustol (Schlicht, 1896) is an insoluble compound of formaldehyde and gelatin, which holds the greater part of the formaldehyde so firmly that it is practically useless (Sollmann, 1908). Other protein compounds were also disappointing. Classes introduced compounds with carbohydrates: Starch (amyloform), dextrin, milk-sugar, etc. Their fate was studied by Jacobson, 1906. There were also combinations with phenol, urea (Cohn, 1897), etc. Anhydromethylenecetarsit (starina) splits off CH₂O too readily (Nicolais, 1906); whilst methylenedisalicylic acid is not decomposed in its passage through the body (Sollmann, 1908).

HEXAMETHYLENAMIN

General Statement.—Hexamethylen-tetramine, N₆(CH₂)₆, is formed by the action of ammonia on formaldehyde. It is itself quite devoid of antiseptic, irritant or toxic actions. Its solutions, however, dissociate slowly with the evolution of formaldehyde. This decomposition is favored by the presence of free acid, and arrested by alkalii.

Hexamethylenamin is rapidly absorbed, distributed through all the tissues and secretions, and excreted mainly in the urine. By far the greater part is unchanged, but a small fraction is changed into formaldehyde wherever it meets an acid reaction; especially during the secretion of acid urine, and perhaps exceptionally elsewhere in the body. The degree of decomposition depends entirely on the acidity. The presence of free ammonia prevents the formaldehyde liberation completely.
The liberated formaldehyde exerts a more or less marked antiseptic effect. The concentration is rarely sufficiently high to cause sensible irritation, except in specially susceptible individuals. It never causes systemic poisoning, even with very large doses.

This antiseptic action renders the drug an effective prophylactic and sometimes curative remedy against inflammations and suppurations of the genito-urinary tract. By misconception, it has also been used in other conditions, where it is doubtful whether effective quantities of formaldehyde can be liberated: In typhoid bacilluria, infections of the bile-passages, meninges, respiratory tract, and accessory sinuses. It is the most effective of urinary antiseptics, provided that the urine is acid. In alkaline urine its effects are slight, and in ammoniacal urine it is inactive. The tendency to gastric and vesical irritation (painful micturition, hematuria) is lessened by liberal dilution.

Historical.—The substance was first prepared by Butenroth in 1850. It was introduced into practice as a urinary antiseptic by Nicolaier, 1895 and 1890. Richardson, 1895, popularized its use against typhoid bacilluria. Crowe, 1906, demonstrated it in bile and other body-fluids, and suggested its administration in this connection.

Formation of Formaldehyde.—The reaction between ammonia and formaldehyde is somewhat reversible, \( 4 \text{NH}_3 + 6 \text{HCHO} \rightarrow \text{N}_2(\text{CH}_2)_4 + 6 \text{H}_2\text{O} \). In watery solution, the reverse reaction, resulting in the liberation of formaldehyde occurs very slowly in the cold, somewhat more readily on heating, especially in the presence of acids (which combine with the ammonia). It increases with the degree of acidity (free hydrogen ion). Little if any formaldehyde is liberated in neutral, and none in alkaline liquids. In body-fluids and in tissue-extracts, the liberation proceeds as in aqueous solution (Hanislik and Collins, 1913). Exact estimations of the proportion of free formaldehyde have not been made for want of quantitative methods which would distinguish between this and hexamethylenamin. The presence of free ammonia prevents the reaction, and it is perhaps also diminished by the presence of salts. It would be proportional to the concentration of the hexamethylenamin.

An approximate estimation of the liberation of formaldehyde was made by Jordas, 1911. Incubating a 1:1,000 hexamethylenamin solution at body temperature for twenty-four hours, he found that the concentration of free formaldehyde reached 110,000 if the reaction was slightly acid; 120,000 if neutral. None could be demonstrated with alkaline reaction. Hanislik, 1913, found similar results.

Absorption, Distribution and Excretion of Hexamethylenamin.—The absorption from the alimentary canal is rapid and complete: The excretion by the urine—the main channel of its elimination—starts within eleven minutes after oral, rectal or hypodermic administration, reaches its maximum in one to three hours, and practically ceases in four to eight hours, according to the dose. After twelve hours only very small amounts are excreted, although the blood may contain faint traces after twenty-four hours (Sollmann, 1908; Crowe, 1908; Burnam, 1912; Falk and Sugiru, 1916). Approximately the same time relations obtain for its concentration and disappearance from the other secretions and tissues. Its distribution is universal, since it has been demonstrated in all parts of the body in which it was sought. By far the greater part is excreted unchanged, only a small fraction being converted into formaldehyde in the urine. A variable proportion is completely destroyed in the body.

The Concentration of Hexamethylenamin.—This depends on the dose, and in the case of urine at least, very largely on the ingestion of fluid.

1 The following structural formula has been suggested:

\[
\begin{align*}
\text{N-CH}_2 - \text{N} & = \text{CH}_2 \\
\text{CH}_2 & = \text{N} - \text{CH}_2
\end{align*}
\]
Quantitative Excretion.—The total recovered in the urine varies from 12 to 80 per cent. of the dose administered (1 Gm.), the higher figures corresponding to greater water intake. With continued administration, three times daily, the concentration in the urine ranged from 1:71,400 to 2,800 for doses of 0.57 Gm.; between 1:2,200 to 14,000 for 0.33 Gm. The excretion is diminished in renal impermeability (Falk and Sugira, 1916). In other secretions and in the tissues, the concentration is probably lower.

Presence of Free Formaldehyde in the Tissues.—Tests for free formaldehyde (as distinguished from hexamethylenamin) have been applied only by a few investigators. It could occur only in situations where there is free acid; i.e., normally only in the gastric juice and urine. Accordingly, the results with other normal fluids have been uniformly negative (milk, Schmid and Schroeter; saliva, Hanzlík; bile, cerebro-spinal fluid and sputum, Burnam, 1912; various situations, McGuigan, 1912). It is conceivable, however, that acid reaction may obtain strictly locally in other situations under pathologic conditions. Indications of this were found by Hanzlík and Collins, 1913. However, the formaldehyde liberation was so small as to be ineffective (Hanzlík, 1914; Hyman, 1914).

Presence of Free Formaldehyde in the Urine.—The amount of formaldehyde liberated depends upon the acidity, the concentration, the time of standing, and perhaps on other unknown conditions. The liberation may occur in the kidney (Burnam) and increases in the bladder (Sollmann; Hinman, 1913). Burnam found it often absent with small doses, but believes that with larger doses the concentration of free formaldehyde may exceed 1:5,000. Smith found that 0.5 Gm. always gave formaldehyde in acid urines, while 0.3 Gm. was inconsistent. Alkaline urines do not liberate formaldehyde, but the formaldehyde liberated in the acid kidney may persist for a short time in the alkaline bladder. Kidney disease does not modify the liberation (Hinman).

L’Esperance and H. Cabot, 1912, found free formaldehyde in about half the hexamethylenamin urines examined. They believe that the liberation is not affected by the dosage or by the reaction of the urine. This conclusion can only have been based on faulty methods of estimating the acidity; for G. G. Smith, 1913, and Hanzlík and Collins showed definitely that all acid urines liberate formaldehyde. Smith and Jenness, 1913, also found 5 in about half the cases.

Concentration of Formaldehyde in Urine.—With the present rather unreliable methods, Hinman, 1913, claims that this is below 1:40,000 in half the cases; 1:16,000 in 25 per cent.; and over 1:2,000 in 2 per cent. of the urines.

Antiseptic Action.—Hexamethylenamin itself is not at all antiseptic, if the liberation of formaldehyde is prevented by alkalies (Hanzlík, 1913). A concentration of 5 per cent. is required to check the growth of Staphylococcus in neutral broth cultures; and this may be attributed to the free formaldehyde (Jordan). The antiseptic action is always parallel to the concentration of free formaldehyde (Hanzlík and Collins). Formaldehyde in concentration of 1:50,000 to 1:30,000 has a distinct though limited antiseptic effect (Mosso and Paleotti).

Antiseptic Effects after Administration.—These are especially marked in acid urines, as might be expected. However, Crowe, 1908, claims that the administration of 5 Gm. per day also renders the bile and other body-fluids antiseptic. Exact observations have not confirmed this (Hanzlík and Collins), and the idea of producing a "tissue-antiseptic" by its use must be abandoned.

Therapeutic Use as Urinary Antiseptic.—Hexamethylenamin is by far the most effective urinary antiseptic, provided that the reaction of the urine is acid. In neutral or alkaline urine, its efficiency is practically
nil (Jordan, 1917). In ammoniacal urines it would be useless. It would therefore be especially valuable as a prophylactic, for, in catheterization (Burnham, 1912), it has also been advised to prevent the growth of typhoid bacilli (Richardson, 1898); but its efficiency is doubtful. It may be used in inflammation or suppuration of the renal pelvis, bladder or urethra. The dosage should be from 0.25 to 0.5 Gm. (4 to 8 gr.) in half a glass of water, four or five times a day. Burnham, 1912, recommends increasing the dosage until formaldehyde appears in the urine. In typhoid fever, the same dosage would be employed continuously, from the time when the diagnosis is made. If the urine is alkaline, acid sodium phosphate (NaH₂PO₄) should be administered, 2 to 2 Gm. every one to four hours, until the urine is acid. This often causes diarrhoea.

Acidulation of Urine.—The official sodium phosphate, NaH₂PO₄, does not alter the reaction of the urine. The acid salt may be prepared extemporaneously: 4 c.c. of 95% alcohol, 15 c.c. Normal Phosphoric Acid, 15 c.c. Water. A tablespoon represents about 1 Gm. of acid phosphate. It should be diluted in a tumbler of water. Benzoate has a tendency to render the urine acid (Jordan, 1913); also boric acid, 2 Gm. daily (G. G. Smith, 1913). A table-spoon represents about 1 Gm. of acid phosphate. It should be diluted in a tumbler of water. Benzoate has a tendency to render the urine acid (Jordan, 1913); also boric acid, 2 Gm. daily (G. G. Smith, 1913).

Relative Value of Other Urinary Antiseptics.—Using the ordinary therapeutic dose in a normal subject, Sollmann, 1905, found that urinary decomposition was prevented at incubator temperature, with hexamethylenamin, for three days to three weeks; all discolours for a day; benzoate, phenolphthalein and boric acid had no discernible effect. Churchman, 1906, concludes that hexamethylenamin surpasses methylene blue (Jordan, 1911), found it much superior to salicylic acid and salntal oil. The difference is of course most marked in acid urines, although this increases the efficiency of all the antiseptics. The greatest effect of Salant oil was on Staphylococci. He found benzoic acid the best antiseptic for alkaline urines (1913).

Solvent Action on Uric Acid.—Hexamethylenamin has been proposed as a remedy for uric acid and urate calculi. It, as well as formaldehyde, dissolves uric acid, with the formation of a series of paired compounds (Nicolaier, 1906). However, the solvent action is really very slight (Stevens and May, 1911), and the experimental and clinical results have been disappointing (Hanlik, 1916). Hanksin, 1915, found that the administration of hexamethylenamin in doses of 4 to 5 Gm. does not confer any solvent action on the urine. Doses of 4 Gm. made the urine distinctly more soluble; but equal results are secured by making the urine slightly alkaline (p. H. = 7.1 to 7.4) as may be easily done by administering sodium bicarbonate or acetate. These results were also confirmed by adding hexamethyleneamin directly to water, urine and phosphate mixtures.

Antiseptic Action on Bile.—Crowe, 1908, claimed that the administration of at least 5 Gm. (75 gr.) per day renders the bile unsuitable for the growth of bacteria, and completely antiseptic to typhoid bacilli. It was therefore advised as a prophylactic against biliary infection after operation on the gall-bladder or ducts. Recent observations (Burnham, Hanlik) have not confirmed these claims, and it may be concluded that there is ordinarily no antiseptic effect on the bile.

Meningeal Infections.—The excretion of hexamethylenamin into the cerebrospinal fluid (Crowe, 1908; it reaches the concentration of 1:20,000 even after a single dose of 1 Gm. (Hald, 1911)) was claimed by Crowe, 1908, to restrain the development of bacteria, although the concentration is not sufficient for disinfection. Clinically early and large doses were said to afford at least a considerable degree of protection against infective diseases of the meninges (poliomyelitis, Flexner and Clark, 1911; epidemic and postoperative meningitis (Crowe, 1912), etc. Here again, the recent exact observations are negative (influenzal meningitis, Fraser, 1914). Usser, 1915, claims that diminished excretion into the cerebrospinal fluid is diagnostic of tuberculous meningitis.

Administration for Systemic Disinfection.—To obtain the claimed effects on the bile, meninges or respiratory passages, relatively large doses were employed: at least 1 Gm. (15 gr.) in a glass of water, five times per day; in meningeal infections even to 20 Gm. per day. The dosage should be reduced if irritant effects are noted. The
administration of sodium acetate or citrate would probably lessen the liability to urinary irritation, without inhibiting any systemic antisepsis. Crowe, 1912, advocated the addition of 5% of the drug to all liquids taken by very ill patients, the rectal injection, a drop at a time, of a liter of saline solution containing 3 to 6 Gm. of the drug.

**Middle Ear.**—The excretion of hexamethylenamin in this situation was demonstrated by Barton, 1910, it appeared to cut short supplicative infection. It was therefore recommended as a prophylactic in scarlet fever, etc. Similarly, it was claimed to be useful against acute and chronic *sinus infections* (Burton, 1910); and in *urina* (A. Miller, 1911), bronchitis (Vanderhoff, 1910), and *influenza* (Eisenberg, 1912), and even as a pulmonary disinfectant (Zeik, 1912). The observations of Shattuck, 1911, on pneumococcus empyema were negative, although hexamethylenamin was present in the pus. Crowe, 1912, doubts its efficiency in lobar pneumonia and in tuberculosis.

**Excretion in Eye.**—Gradle, 1912, found it in the anterior chamber, its excretion being hastened by mydriatics; however, its concentration is not sufficient to be antiseptic. (Witham, 1913, thinks that there is a slight antiseptic action.) In cata. Remély, 1910, found it in the aqueous humor shortly after the intravenous injection of 5 Gm. He also claims that traces of formaldehyde are present within one-half hour and persist for nineteen hours.

**Excretion in Milk.**—This was announced by Bucura, 1905, and confirmed by Crowe, 1908, Woltersijn, 1910, and by J. Schmid and Schroeter, 1910, who found no free for- maldehyde. Reider, 1912, found that the highest concentration was reached after an hour, but that this was not sufficient to be antiseptic.

**Excretion in Saliva.**—This contains no free formaldehyde, but only the unchanged drug. The excretion reaches its maximum in half an hour (Hanlik).

**Undesirable Effects.**—Hexamethylenamin does not cause any systemic effects, even on the intravenous or hypodermic injection of enormous doses (Crowe, 1908; Burnam, 1912). Nor does it have any local action, so that it may be given hypodermically (Gundrum, 1911) or injected into the bladder in 50 per cent. solution (Burnam), with practically no irritation. However, in the bladder of the masticated, this will form albumin, but only with large doses and in specially susceptible individuals. This causes painful micturition and eventually cystitis and hematuria. In Crowe's cases the hemorrhage was from the bladder. The kidneys may probably also be irritated. The cystoscope shows hemorrhagic cystitis; and post-mortem examination also hyperemia of the pelvis (J. A. Abt, 1914). J. A. Abt, 1917, believes that its use has caused severe and fatal nephritis; this requires confirmation. Other occasional symptoms (Coles- man, 1903) are: rubecular skin rashes, catarrhs of various mucous, and digestive disturbances. These irritant effects are quite exceptional if the drug is given in sufficient dilution. They disappear promptly and without any permanent damage, if it is discontinued.

In dogs, Wiggs, 1910, obtained marked nephritis from relatively small doses. Rabbits show hematuria only with 8 Gm. per day (D. L. Simon, 1914). In guinea pigs, hypodermic injections (Frithingham, 1909) produce local necrosis, and gastric congestion hemorrage and ulceration. Intravenous injection is practically no more harmful than oral administration. Læser and Grosdier, 1918, prefers the intravenous route for therapeutic administration (for man, 0.5 to 2 Gm. as 25 per cent. solution). This has little justification, in view of the ready absorption.

**Incompatibilities.**—Hexamethylenamin is a fairly strong base, gradually displacing ammonia from its salts. It is decomposed by acids (even acetyl-salicylic acid) and by acid salts with the liberation of the irritant formaldehyde. It is also incompatible with tannin, mercuric chloride and oxidizing agents (J. A. M. A., Feb. 8, 1913, p. 463).

**PREPARATIONS—HEXAMETHYLENAMIN**

*Hexamethylenaminina* (Hexam.). U.S.P.; *Hexamina*, B.P. (Hexamethylenetetramin), (C6H11N4).—It was introduced as *urotopin* and is also marketed under other numerous
and confusing trade names. These commercial brands are in no way superior to the official substance (Baer, 1907). It occurs as colorless, lustrous, odorless crystals, of sweet, then bitter taste. Solutions react alkaline to litmus. It is freely sol. in water (1:10), and alc. (1:10). Dose, 0.25 Gm., 4 gr., U.S.P.; 0.5 to 1 Gm., 5 to 15 gr., B.P.

Halocarbon Salts.—A number of these are described in N.N.R. but they have no serious advantage. Borutta, 1914, claims that the urinary antisepsic action is somewhat greater with hexamethylen salicylate or camphorant, and that the urate solvency is higher with the citrate, borate or sulfo-salicylate.

Jacobs and Heidelberg, 1915, report experiments with some quaternary derivatives that appear promising. The activity of these does not seem to depend on the liberation of formaldehyde, so that they are not inhibited by protein and do not require acid.

CHLORIN ANTISEPTICS

General Statement.—Strong and prompt germicidal effects are produced by chlorin as gas or in solution, and by substances capable of yielding "active" chlorin, such as the hypochlorites and chloramins (i.e., compounds containing NCl groups). However, they attack all organic matter, and are thus likely to be corrosive and to become inactive. These objections can be overcome by proper technic and selection of the preparations. They have been greatly developed in the war, and the importance of this group has correspondingly increased.

Mechanism of Action.—Chlorin itself acts partly by oxidation, partly by the chlorination of the organic matter. With the hypochlorites the chlorination appears to be the chief element. It is supposed to occur in the amino-acid groups of the proteins, yielding chloramins.

\[
\begin{align*}
H & \quad H \\
R-C-\text{CO} & \quad \text{NZCO}
\end{align*}
\]

The chlorin of the chloramins is still "active" (i.e., capable of liberating iodin from iodides), and is probably capable of effecting further chlorination. In any case, the chloramins are themselves directly germicidal, often more so than the corresponding amount of chlorin in the form of hypochlorite (Dakin, 1916). Toxins are also destroyed.

Historical.—A review of the use of hypochlorites is given by Dakin, 1915.

Hypophosphite.—These are not germicidal, since they do not react with protein.

Chlorinated Lime.—(Bleaching powder).—This is quite irritant, and therefore not well adapted to application to the tissues: but is used largely as disinfectant for excreta. High dilutions are employed to sterilize water, especially for temporary emergencies.

Toxicology.—When swallowed, bleaching powder produces gastro-intestinal irritation. The treatment would be by evacuation and demulcents.

Disinfection of Excreta.—Six ounces of chlorinated lime are mixed with a gallon of water: a quart of this is added to each discharge and allowed to stand an hour.

Sterilization of Water.—Five to 15 pounds of chlorinated lime are used per million gallons, according to the impurities and other conditions. This imparts a slight taste, but no other bad effects have been demonstrated. On a small scale a level teaspoonful is rubbed with 4 cups of water and a teaspoon of this solution is added to 2 gallons of the drinking water, and left for at least ten minutes.

For Swabs, Bites, to c.c. of a 1 per cent. solution is injected hypodermically about the wound. (Calmette, 1907).

For the disinfection of the hands, these are moistened and rubbed with a little dry chlorinated lime and washing-soda.

labarrique's solution is used as a deodorant on fetid alveus, being diluted 10 or 20 times. Chlorinated lime itself has been used on wounds; 2 tablespoons of the compound being dissolved in a basin of warm water and used as a lotion, twice daily. (Mench.
CHLORIN ANTI SEPTICS

Internally, it has been tried as a gastro-intestinal antiseptic, but would be n the presence of organic matter. Liqu. Chlori Co. is employed as a gargle in s of the throat, being diluted with 6 or 8 parts of water.

Gical Solutions of Hypochlorites.—(Dakin’s Solution, etc.)—Experience in the war has shown that the continuous saturation of with dilute hypochlorite solutions practically abolishes sepsis, es dead tissue, and promotes healing. To be effective, the solutions contain between 0.43 and 0.48 per cent. of available chlorin, corre cing to 0.45 to 0.5 per cent. of NaOCl. Higher percentages are too . Free caustic alkali must also be avoided. The solutions must aerated and titrated with great care.

The skin must be protected by petrolatum gauze, since it is often d even by the correct solution.

Dresene’s formula is now generally employed. It is made by treat ing with a mixture of sodium carbonate and bicarbonate in N.N.R.

Older formulas (for instance “Eusol”) employed boric acid. Magnesium hypo is urged by C. Mayer, 1910.

acid, a dry mixture of equal parts of chlorinated lime and boric acid has been used as a dusting powder (Lorian, Smith, et al, 1913). It is apt to be irritant.

Unity.—The reaction of the Dresene solution is not strictly neutral. The concentration should be between 0.9 and 10 i.e., somewhat more alkaline than bicarbonate (Cullen and Austin, 1918). Solutions of higher or lower alkalinity are more irritant (Cullen and Taylor, 1918; rabbit’s ear).

Of Action.—Hypochlorite solution is markedly solvent for necrotic tissues, en the reaction is strictly neutral (Taylor and Austin, 1917). This helps to ter access to the bacteria. At best, however, the action is superficial and t tissue must be promptly excised.

Ramin and Dichloramin T are without solvent action (Taylor and Austin, 1917).

Tissues.—There is also a fibrinolytic action on living tissue cultures (Lamb 5). However, the injury to the phagocytes and other living cells is distinctly us than with most antiseptics.

serum.—Silk ligatures are soluble in hypochlorite, and can therefore not be used.

Gut ligatures tend to slip, and thus incline to secondary hemorrhage (K. 1912).

Effects from Serum Cardio.—Intraperitoneal injection produces experi marked irritation, corrosion, collapse and death.

serum injection is relatively less toxic; but larger doses cause lacking and delay elation time (Mann and Curney, 1918). The hypochlorite is rapidly des y the blood serum, which partly accounts for the low toxicity (Dakin, 1916).

Coagulation.—The addition of Dakin’s solution to blood (1:10) prevents by interfering with the thrombin. Clotting occurs if tissue extract is added, he interference would not be important in wounds (Guthens and Meltzer, 1918).

bramin T.—Sodium Para-Tolueno Sulphochloramid (N.N.R.) also Chlorazene, Tolamine (CH₂C₆H₅SO₂Na: NCl+3H₂).—This may be u sed in place of Dakin’s solution and has the advantage that its watery solutions are practically stable. In equimolecular solution it is about four times as germicidal as NaClO. This may perhaps be explained by less side reactions with non-bacterial proteins. Weight for weight, NCl the germicidal power is about the same. It is less irritat ing and has but little solvent action on necrosed tissue, composed by oils.

solution.—It is employed in wounds as 1 to 2 per cent. solution, by the saturation 1 A “bath” of 1 per cent. of the drug in 2 per cent. sodium stearate is mildl and is used to prevent re-infection of wounds.
Strengthen the solutions for eye, 0.1 per cent.; nose and throat, 0.2 per cent.; bladder and urethra, 0.25 per cent. (Dakin, 1916; Eicher, 1917).

**Dichloram T** (Toluene parasulphondichloramin, N.N.R.). This is much more germicidal than chloramin T. Only traces dissolve in water, but it is readily soluble in most organic solvents and oils, sparingly in paraffin and petrolatum. When such solutions are applied to the tissues, they give up the drug very slowly and thus exert a continuous antiseptic action, according to the strength of the solution (Dakin, Estell, et. al., 1917).

The results are about as good as with Dakin's solution; whilst the application is much more convenient. There is but little irritation of the skin. Catgut is not affected, so that the danger of secondary hemorrhage is avoided (F. Rosengarten, 1917; Lee and Furness, 1918).

On the other hand, the solution causes rather painful though short smarting of sensitive wounds; is more or less irritant to granulations; and is said to retard epitheliation; the dressings adhere to the wound, causing mechanical injury (Morrison et al., 1918).

The solvent action on dead tissue is less marked than with Dakin's solution (Taylor and Austin, 1917). However, Dakin's solution and Chloramin tend somewhat to prolong capillary hemorrhage (Hanzlik, 1918).

Application to the peritoneum produces inflammation (Reismann and Magoun, 1918). Injection into the gall-bladder is followed by induction. Introduction into the pleura is followed by rapid death (Reid, 1918).

**Application.**—The dichloramin T is generally applied as solution in "chlorocose" (N.N.R.), a paraffin liquefied by chlorination. (Chlorinated eucalyptol was used at first.) These solutions deteriorate rather rapidly, but retain considerable activity for a week or longer.

The usual concentrations are: for open wounds 2 to 10 per cent.; sterilization of the nasopharynx, 2 per cent., spray for fifteen minutes, several times daily (Dakin and Durham, 1917); for eye-infections, 0.5 to 1 per cent. every four hours (Green and Green, 1918).

Contact with yellow petrolatum destroys dichloramin T very rapidly. A paraffin ointment (Surgical paraffin, 3; liquid petrolatum, 7) is very much less destructive, and may be used as a covering, especially in burns, to prevent adhesion of dressings to the wound (Sollmann, 1910).

**Solvents for Dichloramin T.**—These are discussed by Hemler, 1918.

**Halozzone.**—Para-sulphon-dichloramin-benzoic Acid.—This was introduced by Dakin and Dunham, 1917, for the temporary purification of drinking water (4 mg. per liter). It sterilizes in about 30 minutes, and has very slight taste.

**PREPARATIONS.—CHLORIN**

*Calx chlorinata* (Calx Chlorin), U.S.P., B.P.; Chlorinated Lime (Chlorid of Lime— Bleaching Powder).—A product resulting from the action of chlorin upon calcium hydrosulphite and containing 30 per cent. of available chlorin. Consists mainly of a mixture of weak compound of calcium hypochlorite and calcium chlorid. It occurs as a greyish-white granular powder of chlorin odor and repulsive salty taste. It is only partially sol. in water or alc.

Lig. Calci Chlorin., B.P.—10 per cent. of Calx Chlorin, representing 3 per cent. of available chlorin.

CHLORIN ANTISEPTICS

Javelle Water is a similar preparation of chlorinated potash.
*Surgical Solution of Chlorinated Soda, N.Y.R.—Carrel-Dakin Solution; Daufresne solution. See text.
*Chloramin T, N.N.R.—See text.
*Dichloramine T, N.N.R.—See text.
Halazon, N.N.R.—See text.
Chlorosane, N.N.R.—A chlorinated paraffin, used as a solvent for Dichloramine T. Its chlorin is not "active" nor antiseptic, but serves merely to protect the dichloramin T.

SULPHUR DIOXID (SULPHUROUS ACID)

This was formerly used extensively for the disinfection of rooms, but not reliable against bacteria (Koch), and has the objection of bleaching colors. However, it is effective against insects (McClintock, etc.), and therefore against insect-borne diseases, malaria, yellow fever, etc.

It is generated by burning 3 pounds of sulphur for each 1,000 cubic feet of space. To avoid danger of fire, the sulphur is placed in tin pans raised from the floor by bricks. Its action is materially greater when the air is saturated with moisture.

Toxic Effects.—These arise from its use in disinfecting and bleaching. Large quantities occur also in coal smoke, and become particularly objectionable in foggy weather. It is eventually oxidized in the air to sulphuric acid (T. W. Schaefer, 1907). Its inhalation produces irritation of the respiratory passages, etc. and extreme discomfort if inhaled. Its effects are prompt and fatal by paralysis of the respiratory center (Ogata, 1884; K. B. Lehmann, 1891).

PREPARATIONS—SULPHURIC ACID
Acidum Sulphuricum (Acid. Sulphuric.). B.P.—An aqueous solution corresponding to 5 per cent. of SO3. Dose, 2 to 4 c.c., 1/2 to 1 dram, B.P.

SODIUM SULPHITE AND THIOSULPHATE (HYPOSULPHITE)

These are rarely used in medicine, as mouth wash in aphthae, and as 1 per cent. lotion in ringworm and other parasitic skin diseases (pityriasis versicolor). The thiosulphate is the more powerful and is sometimes used also as a cathartic.

The principal importance of the sulphites arises from their use in preserving foods. The quantities ordinarily used do not seem to be directly harmful. Even much larger quantities do not act systemically, being rapidly oxidized to sulphates; but they may produce local gastric irritation by the liberation of sulphuric acid. Their harm is mainly indirect in that they improve the odor and appearance of spoiled meat so that it sold as fresh. They are therefore properly prohibited.

Toxic Effects.—The harmfulness of ordinary quantities even when continued for very long periods has been shown particularly by Rost and his co-workers (1904, 1912) and by Lehmann and Treitschin, 1909 (Long, 1912). The metabolism is not deranged. At the larger doses by mouth, there are signs of gastro-intestinal irritation, due to the liberation of sulphuric acid (Jacob and Walbaum, 1906). Klonka and Ebeinstein, 1902, and Harrington, 1904, described hemorrhagic and inflammatory lesions in the kidneys and other organs after long-continued use, but these have not been confirmed by later observers and were probably accidental. The absorbed sulphite is rapidly oxidized to sulphate (Pfieffer, 1883; Rost and Sonntag, 1904) and it is only when this capacity is exceeded by very large doses or intravenous injection that toxic effects appear. These lower the blood pressure, depressing the central nervous system, especially the medulla, and the cardiac and arterial muscle. Death occurs by paralysis of respiration (Rost, 1912). In man, 1 Gm. produced no effects; 4 to 6 Gm. caused violent colic, diarrheas and circulatory disturbances (Rost; Franz, 1912).
OXIDIZING AGENTS

OZONE

This is a polymeric form of oxygen (O₃), which decomposes very readily with the liberation of active oxygen. It is therefore strongly oxidizing, deodorant and antiseptic; but is too easily destroyed in the presence of organic or other oxidizable matter. Efficient concentrations are also highly irritant and produce toxic depressant systemic effects. It is being used for the sterilization of water. Traces of ozone are contained in the air, especially after thunder storms, but the quantity is much too small to have any effect whatever; in fact, concentrations far beyond human tolerance are of uncertain efficiency (J.A.M.A., 57: 1370, 1911). At most, its persistent presence is an indicator of the absence of organic matter in the air. The odor of ozone is characteristic and disguises other odors.

Effects of Inhalation.—The older methods of preparing ozone developed irritant nitrogen oxides. The modern machines are free from this defect. By their use, concentrations of 5 to 10 per million, inhaled for a short time, produce in man increased amplitude of the pulse, drowsiness, and persistent headache—the latter probably by irritation of the sinuses. Ten per million inhaled for fifteen minutes produces sore throat. One per million diminishes the oxygen intake and the CO₂ output. Prolonged exposure to concentrations below 1 per million does not produce noticeable disturbance; but with higher concentrations there is irritation of the respiratory tract and other mucous membranes, leading to fatal pulmonary edema; or in acute toxic concentrations to initial restlessness followed by depression and coma (Jordan and Carlson, 1915; Hill and Flack, 1911; Sigmund, 1905; DuMont, 1891). Exposure for two hours to 10 or 15 per million is dangerous to life, but the irritant effects, cough, headache, etc., give ample warning to avoid the danger. For an antiseptic action, at least 13 per milliliter would be necessary (L. Hill and Flack, 1911). The air contains at most 0.00015 to 0.158 per million. Its seasonal occurrence is discussed by Holmes, 1912.

HYDROGEN PEROXIDE

The peroxides are fairly stable in pure solutions, but on contact with catalysts, inorganic or organic (catalase), tissues, etc., they split off active oxygen and are therefore strongly antiseptic and deodorant. The action lasts only so long as oxygen is being evolved, and is therefore brief and superficial. In deep and closed cavities, the rapid evolution of gas presents danger of mechanical injury and embolism.

Uses.—Hydrogen peroxide is employed for washing fetid wounds and ulcers; as injection for gonorrhea; as mouth wash, etc. It is non-toxic and scarcely irritant, but is best diluted with 2 to 10 parts of water. A stronger (50 per cent.) preparation is caustic. In contact with pus it foams, and this aids mechanically in cleansing the wound. Hydrogen peroxide is also a chemic antidote for cyanid and phosphorus poisoning. It is often used for bleaching the hair and fabrics. The concentration of 0.35 per cent. (absolute) in milk inhibits the development of pathogenic bacteria (Budde, 1903) but it also destroys the ferment of milk and is of questionable utility (Heinemann, 1913). Sieber, 1901, claims that it destroys toxins. The germicidal action is feeble (Albert and Taylor, 1918).
Phagocytosis.—This is stimulated in vitro by hydrogen peroxide; whereas free oxygen generally depressant (H. J. Hamburger, 1915). Potassium chlorate and ferricyanide are inactive.

**PREPARATIONS—PEROXIDS**

*Liquor Hydrogenii Dioxidii* (Liq. Hydrog. Diox., U.S.P.; Lq. Hydrog. Perox. P.; Solution of Hydrogen Dioxide (Peroxid).—A slightly acid aqueous solution of \( H_2O_2 \) (approximately \( 1 \) per cent.) corresponding to about 10 per cent. (volumes) of usable oxygen. Stronger solutions are also marketed. It occurs as a colorless liquid, clear, or slightly acid taste, producing a peculiar sensation and soapy froth in the mouth.

It keeps best in bottles stoppered merely with a plug of cotton, and standing in a cool place. It is incompatible with easily oxidizable substances. It decomposes slowly.

This is not due to impurities (Clover, 1913). The decomposition is retarded by small quantities of acid or acetic acid. The latter is used in most brands (Kebler, 1907), but in time these acquire a yellow tint and an odor of nitrobenzol, and should not be used. Dosage, 1 c.c. to 1 dram, U.S.P.; 2 to 5 c.c. 1/2 to 2 dram, B.P.

*Solid Peroxide* consists of easily soluble compounds with urea, containing about 1 per cent. of absolute peroxide.

**PEROXIDS OF METALS**

These may be conceived as compounds in which the \( H_2O_2 \) of hydrogen peroxide has been replaced by metals, and which are readily decomposed with the formation of \( H_2O_2 \) or of active oxygen. They have been suggested as substitutes for hydrogen peroxide. The commercial products are usually mixtures containing 15 to 25 per cent. of the real peroxide. The impurities of the various metals vary considerably in their stability and solubility, in the ease with which their solutions are decomposed. Acids convert them rapidly to hydrogen peroxide, \( \textit{fi.} \), MgO\( _2 \) + \( H_2O_2 \) = MgSO\( _4 \) + \( H_2O \). In this way the ypn is made promptly available. Water decomposes them more slowly, inversely to their solubility; \( \textit{fi.} \), ZnO\( _2 \) + \( H_2O \) = Zn(OH)\( _2 \) + \( H_2O \). Their action is therefore prolonged. The therapeutic effect is also modified by the nature of the base; thus zinc peroxide would yield a solution sufficiently alkaline to be caustic. Magnesium zinc peroxide is therefore generally preferred.

Uses.—The antiseptic effects are utilized in skin diseases (ZnO\( _2 \)); dentifrices (MgO\( _2 \)); against gastro-intestinal fermentation (ZnO\( _2 \)). These compounds are described in N.N.R.

**Sodium Perborate**.—This also yields hydrogen peroxide on contact with water, being transformed into carbonate which acts as a mild alkali, Na\( _2 \)BO\( _3 \) + \( H_2O \) = \( H_2O_2 \) + \( NaOH \). It is used as a dusting powder or a 5 per cent. solution, as a substitute for soap. The substance is described in N.N.R.

**ORGANIC PEROXIDS**

These were introduced by Novy and Freer, 1902. Acetyl-benzoyl peroxide (Acetone) and succinic dioxid (Alphzone) are described in N.N.K. They may be considered \( H_2O_2 \) in which the \( H \) has been replaced by organic radicals. In the presence of water they are slowly hydrolyzed, forming organic per-acids, with very active oxidizing and mucidal properties, \( \textit{fi.} \), the acetyl benzoyl peroxide decomposes into acetyl peroxic acid, etc acid, and the insoluble dibenzoyl peroxide, according to the equation \( \text{CH}_3\text{CO-OO-COCH}_3 \) + \( H_2O \) = \( \text{CH}_3\text{CO-OOO-COCH}_3 \) + \( \text{CH}_3\text{COH}\_2 + \text{CH}_3\text{COO-CH}_2 \). They are somewhat used as local and intestinal antiseptics, but are of doubtful efficacy for the latter purpose. They should not be mixed with organic liquids, nor be in a warm place, as they tend to explode. They are described in N.N.R.

**IDOXYBENZOIC ACID**

This has a strong oxidizing action, even in the body, and is therefore of considerable medical interest. Leovenhart and Grove, 1912, have investigated the sodium salts the three compounds: (a) Iodoxybenzoic acid, \( \text{C}_9\text{H}_4\text{O}_2\text{H}-\text{I} \).

(b) Iodosobenzoic acid, \( \text{C}_9\text{H}_4\text{O}_2\text{H}-\text{I} \).

(c) Iodoxybenzoic acid, \( \text{C}_9\text{H}_4\text{O}_2\text{H}-\text{I} \).

(2) and (3) have a metallic taste, resembling hydrogen peroxide, presumably due to the active oxygen.

They oxidize hemoglobin to oxyhemoglobin. (2) is irritating, (3) and (1) very mildly. The systemic effects were studied by intravenous injection. (2) has very little action. The oxygenated compounds (2) and (3) produce the phe-
nomena of apnea: marked and continued fall of blood pressure by depression of the vasomotor center; brief arrest of respiration, also by depression of the medullary center. The vagus center is not affected. These actions are due to the active oxygen. (This can not replace ordinary molecular oxygen for maintaining the cardiac activity, Loewenhart and Eyster, 1913.)

Antiseptic Action.—The oxidizing property promises an antiseptic effect, perhaps even in the tissues, since it is not inhibited by serum. (1) and (3) are much more bactericidal than (1) (Arkin, 1911). Iodoxybenzoate increased the production of antibodies in dogs (Hektoen, 1911); also the production of hemolysin and agglutinins in rabbits, when injected intravenously shortly after immunization. It stimulates phagocytosis (Arkin, 1915). Its injection also lessens inflammation by mustard oil or allergy, whilst this is increased by cyanid, indicating that edema is lessened by oxidation and increased by asphyxia (Amberg and Knox, 1911; Amberg, 1913). Iodosobenzoic acid has also been studied by Jahn, 1912). It reduces the toxicity of tuberculin in vitro (Arkin, 1916).

POTASSIUM PERMANGANATE

In the presence of organic matter, this splits very readily into MnO₂ (forming a brown precipitate), and into oxygen. It is therefore as effective oxidizing agent and disinfectant; but its efficiency is limited by any excess of organic matter. Its action is only superficial, and it is markedly irritating. It is used as an antiseptic for mucous membranes, especially the urethra (1:4,000 to 1:1,000). A 1:5,000 solution is said to be a satisfactory anesthetic for introducing urethral sounds (Barton, 1913). Beck, 1913, recommends it against burns (1:4,000 to 1:1,000 on gauze and as lotion).

It is an antidote to organic poisons, especially morphin, hydrocyanic acid, and phosphorus (1:1,000 to 1:500). A saturated solution may be employed for disinfecting the hands, the color being removed by oxalic acid. Large doses by mouth cause death by gastrointestinal.

In snake-bite, it is effective, but only if used within 5 minutes (1 per cent, applied to free incisions after double ligature, if possible; Weidenmann, 1915).

PREPARATIONS—PERMANGANATE

*Potassii Permanganati (Pot. Permang.), U.S.P.; B.P.; KMnO₄—Slender, flat purple prisms; odorless; astringent taste. Sol. in water (1:1:3:2); decomposed by acid and all organic matter; explosive. Dose, 0.05 Gr. (1/8 Gr.), U.S.P.; 0.06 to 0.1 Gr. (1/10 to 1/5 Gr.), B.P.; diluted.

Liq. Pot. Permang., B.P.—1 per cent. Dose, 7 to 15 C.C., 2 to 4 Drams, B.P.

BORIC ACID AND BORAX

These combine a fair antiseptic power with a low toxicity to higher animals. They are also less irritant than most other antiseptics. Boric acid is employed in surgery as dusting powder, as saturated (4 per cent) aqueous solution, as boroglycerite, and in collyria (1 to 2 per cent. of boric acid or sodium borate). Boric acid is a mild acid, and increases the acidity of the urine; borax acts as a weak alkali. It dissolves mucus, lessens the urinary acidity, and is used for cleansing. The acid and alkali characters are very weak. The borate ion has no other therapeutic use.

Use as Food Preservative.—Boric acid and borax have been extensively employed for this purpose. Single doses are generally innocuous: but their continued use produces slight but cumulative effects, so that their employment is not advisable.

Antiseptic Efficiency.—Boric acid is not a disinfectant. Even saturated solutions do not kill bacteria, but solutions of 0.3 per cent. check putrefaction and decomposition (but not the growth of pathogenic organisms, Bernstein, 1910).
The antiseptic efficiency varies for different bacterial cultures. It begins with about turratic larger for most is complete with about 25 mg. of 0.5% of. Borax is somewhat less efficient. Their popularity as food preservatives is stable to the absence of distinctive odor and taste, and to their relatively low

The question of their toxicity has been investigated extensively. It is presumed that boric acid and borax behave exactly alike. A man living largely served food may ingest as much as 0.5 Gm. of boric acid (or its equivalent in per day; the consumption would generally fall below this figure, but could rise

All investigators agree that quantities to 0.5 Gm. have no immediate of any kind in healthy individuals. When, however, the consumption is con-

for a long time, quite marked effects are produced (Forster, 1885; Heffter, Cukiner, 1902; Rost, 1902, 1903, 1905; Wiley, 1904). The digestion becomes some-

meranged; the body weight lessens; the feces become more watery (but there is no diarrhea). The absorption of fat and of nitrogen is somewhat

The urine nitrogen is slightly decreased, whilst the phosphates rise

The quantity of urine is scarcely altered. If a slight albuminuria was

is increased (Wiley). Boric acid therefore seems to have a cumulative effect on digestion and absorption, metabolism, and the kidneys. The cumulative may be explained by the observation that the excretion of boric acid is slow, ing several days. (However, it begins within ten minutes, and reaches its maxi-

mum in the second hour.) On the average, 15 per cent. is retained, the other 85 per

in excretion mainly by the urine, to a slight extent by sweat and milk, and

lycally none by the feces (Wiley). The excretion is not hastened by diuretics.

in milk and eggs (Bertrand and Aguhon, 1922). The effects of such doses as are actually consumed would therefore not be very severe, even if the consumption of preserved food were continued for a long time.

ers, the results are somewhat deleterious, even in normal individuals; and they probably would be very undesirable in patients with digestive or renal disturbance.

boracitic dose, 1 to 3 Gm. per day, may produce the described effects more

and more severely. Headaches appear. With 5 Gm., the subject soon becomes

to do any work. Quantities above 5 Gm. per day may be condemned as disas-

sirable, even after any hesitation. (Some subjects hold the edema, report

siveness, ease of digestion, and the temperature, collapse. The

ay visible change; but their osmotic properties are altered, so that they become

ferred to isotonic salt solutions. This alteration is due to the presence of

acid within the cells, for lacking does not occur if the corpuscles are washed in hyper-

salt solutions (Kokskai, 1919).

PREPARATIONS.—BORATES

Sidum Boricum (Acid. Bor.), U.S.P., B.P.; Boric Acid (Boracic Acid), H3BO3—

inent colorless scales, or light very fine bulky powder, neutral to the touch;

of slightly saline taste. Slowly sol. in water (1:48); sol. in alc. (1:18); freely

dose, 0.5 Gm., 4 gr.; U.S.P.; 0.3 to 1 Gm., 5 to 15 gr., B.P.; as

antiseptic. Locally, in lotions, injections, gargles, etc., 2 to 4 per cent. (156

tempos per pint.) A saturated watery solution contains about 2 per cent.,

per ounce.
USES. — This is obtained by the action of iodin on alcohol, acetone, etc., in the presence of alkalis. It has been known since 1832 and was introduced as antiseptic about 1879. It acts probably by dissolving iodin; but this shows some peculiarities, due to the manner in which it is produced. Iodiform itself is practically insoluble and probably inactive. It is also quite stable outside of the body; but in contact with tissues or their extracts, and particularly with diseased tissues and with bacteria, it slowly evolves iodin (Altenburg, Schmidt, 1901). This occurs so slowly that the effects are mild, but quite sufficient to be marked antiseptic to bacteria, and stimulant to the cells. It also dries the wound secretions, and is mildly hemostatic and analgesic. Hamburger found that it stimulates phagocytosis. Its injection into dogs leads to persistent leucocytosis (W. Well, 1913).

These actions make it valuable in treating open wounds, since it promotes healing by stimulating granulation and lessening or preventing infection. It is the most widely used dusting powder; it is also injected into tubercular joints, usually as an emulsion with glycerin (iodoform 30, alcohol and glycerin each 45).

Iodiform has, however, a number of disadvantages: The most objectionable feature is the persistent odor, which can not be disguised by any perfume. Iodiform is also apt to develop iodism and irritant phenomena in susceptible individuals, producing particularly eczemas, even in minute amounts. It may also cause severe poisoning with narcotic symptoms, different from those of other iodides.

General Intoxication. — (P. Mulzer, 1905). This may occur when iodine is applied over a large area, or when it is injected. The symptoms consist in dizziness, lassitude and somnolence, hallucinations, diminished reflexes, light convulsions, and paralyses. The temperature falls. Death occurs through general paralysis of the central nervous system. Sodium bicarbonate is said to be antidotal. Chronic poisoning is also characterized by paralytic phenomena. The heart, liver and kidneys exhibit fatty changes. Iodiform dermatitis is sometimes seen. It resembles lye poisoning (Bryan, 1905). The idiosyncrasies are not analogous to anaphylaxis, for they can not be transferred positively (Stopeni, 1912). Fatal poisoning from intraperitoneal injection is reported by v. Bonsdorff, 1916.

Excretion. — Iodoform is not excreted as such, either by the kidneys or lungs. It appears in the urine as iodid and iodate, and as unknown organic compounds (Miglioli, 1903; Harnack and Grundler, 1883).
**IODOFORM**

623

**Iodoform Substitutes.**—The disagreeable qualities of iodoform justify the search for efficient substitutes. A number of odorless iodin derivatives were tried, especially *thymol iodide* (aristol), but their popularity was short-lived, since they do not seem to possess the peculiar activity of iodoform.

**PREPARATIONS—IODOFORM**

*Iodoformum* (Iodol.), U.S.P., B.P. (Triiodo-methane), 1/100—Contains 97 per cent. of iodin. Usually obtained by the action of iodin upon alcohol or acetone, in the presence of an alkali. Fine, lemon-yellow powder, or crystals; peculiar, very penetrating and persistent odor; unpalatable, slightly sweetish taste suggestive of iodin. Nearly insol. in water; sol. in alc. (1:50), in glyc. (1:500); or olive oil (1:50); freely sol. in eth. (1:2). Dose, 0.25 Gm. to 4 Gm. U.S.P.; 0.025 to 0.6 Gm., 1/2 to 3 gr. B.P.; in pills or capsules. Maximum dose, 0.75 Gm., 4 gr.

**Iodoform Substitutes**—U.S.P., B.P. 1/100, U.S.P., B.P.—10 per cent. in hard. Iodoform (and other loose iodin derivatives) are *incompatible with starch*. They are generally decomposed by heat, and can therefore not be sterilized in this manner. Since they become antiseptic when applied to wounds, sterilization is usually superfluous.

*B.I.P.* (Bismuth-iiodoform-petrolatum paste). This ointment has been used as a dressing for infected wounds. It is a mixture of one part of bismuth subnitrate and two parts of iodoform, with sufficient liquid petrolatum to make a paste (Morison, 1930). A similar mixture was used by Calandra, in 1908.

The Iodoform Substitutes are also injured by heat and light. They are all insol. in water and are used like iodoform.

*Thymol Iiodidum* (Thymol. Iod.). U.S.P. (Dithymol-diliodid; Aristol); (CaHs)-CH2-C6H6-0I—Contains at least 43 per cent. of iodin. Chocolate-colored powder with slight aromatic odor. Insol. in water or glyc.; slightly sol. in alc., readily in oils, eth., etc.

**GENERAL CONSIDERATION OF ANTISEPTICS**

**Toxicity and Resistance.**—The protoplasm of bacteria is fairly readily injured by many substances and by physical changes. The conditions under which it exists are, however, somewhat peculiar. By virtue of a highly impenetrable cell wall, and by the formation of very resistant spores, bacteria are able to survive conditions which would kill other cells. Under these adverse conditions the microorganisms are indeed unable to grow and multiply; but by passing into a dormant state, particularly by spore formation, they are able to preserve their vitality for a considerable time, and to recover their power of growth as soon as the conditions become more favorable. Substances which merely suspend the vitality of bacteria are called *antiseptics*; whilst those which kill them outright are *germicides*. A third class of disinfectants is formed by the *detergents*, which obscure or destroy the odorous bacterial products, but which have little action on the bacteria themselves.

**Factors Determining Usefulness.**—The nature of the antiseptic substance, or the strength in which it is used, are by no means the only factors determining its efficiency and usefulness. Among the other more important factors may be mentioned:

The nature, peculiarities and number of microorganisms; the time of exposure; the influence of organic matter; the penetration, toxic and corrosive actions of the agent; and in some cases, its cost.

Widely advertised antiseptics especially present a very striking disproportion between cost and efficiency.

**The Influence of Proteins and Other Organic Matter.**—Many substances which are strongly germicidal when acting on the bacteria alone are much weakened by entering into chemical reactions with the medium.

Thus, potassium permanganate is *destroyed* by all organic matter; mercuric chloride is *precipitated* by proteins; silver nitrate by chlorids, etc. These insoluble combinations are no longer germicidal. Further, they *hinder the penetration* of the antiseptic, a condition of considerable surgical importance. The antiseptics of the aromatic series are relatively little affected. From the standpoint of antiseptic efficiency and penetration, the phenols stand highest, experimentally (Kclty and Packer, 1913), for relative place of other antiseptics, the original paper must be consulted). However, even these are markedly impeded by serum, even when there is no precipitation (Bechhold and v. Bisch, 1900). Indeed, serum and body fluids in general interfere very much with the activity of all antiseptics (Verhoeff and Ellis, 1907); but the flavin dyes are said to be more effective in serum..
The Disinfecting Power of the Commonly Used Antiseptics.—On account of the different resisting power of different bacteria, and the ease with which the antiseptic action is modified by circumstances, the results of experiments directed to comparing the different so-called antiseptics can not be generalized. Tables of antiseptic values are therefore unsatisfactory. In a general way, it may be said that mercuric chloride and silver nitrate are the most powerful. Then come copper and zinc salts; then formaldehyde, chlorin, and hydrogen peroxide; then the cresols, then carbolic acid. Salicylic acid, boric acid, sulphurous acid, and the essential oils are antiseptics rather than germicides. Iodiform manifests its action only under special conditions. Ferrous sulphate is merely deodorant. Lepine, 1886, claims that mixtures of antiseptics are often more efficient than would be expected from their ingredients.

Specificity of Antiseptics.—Some antiseptics act fairly uniformly on all bacteria; others, especially the dyes, show a high degree of specificity (see, for instance, R. Taylor, 1907; P. A. Lewis, 1917).

The relative susceptibility of bacteria and cells has been investigated on tissue cultures by K. A. Lambert, 1916.

The Preservation of Food.—The liability of organic food-stuffs, especially meat and milk, to bacteriological decomposition, often renders their chemical preservation a matter of economic necessity. Asepsis, refrigeration, or sterilization by heat, are not always applicable. That the use of chemic preservatives is theoretically undesirable, or at least undesirable, on account of their possible deleterious action, is universally granted; in practice, however, this evil may be less than those resulting from the consumption of partly decomposed foods. The time-honored use of sugar or salt-cured, corned, and smoked meats of vinegar, spices, etc., is a sufficient proof of the comparative innocuousness of some of the preservative measures. More recently there have been introduced a number of preservatives which are more powerful, and which can not be detected by the taste. These offer a special interest, and they have accordingly given rise to much discussion. It is self-evident that markedly toxic and irritant substances, such as formaldehyde, should be entirely excluded. The principal difference of opinion is in regard to substances, such as benzoates, borates, sulphites, saccharin, etc., which do not produce marked effects in the quantities ordinarily used. Their opponents rest their objections mainly on their action on weak or diseased individuals, on infants, nephritics, and diabetics, the cumulative effects of their continued administration. There is, however, no evidence as to the degree of danger from their intermittent use, under the actual conditions. At all events, the consumer should be made aware of the addition of such preservatives and of any possible dangers.

Urinary Antiseptics.—The urine and the bladder may be disinfected to a considerable degree by drugs administered through the mouth. The efficiency of the urinary antiseptic is naturally limited by the brief contact. It is therefore not necessarily reflected in the phenol-coefficient (Himman, 1915). The antiseptics of the aromatic series are sufficiently concentrated, in the course of their excretion, to be effective, e.g., in gonorrhoea. Sodium salicylate or benzaote or salol are used for this purpose, as also cepsas, cubebas, sandal-wood, methylene blue, etc. Sarsal is especially useful against staphylococcus; but none of these antiseptics are very powerful (Himman, 1913). The most useful product, however, is hexamethylenamin, which yields formaldehyde. This is used in pyelitis, inflamed bladder, and for rendering the urine aseptic (as in typhoid fever). Increased acidity of the urine also destroys bacteria. Dilute mineral acids, or acid sodium phosphate, may be used (Jordan, 1911). Alkalinity interferes greatly with the activity of benzoates, salicylates and hexamethylenamin; not so much with benzoate or salol (Jordan, 1914).

Intestinal Antiseptics.—The disinfection of the alimentary canal would be useful in various dyspepsias, intestinal putrefaction, in typhoid fever, cholera, etc. Many experiments have been directed to this end. As a result, it may be concluded that complete asepsis is impossible in this situation.

This is easily comprehended if one stops to consider the large number of bacteria present, especially in the colon; the large mass of material in the intestine, tending to weaken the antiseptic and to prevent its access; the ready absorption and consequent danger of general poisoning; the sensitiveness of the intestinal canal to irritating agencies; the fact that ferment action is diminished by all antiseptics, etc.

When the antiseptics are used in such an amount as to injure the mucosa, they may even increase the number of bacteria. It was also argued, at one time, that antiseptics would be injurious by checking the saprophytic bacteria, which were supposed to be necessary for digestion. This theory has been disproved; nor do they appear to hinder the digestive ferments materially, although they tend in this direction (Heineberg and Bachmann, 1909).

Although a complete intestinal asepsis is an impossibility, a relative asepsis, a
SERUMS AND VACCINES

on of an abnormally increased bacterial action, is rather probable; it has not
ever been satisfactorily demonstrated (Harris, 1912). Bacteria in the lumen of the intestine would be much more readily acted upon if they had already obtained a nidus in the intestinal walls, and antiseptic treatment would be of greatest benefit against the unprotected bacteria. Antiseptics, at best, seem to be inferior to suitable modifications of diet and treatment of the intestines (Friedenwald and Leitz, 1909). For antiseptics, more speaking, the preference is given to those which are only sparingly soluble, so that they will not be absorbed before reaching the colon. The most useful intestinal antiseptics are naphthalin, naphthol, the cresols, and guaiacol, thymol, camphor, salol, and similar drugs, and these and others were made by Hirata, 1910.

SERUMS AND VACCINES

Toxic Serums.—These contain antitoxic substances, produced by the action of bacterial toxins into living animals, in practice usually by injection. Definite globulins of the serum of such immunised animals contain specific antibodies, which combine with the corresponding toxins armless compounds. The injection of these serums into patients confers a passive immunity to the disease, without other direct action. According to the time and place of injection, rapidity of absorption, accessibility of the toxins and bacteria, the effect may be curative or only prophylactic. The protection persists only for a few weeks, however, the antitoxin is destroyed or excreted. The serum proteins often constitute the slight irritative phenomena of "serum disease," and sometimes anaphylaxis.

Treatment with antitoxins is limited to a few diseases, especially diphteria exanthem. Most other bacteria, especially those with endocellular invasion, do not provoke the formation of soluble antibodies, at least in any amount to be effective.

Vaccines.—These provoke the formation of specific antibodies by injection itself, by inducing a mild or modified harmless attack of the disease. They therefore confer active immunity, which is much more than the passive. Their field of use is wider than that of the toxic serums, since probably all bacteria and their products can act as antigens. The bacterial vaccines are usually suspensions, extracts or cultures of the specific bacteria. Those prepared from organisms obtained from the patient himself (autogenous) are usually more effective than "stock" vaccines. As vaccines do not contain bacteria, they do not produce "serum disease," but their toxins usually do not induce local reactions. Their value is most striking with diphtheria; in this way they may be effective even after exposure, before the disease has developed. They may also be curative, especially in stationary localized infections.

Cholera Vaccines.—The cholera vaccines are largely based on the production of antitoxins, but partly also by stimulation of the leukocytes and other activities in the body (Kjeldsen, 1916). Increase of protease and lipase may be important factors (Jolting). These mechanisms are involved especially in the activity of the specific factors such as the injection of non-specific bacteria and toxins, protein, or products, kaolin, etc.

Virus Vaccines.—The virus vaccines contain specific antigens are generally less powerful than the ordinary bacterial vaccines, but their action is somewhat more difficult than that of the ordinary bacterial vaccines; but
as they are absorbed more slowly, they produce less local and systemic reaction. They are also more stable (Whitmore et al., 1918).

Limitations of the Text.—The theories of the nature and formation of toxins and antibodies are usually assigned to bacteriology and pathology, and need not be considered here; nor will it be profitable to discuss the numerous agents whose value is not yet established. Those which are more or less promising are described in N.N.R.

Non-specific Protein Injections.—The injection of various proteins, and particularly of proteoses or bacterial vaccines, produces acute febrile reactions. These often result in an acute crisis of any existing infection. They have been used in rheumatic conditions, but are not without danger (see Typhoid Vaccine).

It is not known how the "reaction" is beneficial. A possible and at least partial explanation of the effects of non-specific proteins and bacterial injections is the observation of Hektoen, that they increase the production of antibodies against other antigens that may be present.

Other effects have been described under "Pyelone." Clinical Results.—These are often good, but sometimes fail. Severe reactions are quite common. They include cardiac dilation, sometimes fatal; hemorrhages from nose and intestines; etc. (Irons, 1917; Cecili, 1917).

DIPHTHERIA ANTITOXIN

This was discovered by Behring in 1890, and applied therapeutically to man by Roux in 1891. The results are strikingly successful. It arrests the local process and the systemic symptoms, and reduces the mortality of the disease to about one-fourth. It should be administered in adequate doses, as early as possible; for the mortality increases from 4 or 5 per cent. if it is given on the first day, to over 20 per cent. if delayed beyond four days (Park, 1906).

Production.—The antitoxin is produced by injecting healthy horses hypodermically, at four-day intervals with diphtheria toxin, i.e., with filtered sterile broth cultures, beginning with very small doses, which are increased at varying intervals, according to the amount of reaction. This treatment is continued for from four to six months, until a high antitoxic power has been reached (as determined on small samples of blood withdrawn from time to time). The horse is then bled from the external jugular vein, with strict asepsis. This can be easily done without anesthesia. Seven to 10 liters are collected in sterile bottles. When the serum or plasma has separated, it is filtered through Berkefeld filters, and some antisepptic (phenol or cresol), is added. The antitoxic strength is determined, and the appropriate doses are marketed in aseptic glass syringes, to obviate contamination during administration. Weaker serums may be reduced in bulk by partial evaporation in a vacuo.

Standardization.—The strength of the antitoxic sera has to be determined by testing its protective power on guinea pigs. The original immunity unit was ten times that quantity of antitoxin which would completely protect a 250-gram guinea pig against ten times the fatal dose of toxin; in other words, each immunity unit neutralized a hundred fatal doses of toxin.

It was found, however, that a given serum seemed to have a different antitoxic value when tested with different samples of toxin. This was explained by Ehrlich by the assumption that the filtered broth culture contains several constituents capable of neutralizing antitoxin; and that only one of these is toxic. The proportion of toxic to non-toxic neutralizing elements varied in the several cultures, so that the neutralizing and toxic qualities would not go parallel. To obviate this uncertainty a standard serum was prepared from a certain standard toxin. This standard antitoxin is issued by the U. S. Public Health Service to manufacturers, and is in turn used for determining the "test dose" of the toxin to be employed in the actual standardization. This is the largest quantity of toxin which can be completely neutralized by the unit of standard antitoxin, so that a 250-gram guinea pig will survive for four days. This toxin is then used in standardizing the serum to be tested; the smallest quantity of serum which neutralizes a test dose of the toxin contains one unit of antitoxin. This new unit, which is now employed universally, is approximately equivalent to the old unit, but is more uniform.
SERUMS AND VACCINES

"Purified Antitoxin."—If the proteins of antitoxic serum are separated by fractional precipitation with salts, the antitoxin is found practically completely in the pseudoglobulin portion (Gibson and Collins, 1907; Banzhaf and Gibson, 1907). The non-antitoxic proteins may thus be largely eliminated. These "refined" serums permit reducing the bulk of the injection and are said to lessen the liability to rashes but not to naphylactic shock (Park, 1913).

The Gibson process of purification consists in precipitating all the globulins by an equal volume of saturated ammonium sulphate solution (other sulphates may be used); the precipitate is then treated with saturated solution of sodium chloride, which dissolves the pseudoglobulin. This is again precipitated by acetic acid, and this precipitate is dialysed to reduce the salt to 0.8 per cent. The pseudoglobulin fraction of normal serum is about 40 per cent. of the total proteins; in immunized serum it is about 75 per cent.; so that this process eliminates only about one-fifth of the total proteins. The proportion can be raised by heating the serum for several hours at 57°C, before proceeding to Gibson's process (Banzhaf, 1911). This Banzhaf process eliminates about 50 per cent. of the proteins, without material loss of antitoxin (Park, 1912).

All attempts to separate the antitoxin from the globulin have been unsuccessful (Crawford, 1918); perhaps the globulin is itself the antitoxic constituent.

Deterioration.—The antitoxic power of serum, plain or purified, diminishes gradually, the loss averaging between 10 and 30 per cent. per year. I kept on ice, the yearly loss is only about 0.6 per cent. (Anderson, 1909). I aged serums are used, allowance must be made for the deterioration; otherwise their use is quite safe. Dried serum does not deteriorate, but is inconvenient to dissolve.

Clinical Efficiency.—The antitoxin is not directly bactericidal; but by nactivating the toxin, it arrests promptly both the systemic and local phenomena of the disease, the more strikingly and promptly the earlier it is used. The exudation ceases to spread and clears more rapidly; rarely extends to the larynx; the swelling of the cervical glands subsides; the fever falls promptly, and the general condition improves quickly. The occurrence of paralysis is not affected.

The very much superior results of early administration make it incumbent to employ the antitoxin just as soon as a well-founded suspicion of diphtheria exists; i.e., without waiting for a positive diagnosis. The possible dangers of the treatment are so slight as to be negligible in view of its great benefits. It is even advisable to employ immunizing doses in case of exposure, before the disease develops.

Failure to Prevent Paralysis.—H. Meyer, 1905, attributes this to the absorption of the toxin through the nerve sheaths, where it would be protected against the antitoxin.

Circulatory Collapse.—This is prevented if the antitoxin is administered before the food pressure has started to fall; after this, antitoxin is useless (H. Meyer, 1909), the toxin being presumably fixed in the cells.

Administration.—All immunizing sera are practically inactive when taken by the alimentary canal (McClintock and King, 1909, p. 294). They are therefore injected into the loose subcutaneous tissue of the abdomen, neck or flank. The skin and needle should be cleansed with alcohol. The injection is made slowly. Intravenous injection has been advised in urgent cases. It does not seem to be dangerous if proper precautions are observed (Levin, 1909; Park, 1912).

Absorption.—This is quite slow, the maximum concentration of antitoxin in the blood being reached only after a day with intramuscular, and in three days with ipodermic injection (Levin, Park). The distribution has been studied by Hektoen and Arison, 1920.
The concentration of antibodies generally, both in active and passive immunity, decreases in the order of serum (highest), thoracic lymph, neck lymph, pericardial fluid, aqueous humor, cerebro-spinal fluid (least). This indicates that they pass from the blood into the lymph (Becht and Luckhardt, 1916).

**Dosage.**—This varies with the stage and severity of the disease; the age of the patient need not be considered. The **immunizing dose** is from 500 to 1,500 units. The **curative dose** is usually 5,000 units in mild cases; 10,000 in severe, and 20,000 in malignant cases. Larger doses do so further good (Park, 1914). Half the initial dose may be repeated two or three times at intervals of about twelve hours, according to the progress of the disease; but it is better to make the initial dose sufficiently large, since experiments have shown that this insures a higher concentration in the less sensitive (Park, 1913).

**Side Actions and Accidents.**—In perhaps a third of the cases, the administration of serum is followed by the insignificant phenomena of "serum disease." Very rarely severe or fatal collapse, presumably analogous to anaphylaxis, occurs within fifteen minutes. The two phenomena are quite distinct, but both are due to the serum proteins and not specifically to the antitoxin. They are produced by all serums. The serious cases are so exceptional that they should not restrict the use of antitoxins; but they should enjoin caution in sensitive patients.

**Serum Disease.**—After an incubation of eight to twelve days, or a somewhat shorter time if the injections are repeated (Goodall, 1911) a rash develops on the skin, with swelling of lymph glands, a slight fever, and sometimes (3 or 4 per cent. of all injections) pain in the joints. The rash varies but is commonly urticarial or erythematous. It is sometimes preceded by prodromal sensitiveness and slight redness of the skin at the site of injection.

There are also indications of transient renal impairment (especially retention of water and chlorid; Rackemann et al, 1916).

The coagulation time of the blood is markedly slowed during serum disease (H. F. Shattuck, 1917).

The phenomena of serum sickness are less common with purified antitoxins; with serums of other animals they are more severe than with horse serum.

Statistics of serum sickness are presented by Sturtevant, 1916. Netter, 1906, claimed that the rashes are less frequent if calcium chlorid is administered: 1 Gm. daily by mouth, on the day of injection and on the two following days.

**Relation of Serum Disease to Antibodies.**—In man, anaphylactic antibodies are not present during the early period of serum sickness, but they reach their maximum toward the close. This indicates that the antibodies are concerned in the recovery rather than in the causation of serum disease (Longcope and Rackemann, 1916).

**Anaphylactic Phenomena.**—These occur, but very rarely, in patients disposed to asthma and hay fever, or those having idiosyncrasies against horses; they generally have a status lymphaticus. Serious symptoms occur in something like 1:10,000, death in 1:100,000 injections (Park, 1913). The effects set in very suddenly with swelling of the respiratory mucosa, intense dyspnea, failure of respiration, collapse, and asphyxial death within ten or twenty minutes. These phenomena resemble very closely those seen in experimental anaphylaxis, but they occur generally with the first injection of serum. The most promising treatment of such cases is atropin and ephedrin, to paralyze the bronchial muscles. If there is cause for apprehension before giving the serum, the susceptibility of the patient may be tested by injecting a small dose (0.5 c.c.) of
Atropin may also be sed as prophylactic.

Very slow Intravenous injection of diluted serum might perhaps avoid the occurrence of acute anaphylactic shock. Sensitized animals, at least, tolerate more than the dietary fatal dose of the antigen when it is injected in that manner. (J. H. Lewis, 1920).

Active Immunization.—R. Behring, 1913, attempted this with overneutralized mixture of diphtheria toxin and an excess of antitoxin (Hormann, 1913), with or without cell walls from killed diphtheria bacilli. Park, et al., 1914 and 1915, have check results with the Schick test. Natural immunity is greatly increased by the treatment, but this would be superfluous. In susceptible individuals, the immunity is induced very slowly; but little has developed in four to six weeks, but it continues to increase for a year or longer. The method is therefore of little value for immediate immunization, but promising for permanent protection.

PREPARATIONS—ANTIDIPHTHERIA SERUM

*Serum Antidiphthericium (Ser. Antidiph.), U.S.P. (Diphtheria Antitoxin).—The rum of horses properly immunized against diphtheria toxin. It must be kept in sealed glass containers in a dark place at a temperature between 4.5° and 15°C. A yellowish transparent or slightly turbid liquid, of at most slight odor. A tube of antitoxin once opened should not be used again. The serum must be prepared in establishments licensed and supervised by the U.S. Public Health Service; it must come from healthy animals; it must be sterile, free from toxin and bacterial products, and must contain more than 0.5 per cent. of phenol or 0.4 per cent. of cresol; the total solids must not exceed 20 per cent.; and the potency must be at least 150 units per cubic centimeter. The standard of strength, expressed in units of antitoxic power, shall be rat established by the United States Public Health Service. Antidiphtheric Serum gradually loses in potency. The label must state the date beyond which the contents in not be expected to yield its specific results. Average dose, Curative 10,000 units; protective, 5,000 units, U.S.P.

*Serum Antidiphthericium Purificatum (Ser. Antidiph. Purif.), U.S.P.; (Antidiphtheric Globulins; Refined and concentrated Diphtheria Antitoxin).—A solution in 8 per cent. NaCl solution of antitoxic globulins, prepared by Gibson’s method, and complying with the regulations for the plain serum.

Ser. Antidiph. Std., U.S.P.; Dried Antidiphtheric Serum.—Obtained by evaporation either of the preceding at a low temperature. It must be readily soluble in 5 parts water.

ANTIPOLIOMYELITIS HORSE SERUM

Results have been fairly promising, but not decisive (Neustaedter and Benza, 97). Human serum from recovered poliomyelitis cases is being tried. Its value is not established; but if given early, it appears to diminish the subsequent paralysis (Draper, 99).

TETANUS ANTITOXIN

This is prepared in the same manner as Diphtheria Antitoxin, except that tetanus toxin is used for the immunization. It has a high protective value if used early; and it would be desirable to administer it in every suspicious case, but without neglecting thorough disinfection. Its curative value, after the symptoms have set in, is doubtful and at best limited. It does not affect the toxin which is fixed in the nerve cells, and could only reach that which is still free or being formed. The latter can generally be prevented more effectively by surgical procedures.

Immunizing Dose.—This consists of four hypodermic injections, each of 500 U. S. units, given a week apart (McCoy, 1917). The wound may also be dressed with dry serum but this has not found much favor (ibid.). The protection lasts two or three weeks.

Curative Dosage.—In view of the slow absorption, and the importance of gaining time, hypodermic administration alone is insufficient. Large
doses must be introduced by several channels. Park, 1910, 1912 and 1914, advocates the subdural injection of 3,000 to 5,000 units, followed by 10,000 to 15,000 units intravenously; the spinal injection is repeated in twenty-four hours, and a hypodermic injection of 10,000 units is given three days later (Park and Nicoll, 1914; Nicoll, 1915). Dreyfus, 1914, urges daily injections, combining vein, lumbar, endoneural and local.

Intraneural Injection was advised by Meyer and Ransom, 1903, since they found that the toxin travels largely by nerve sheaths. It has not maintained itself in practice, but is again advocated by v. Behring, 1914.

Subdural Injection, according to Park and Nicoll, is more effective than intravenous, and vastly better than hypodermic. The antitoxin disappears in twenty-four hours, so that the administration must be daily if this channel is used alone (Dreyfus).

Official Unit (U.S.P.H.S.).—This is ten times the least quantity of serum necessary to save the life of a 350-Gm. guinea pig for ninety-six hours against the official test dose of standard toxin furnished by the U.S.P.H.S. (Rosenau and Anderson).

PREPARATIONS—ANTITETANIC SERUM

*Serum Antiteticum (Ser. Antitetan.,) U.S.P. (Tetanus Antitoxin).—The serum of horses highly actively immunized against tetanus toxin. It resembles Diphtheria Antitoxin and must meet analogous requirements. Average dose, Curative, 10,000 units; Protective, 1,500 units, U.S.P.

ANTIMENINGOCCUS SERUM

This is markedly successful against epidemic cerebro-spinal meningitis due to Diplococcus intracellularis, especially if used early. It reduces all the symptoms, clears the cerebro-spinal fluid, lessens the duration and sequels, and diminishes the mortality (Dunn, 1908; Ladd, 1909; Flemer, 1913). The mechanism of its action has not been decided.

Preparation.—The serum is obtained by the method of Flemer and Jobling 1913 from horses actively immunized by injections of killed meningooccus, autolyzed cultures, and finally living bacteria, successively and in alternation, the treatment being continued for months until the desired efficiency is obtained.

Action.—The serum does not kill the bacteria directly, but causes their disappearance, perhaps by stimulating phagocytosis and intracellular digestion.

Administration.—The action being mainly local, the serum must be injected into the subdural canal, early, and in efficient dosage. As it is absorbed, several injections are generally needed. The usual dose is 15 to 30 c.c; for young infants 10 c.c. Cerebrospinal fluid is first withdrawn, if possible the same bulk as the serum to be injected. The blood pressure should be watched during injection to guard against excessive pressure. A drop in pressure of more than 10 mm. should cause withdrawal of the needle. The administration should be repeated every twelve to twenty-four hours, for at least four injections; and longer if the fluid and symptoms have not cleared. The occurrence of accidents is discussed by Flemer, 1913. They consist in sudden collapse with stoppage of respiration and fall of blood pressure. The effects have been attributed to the preservative (Voegtlin, 1914); but this is probably not the usual cause (Auer, 1914).

ANTIPNEUMOCOCCIC SERUM

This has been developed against strain I of pneumococci (Cole, 1917). Bull. 1915, refers its action to agglutination.

HAY FEVER PREPARATIONS

Pollen Extracts (N.N.R.).—These are used for the diagnosis, prophylaxis and treatment of "hay-fever." The most important pollens are those of grasses for the spring; and ragweed for fall (Scheppgrell, 1917). The susceptibility of the patient can be ascertained by the reaction of the conjunctiva or scarified skin to the pollen extracts (cf. Longcope, 1916).
SERUMS AND VACCINES

Graduated injections of the specific extracts appear sometimes to confer a limited cure of hay fever. Hay fever vaccines are also being tried. Oppenheimer and Gottlieb, 1915, warn against their use.

Serum. This is obtained from horses injected with the pollen-toxin of various plants which are supposed to cause hay fever (Blackley, 1873; Dunbar, 1911). It is said locally in the eyes and nose. Its value is limited; it is not curative, but may give temporary relief. "Fall Pollinaxin" or "Dunbar's Serum" is prepared from ragweed pollen, marketed as serum and dried. Other serums are obtained from goldenrod, etc.

VACCINE VIRUS

This consists of the scrapings from the pustules or vesicles of vaccinia cowpox, of vaccinated, but otherwise healthy calves. It must be moved aseptically, is further sterilized by standing with glycerin, tested for the absence of bacteria, and marketed in tubes or "points." It is ed by inoculation (vaccination) to produce active immunity against smallpox, the protection lasting four to ten years.

Preparation. The "pulp" is cut from the typical vaccinia vesicles. The pulp which flows afterward was formerly used for making "dry points," but as is less potent and generally septic, it should not be used. The pulp is ground with to 50 per cent. of glycerol, and allowed to "ripen." This preserves the virus, but kills some of the bacteria. The establishments must be conducted under federal supervision and license.

PREPARATIONS—VACCINE VIRUS

*Virus Vaccinii (Virus Vaccini.,) U.S.P.; Vaccine Virus (Glycerinated Vaccine rum; Jennerian Vaccine).—The pustules of vaccinia or cowpox removed, under aseptic conditions, from vaccinated animals of the bovine species. Preserved at a temperature between 4.5° and 15° C., protected from light. The vaccine pulp is thoroughly rubbed in a mortar or passed through a special grinder, strained to remove coarse particles, and made into a smooth emulsion with a glycerol solution. Vaccine Virus gradually loses in potency, the loss being more rapid at high temperatures than at low temperatures.

ANTIRABIC VACCINE

This consists of emulsions of the spinal cords of rabbits, which have died as the result of subdural injection of "fixed" rabies virus. If the disease is not too far advanced, so that at least fifteen days of treatment are possible, the mortality is less than 1 per cent., against 15 or 20 per cent. in untreated cases (Stimson, 1910).

Preparation.—Fixed virus is obtained by the passage of rabies virus through a long series of rabbits, till it acquires a fixed incubation period. This fixed virus is less capable of producing rabbits on subcutaneous injection. The spinal cords of the infected rabbits are further attenuated by graduated drying. In the treatment, emulsions of "sense virulence" are daily injected hypodermically, the scheme of dosage varying according to circumstances; but generally beginning with cord dried for eight to twelve days and gradually increasing till "two-day" cord is used.

TUBERCULIN PREPARATIONS

These represent the toxic products of the tubercle bacilli; consisting of emulsions, i.e., filtered germ-free cultures (e.g., old tuberculin); of suspensions of killed and ground tubercle bacilli (tubercle vaccine, tuberculin, emulsion). They are used for the diagnosis and treatment of tuberculosis. The two classes of preparations are practically identical in action, differing only quantitatively and in absorbability. The filtered cultures are more evenly absorbed and therefore permit a better control of dosage, and are thus safer for diagnostic tests and early treatment.
Diagnostic Use.—Relatively large doses of tuberculin have no effect on normal individuals; but in tuberculous patients, there is a definite inflammatory reaction about each localized tuberculous lesion, with slight febrile symptoms. The test is applied in various ways. It requires special knowledge and experience for its proper performance and interpretation; otherwise it may do much harm (Baldwin, 1910).

Therapeutic Use.—It is questionable whether tuberculin ever produces actual immunization, but a course of carefully graduated doses diminishes the sensitiveness to the toxins, and therefore the constitutional phenomena of the disease. The local reaction about the tuberculous foci also tends to their cicatrization and absorption (Trudeau, 1907, Baldwin, 1913). The artificial resistance is gradually lost after the treatment is discontinued.

For therapeutic purposes, the tuberculin must be administered hypodermically. The proper dosage requires experience and judgment. Ready-made "serul dilutions" deteriorate rapidly and are not recommended. Various preparations of tuberculin are listed in N.R.K.; the following are important:

"Old Tuberculin, "O.T.K., Koch's Tuberculin (N.R.K.).—Prepared by concentrating a six to eight weeks' gumcerin-bouillon culture of tubercle bacilli by evaporating to one-tenth its volume, and filtering; contains 20 per cent. of gumcerin.

Tuberculin "Denys", "B.F., Bouillon Filtrate.—A simply filtered culture, not boiled.

New Tuberculin, "T.R.K., Tuberculin Residue, Koch.—This represents a complex extract of virulent human tubercle bacilli; the dried bacteria are subjected to prolonged grinding and thereby killed. They are then suspended in normal saline, centrifuged, and the first supernatant fluid is rejected. The sediment is again ground with saline and centrifuged. This fluid is saved. The process is repeated until almost no sediment remains. The supernatant fluids are mixed, with 20 per cent. of gumcerin and a little formaldehyde and adjusted so that each cubic centimeter represents 10 mg. of dry bacilli.

Bacilli Emulsion, "B.E.", Koch.—A suspension of ground bacteria in 50 per cent. gumcerin, 5 mg. in 1 cc. Any surviving bacteria are killed by heating for an hour at 60° C.

**TYPHOID VACCINE**

This has given completely successful results for immunization (Russell, 1913 and 1914), lasting at least two years (Harris and Ogan, 1914). The injections are now repeated annually (McCoy).

Typhoid vaccine consists of a suspension of avirulent typhoid bacillus, killed by heating for an hour at 55° C., and preserved by 0.25 per cent. cresol. It should be injected subcutaneously (not intramuscularly) in the arm, giving 500 million bacteria at the first injection; and two further injections, each of one billion bacteria, at ten-day intervals. It generally causes some local reaction, and sometimes more or less severe but harmless febrile symptoms (Russell, 1912). It is safer to avoid its administration to any but healthy individuals; not to inject it into a vein or intramuscularly; to avoid exposure of the patients to sun, alcohol or exercise; and not to give it during menstruation or pregnancy (Harris and Ogan, 1914).

The intravenous injection of typhoid vaccines is being used in the developed typhoid fever (E. Fraenkel, 1876; Gay and Chickering, 1910; Hektoen, 1916) and especially against rheumatic fever. It often induces a crisis and prompt recovery. The action is probably not due to specific antibodies, for similar effects are produced by other vaccines, albuminoses, etc. (J. L. Miller and Lusk, 1916; Jobling, 1917). It is apparently a result of the fever.

**Use in Rheumatic Fever.**—The intravenous injection of the typhoid vaccine is followed, after one-half to one hour, by a chill, lasting 15 to 30 minutes, with headache and nausea, fast pulse, cyanosis. This is followed by sweating and relief of the joint pains. The temperature reaches its maximum in 3 to 4 hours, and returns to normal within 48 hours after
injection. The leucocytes show a transient fall, then a marked rise, with its maximum 6 hours after injection. The blood pressure rises during the chill, then falls for 3 or 4 hours. The urine shows no special changes. In unfavorable cases the chill lasts several hours, and is accompanied by marked collapse (Scully, 1917).

Irons, 1917, warns against the promiscuous use of the method, as tending to careless diagnosis; but especially because of the frequent excessive severity of the reactions. Their use is only justified on the basis of special experience.

R. G. Snyder, 1918, considers the foreign protein treatment more effective than other therapy against acute, subacute and chronic arthritis; and believes that it is harmless when used with proper precautions.

GONOCOCUS VACCINE

This is being used with fair results in subacute and chronic gonococcus infections involving the joints. It is less useful in other situations. It is also marketed as "Neisser Bacterin."

THEORIES OF NARCOSIS

General Statement.—The aliphatic compounds or hydrocarbons, like the benzol compounds, resemble each other closely in their main actions. Their most conspicuous effect on the higher animals consists in stupor, passing with larger doses into insensibility and motor paralysis; i.e., into profound narcosis or anesthesia of central origin. Analogous narcotic effects are produced on all forms of protoplasm. Hemolysis is also a conspicuous effect.

Narcosis is one of the most common and striking pharmacologic phenomena. Many attempts have been made to gain a clearer conception of its intimate nature, especially through the study of the aliphatic narcotics. The relations between the chemic structure and the pharmacologic efficiency were extensively investigated. More recently, a deeper insight has been gained by the discovery that the narcotic and hemolytic effects of this series are intimately related to the solvent action on lipoids, or rather, to their "partition coefficient," i.e., their solubility in oils, divided by their solubility in water. The discovery of this law by Meyer and Overton was an important step in the solution of the problem, and opened the way for the intelligent investigation of further theories. Several of these are in the field at present, as will be explained later.

Definition of Narcosis.—This is defined by R. S. Lillie, 1916, as synonymous with anesthesia: "A physiological condition in which the normal responsiveness or automatic activity of the living system—organism, tissue or cell—is temporarily decreased or abolished. The definition is perhaps too comprehensive, but it emphasizes the two essential features, the depression and the reversibility or possibility of recovery. This may be lost if the action is made too energetic.

The definition also brings out the essential similarity of sleep, fatigue, cold, electric inhibition (anesthetosus), and of certain ions to the narcotic effects of the aliphatic series.

Influence of Chemic Structure.—An historical review of the older theories of narcosis is given in Overton's book. The earlier studies indicated that the actions of this series appear to be influenced quantitatively by the chemic structure; and much labor has been expended on determining the share of various side-chains (Blina, 1881; Baumann and Kast, 1890). The results (summarized in Schmiedeberg, Grundries d. Pharmaco-logic, 1909, p. 29) seemed to show certain relations, but the generalizations have not
stood the test of wider experience (Diehl, 1844; Meyer, 1899; Klonka, 1900). In fact, it has been pretty definitely shown that the chemical structure affects the narcotic action only indirectly, namely by modifying the partition coefficient, which varies in a definite manner with changes in composition. However, special side-chains may be responsible for side actions. Thus, chlorin compounds are peculiarly toxic to the heart.

Empiric Relations.—These are practically interesting and important, although they have lost theoretical significance. The following conclusions appear justified: Other things being equal, the strength of action increases with the length of the chain. A limit is soon reached, however, for the drugs become less volatile, less soluble and less absorbable the higher they stand in the series, so that the higher paraffins are entirely insoluble and inactive. The ethyl radical, C₂H₅, seems to be best adapted to therapeutic purposes. The action may be modified by replacing the H of the group by other elements or groups. The compounds so formed all possess the typical action of the hydrocarbon group, but this may be so overshadowed by other actions as to be scarcely appreciable. A good example of this is the introduction of the group NO₂. This acts very much more strongly than the hydrocarbon part of the molecule, and consequently the nitrite action is obtained long before there can be any hydrocarbon action. The same is true if we substitute an aromatic radical. The introduction of certain other radicals weakens the hydrocarbon action to a very great extent. We may mention especially the acid-forming radical CO₂H. The introduction of hydrocarbon radicals into an amin molecule destroys their action entirely. The introduction of more than one OH group also weakens or destroys the action. Aldehyds and ketones are more active than the corresponding alcohols. The introduction of the halogens, and especially of Cl, often enhances the action, but this is not proportional to the number Cl molecules introduced. The introduction of O (others) also increases the action. The introduction of acids (esters) weakens it.

Narcosis and Sleep.—The analogies of narcosis in the higher animals, with the phenomena of natural sleep suggested a common origin to the earlier investigators. Since sleep was then explained by cerebral anemia (Durham, 1856) the same explanation was adopted for narcosis (Bedford-Brown, 1866). However, it was subsequently found that changes in the cerebral circulation are small and variable (Cl. Bernad, 1873).

All the theories of deficient nutrition of the brain—whether through anemia or otherwise—are definitely disproved by the fact that narcosis can be induced in frogs in which all the blood has been displaced by saline solution, or in which the cerebral circulation has been arrested; in excised nerve-muscle preparations; in animals which do not possess blood; in plants; and even in unicellular organisms.

Coagulation Theories.—The aliphatic narcotics coagulate proteins, and this suggested to Cl. Bernad, 1853 and 1875, that narcosis might be due to a semicoagulation of the protoplasm, analogous to the muscle-turgor produced by chloroform. This theory had no direct experimental foundation; but it was elaborated by Bins (Lectures, 1841), who showed histologically that the cells of fresh brain sections are coagulated by solutions of chloroform or morphia; but he had to employ relatively enormous concentrations, nor could it be supposed that the coagulated cells could ever resume their activity. The theory was therefore untenable, at least in this form.

Removal of Lipoids.—Allen and Harless, 1847, immediately after the discovery of the anesthesics, drew attention to the fact that practically all fat-solvents are narcotics, and suggested that they dissolve the fats out of the nerve cells. The difficulty of explaining the rapid recovery proves that this theory cannot be correct. It was accordingly abandoned; but later workers continued to point out more or less qualitative relations. Hermann, 1866, f.i., showed that all the aliphatic narcotics dissolve red blood corpuscles, connected this with their lipid solubility, and first suggested the modern theory. Conversely, Richet, 1895, argued that the narcotic efficiency is inversely proportional to the solubility in water.

Meyer-Overton Law.—The relations observed by Hermann and by Richet were striking but not conclusive. It was only by their combination that an exact quantitative relation could be demonstrated. This was done, independently and practically simultaneously by H. Meyer and by
THEORIES OF NARCOSIS

Overton, 1899 and 1901. They showed a very close parallelism between narcotic efficiency and the "partition coefficient":

Solubility in fat (kω)
The higher this coefficient, the more powerful
Solubility in water (kφ)
be narcotic action. The quantitative relation is so constant and the facts in its support so numerous, that it can scarcely be doubted that the narcotic effects of the aliphatic series depend in some way on their lipid-solvent action, as expressed by this coefficient.

Partition Coefficient.—The experimental determination of this factor is described in Hoebber (p. 106). Berthelot and Jungfleisch, 1877, showed that it is constant, independent of the absolute quantity, provided there is no dissociation. For convenience, it has so far been determined mainly with olive oil. Objection has been made to this (Moore and Roaf, 1900), since this oil differs from the cell-lipoids. The fact that the law holds also for hemolysis, practically disposes of this objection.

Lipoids.—This term is applied to a chemically heterogeneous group of substances, including phosphatids (W. Koch, 1911); especially lecithin and kephalin, cerebrin, cerebrosides, cholesterol, and others. They are waxy substances, which dissolve readily in lipolytic solvents, and take up more water slowly, but not solutions of sugars or salts. They occur in all cells, particularly in the plasma membrane, probably in an emulsified condition. Nervous tissue is rich in these lipoids (Steward's Physiology). The functions of the individual lipoids have certain features in common, but in some respects they behave very differently; i.e., cholesterol and lecithin have opposite effects on hemolysis and phagocytosis (Stuber, 1913).

The term lipins has been introduced to cover all substances that dissolve in fat-solvents; i.e., it covers fats and fatty acids as well as the lipoids.

Evidence for the Meyer-Overton Law.—The narcotic concentrations have been determined mainly on tadpoles; but the law has also been demonstrated on other animals, plants and tissues. According to the theory every absorbable substance which is a fat-solvent should have an anesthetic action; this should be seen in all cells (since every cell contains lipoids); it should occur in the same concentration of solution; the anesthetic action of a mixture should equal the simple sum of the actions of its constituents; the effect should be proportional to the concentration, and not to the absolute dose, etc. These postulates agree very well with the actual facts. The relation of concentration to action is especially interesting. Precisely the same concentration of chloroform or ether produces the same degree of anesthesia in all cells (excepting plants and a few invertebrates). For instance, ordinary anesthesia requires in all animals a concentration of anesthetic to serum, of ether, 1 : 440; of chloroform, 1 : 4,400 to 6,000; but cold-blooded animals reach the same concentration in the blood with a lesser concentration in the air; on account of their lower temperature. Again, in those cases in which the coefficient changes with temperature, etc., the narcotic power changes in the required direction: Meyer, 1901, showed that rise of temperature increases the coefficient and the narcotic action for hydrated chlorn; and depresses both for salicylamid. Fuehner, 1909, investigated the influence of mixed narcotics, and found that the coefficient and narcosis were always modified in the same direction.

It must not be expected, however, that the agreement will hold for every case, for other complicating factors may enter. For instance, the influence of temperature on narcotic efficiency is not always parallel to the partition coefficient nor to the surface tension.

The Meyer-Overton Law Applies Only to the Aliphatic Narcotics.—Casnay has pointed out that many benzol derivatives which are not narcotic have a high partition coefficient. In this case, however, the coefficient modifies the antiseptic action. The peripheral nervous system, although rich in lipoids, is not easily attacked by the aliphatic narcotics. Morphin and other basic and saline narcotics do not obey the law, and must act by entirely different mechanisms. This does not of course impair the validity of the law as applied to the aliphatic narcotics.

Influence of Extraneous Fats on Narcosis.—It might be expected that narcosis would be affected by fatty tissue, deflected a certain amount of the anesthetic; but this does not seem to be the case to a notable degree.

Mansfield, 1905, suggested the low resistance of starved animals to be due to this. The fact is not convincing, for in starvation the resistance is lowered in many other
directions. Indeed, Mansfeld's experiments contradict his explanation; for starvation did not increase the susceptibility to the typical lipolytic narcotics, alcohol and urethane; whilst the susceptibility was increased for morphin, which probably does not act as a lipid solvent. Cotta, 1907, tried the converse experiment, the influence of increasing the fatty tissue; but his results scarcely justified general conclusions.

Nerkin, 1908, claimed that anesthesia can be cut short by intravenous injection of lecithin. This statement has been contradicted by Kramer, 1913, who took the necessary precaution to keep the concentration of the anesthetic constant by intravenous injection. Laties, 1917, stated that fatty food, or the injection of fat-emulsions into the circulation, increases the narcotic action of chloroform, perhaps by lessening the pulmonary excretion. Hanschmidt, 1915, supports Nerkin, and affirms that lecithin has a protective action against narcotics, but also against a number of alkaloids (curare, strychnin, morphin). The results have therefore been contradictory and have little bearing on the lipolytic theory. Salzmann, 1917, reports that cream and other fats delay slightly the absorption and therefore the action of alcohol and other lipolytic narcotics. Murne and Rich, 1917, find that the percentage of fat in the blood is lowered proportionally to the degree of narcosis; but since this occurs also with morphin, it has no bearing on the lipolytic theory.

Changes Effect by Lipoid Solvents.—The partition coefficient does not explain the nature of narcosis, and it is necessary to resort to further theories. The rapid recovery after removal of the anesthetics proves that they can not actually dissolve the lipoids out of the cells. Meyer therefore assumed that they merely liquefy these constituents in the cells and thereby alter their functions. Overton had shown that the selective permeability of cells depends largely on the lipoids of the plasma membrane. Any change in these would necessarily alter the permeability; and it has been demonstrated that narcosis is actually characterized by such alterations.

Polarization Theory of Stimulation.—Narcosis consists in suppression of irritability; and it will be impossible to understand it fully until the nature of stimulation is understood. There is now considerable evidence that stimulation depends upon a change in the electric polarization of the cells, due to a change in the concentration of the ions at the cell membrane (Nernst, 1899), and brought about by a sudden increase of the permeability of the plasma membrane. According to this view, the actions of the lipolytic narcotics would be explained quite simply by their modification of the lipoids of the plasma membrane, rendering impossible the changes in permeability which are necessary for stimulation. Changes in the plasma membrane could also be effected by other means, and the narcotic effects of salts can be explained in this manner. A plausible explanation of the actions of morphin and most of the local anesthetics is still lacking.

Permeability of the Plasma Membranes.—Overton found that cells are generally impermeable to neutral salts, sugars, etc.; but easily permeable to lipolytic substances. This rule is not absolute—there are important exceptions, e.g., for metabolic substances and for some of the dyes, but it is sufficiently general to indicate that cells behave as if they were surrounded by a lipid film. The departures from the rule are perhaps explained by the intermixture of other colloid constituents (A. P. Matthews, 1904). This protective film, the "plasma membrane," is probably formed by the surface condensation according to the Gibbs-Thomson principle—of substances, which lower surface tension, as do the lipoids.

(Schematic presentation of the plasma-permeability method is given by H. Winterstein, 1916.)

Relation of the Membrane to Stimulation.—This subject is well summarized by R. S. Lilly, 1914. The semipermeability serves to maintain the differences of electric potential (as shown by the demarcation current) which is essential to life. This potential disappears with death, and is impaired by all poisons which injure the semipermeability; and amongst these by the anesthetics (Waller and Alcock, 1900). Add—
THEORIES OF NARCOSIS

aldehydes and certain ions also disturb the potential; but these act presumably on the other hand, these phenomena are observable in artificial systems of phosphatid and salt solutions (J. Loeb and Beutner, 1924). Excitability and Conductivity of Nerve.—Narcosis of a nerve, however produced, always lowers both these functions in strict parallel (Vernon, Errengweg, and Mason, p. 122). While a normal nerve conducts without loss of stimulus, a narcotized nerve shows therefore a decrement during conduction (ibid., p. 127).

Relation of Permeability and Stimulation.—This is illustrated particularly by the experiments of R. S. Lillie, 1912, on Arenicola larva. He found that pure solutions of NaCl produce strong stimulation and at the same time increase the permeability, as shown by the diffusion of pigment and the dissolution of cells. Mg, Ca and aliphatic anesthetics produce depression and lessen the permeability, so that they prevent the effects of NaCl. The Mg ions and the aliphatic anesthetics probably act on different constituents of the envelope. It is therefore all the more striking that in both cases the narcosis is characterized by diminished permeability. Similar phenomena are observed in the effects of anesthetics on the sensitive plant. In nerve fibers and in muscle, Hoeber, 1912, found that low concentrations of anesthetics decrease permeability, for they prevent the swelling which normally occurs in solutions of potassium salts. High concentrations increase the permeability; this would correspond to a toxic effect. Both phenomena have been confirmed on fish-eggs by McClendon, 1915. Osterhout, 1912, 1913, 1918, showed that anesthetics lessen the electric conductivity, and therefore the permeability, of plants. (Fatal concentrations again increase the permeability.)

The mechanism by which the lysoleptic agents interfere with the permeability of the lipid membrane is unexplained. It consists probably in a physical change of the colloids. Suggestive, but not altogether consistent, parallels have been drawn with colloidal suspensions of lipids, fats, Hoeber and Gordon, 1913, found an interference of anesthetics with the precipitation of lipid suspensions by calcium; others observed increased solubility of lecithin suspension (Handowisky and Wagner, 1911; A. Thomas, 1912, Clovekov describes a change in emulsions, so as to promote the contiguity of the fatty phase, due to the lysoleptic anesthetics, thus changing the effectiveness of the action of the phosphatides (W. Koch, 1910); so that this cannot be the essential factor in narcosis. S. Loewel, 1913, found that lipid membranes are rendered less permeable to certain test animals, and suggests that the adsorption of the narcotics converts the colloids of the plasma membrane from a hydrophilic to a hydrophobic modification. This would lessen the permeability, and therefore the functions, potential, etc.

The increased permeability is obtained only for the anesthetic concentrations. Toxic concentrations increase the permeability, as seen for instance in hemolysis (Hoeber, 1913, Joel, 1913). Autolysis is similarly increased by high concent ratios (Chari). H. Mori, 1915, has attempted to explain narcosis by increased permeability through liquefaction of the lipoids; but there is no satisfactory evidence for this view.

Emulsion Theory.—The facts exist in the protoplasm as emulsions; and the behavior of artificial emulsions toward anesthetic offers analogies to the phenomena of anesthesia (Clovek; Fischer and Roskin, 1910). Surface-action Theory.—J. Traube, 1904, 1910, 1913, and 1915, contends that the action of the anabolic narcotics is not due to solution of the cell-lipoids, but to condensation or adsorption of the narcotic agent at the surface of the gross or colloid particles of the protoplasm, both lipid and protein. The catalytic activity of these surfaces would thereby be diminished, resulting in the slowing or destruction of the chemical processes, oxidations, etc., and thus of the functions of the cells. Surface condensation is proportional to lowering of surface tension (or inversely, to "solution affinity" or "Hatfminusch," the tendency of a substance to remain in soltion). This proportionality is the basis and test of Traube's theory. Since the surface tension and the partition coefficient are generally parallel, it is difficult to decide between the two views; but there appear to be more exceptions to Traube's rule than to Lillie's (1912). Durrer, 1912, has investigated the question with homologous alcohol and finds that alcohol, and for animals devoid of a nervous system, the efficiency is parallel to the surface tension; but in proportion as the nervous system develops the activity of the ether alcohols becomes relatively greater, and agrees better with the partition coefficient. Jahnska, 1912, also finds a correspondence between hemolysis and surface ten sion in a series of terpen alcohols and ketones; but the chemical characters also had an influence.

Stimulation of Phagocytosis.—Hamburger and de Haan, and Babanovic, 1913, showed that this is stimulated by minute doses of lysoleptic agents, parallel to their partition coefficient. This is probably explained by a lowering of surface tension. Narcotic concentrations paralyze the movements of leucocytes.
Mobilization of Potassium.—Menten, 1912, states that the quantity of potassium ions in modulated nerve fibers is increased by local lipolytic anesthetics and by injury. This is probably an expression of the disturbed permeability; but since potassium depresses the conductivity of the nerves, it is conceivable that this plays a part in narcosis.

Dehydration.—Dubois, 1854, observed evaporation of water in narcotized plant cells, and suggested that narcosis consists in dehydration. Overton, however, showed that the phenomenon is a manifestation of irreversible injury, and not of narcosis.

Verworn’s Theory of Oxygen Deprivation.—Verworn, 1909 (Harvey Lectures, 1911; “Narkose,” Jena, 1912), and his pupils have pointed out that narcosis is generally accompanied by diminished oxidation; and that deficiency of oxygen produces anesthetic phenomena. They therefore believe that narcosis is due to interference with oxygenation; an incapacity of the cell substance to undergo oxidation, even in the presence of oxygen, whilst non-oxidative destruction proceeds unchecked.

Verworn suggests that the transmission of oxygen may be a function of the lipid substances, thus accounting for the Meyer-Overton law, and harmonizing the two theories. Mannfeld, 1909, also assumes that narcotics lessen the solvent power of lipoids for oxygen and so prevent its penetration. This is contradicted by Wintstejn, 1913. A. P. Matthews, 1914, believes that the anesthetics fix the oxygen receptors of the protoplasma into a non-irritable anesthetic-protoplasma combination. Traube believes that the oxygen catalysts are hindered by surface condensation. Warburg and Wiesel find a precipitant action of narcotics on yeast press-juice; parallel to antiferment activity; Batelli and Stern describe precipitation of nucleo-proteins in cell extracts, parallel with checking of oxidases. On the other hand, Buercker, 1901, and Baglioni believe that the narcotics combine with the oxygen.

Verworn concedes that high concentrations cause other changes, such as coagulation; but states that these are non-reversible, and therefore not concerned in true narcosis.

Verworn’s facts do not prove his theory; for since narcosis suppresses irritability, it would naturally depress oxidation; this would be the effect instead of the cause of the narcosis. Conversely, the suppression of irritability by oxygen deprivation does not prove that every narcosis must be due to oxygen deprivation. This could be accepted only if interference with oxidation and narcosis were always strictly parallel. This is not the case, and the theory is therefore not tenable.

Anesthetic Effects of Oxygen Deprivation.—The anesthetic effects of asphyxial have long been familiar. As examples of the evidence for Verworn’s theory may be cited the fact that frog perfused with saline solution becomes inexcitable; but that the excitability is preserved or reappears if the solution is oxygenated (Verworn, 1900).

Similarly, excised nerve loses its excitability in an atmosphere free from oxygen (Froelich, 1904). Mannfeld, 1909, showed that the results are additive; the paralyzed narcosis in tadpoles being increased by degrees of oxygen deficiency which are in themselves harmless. He also pointed out, 1910, that oxygen deficiency, like narcosis, decreases the current of rest in frogs’ skin. Froelich and Heston, and Ishikawa showed that oxygen deprivation delays recovery from anesthesia.

On the other hand, there are instances (nervous trunks, vincetoxa, cilia) in which oxygen deprivation acts very slowly, while anesthetics act very promptly. HCN, which is a strong asphyxiant, is a weak anesthetic. Anaerobic organisms are also subject to narcosis, showing at least that this has nothing to do with free oxygen of its penetration into the cells.

Diminished Oxidation in Narcosis.—Herter found that the oxidizing capacity of tissues for methylene blue is greatly diminished in anesthesia. Vernon, 1906, claims a quantitative relation between the hemolytic effect of alcohols and their influence on the respiration of excised kidneys. Tashiro, 1913, found that anesthetics greatly diminish the CO₂ output of nerves. Alexander and Cerna, 1913, claim that anesthetics and morphine diminish the oxygen consumption and CO₂ formation of the brain.

Verworn, 1913, and others have shown that various anesthetics inhibit oxidases parallel to their anesthetic activity. However, the required concentrations are of the toxic rather than of the anesthetic magnitude.
Interference of narcosis with oxidation is the general rule; but there are important exceptions. Wintzstein, 1915, points out that anesthesia, even when continued for days, need not increase the activity of the central nervous system; while asphyxia (oxygen deprivation) always increases the acidity. Anesthesia therefore does not always diminish oxidation. Warburg, 1910, and Loeb and Wasteneys, 1913, finds the oxygen consumption normal in narcotized sea-urchin eggs.

Blood-catalase.—Burge, Well and Ashman, 1918, claim that narcosis is accompanied by a decrease of the catalase content of the blood, roughly parallel to the depth and rapidity of the anesthesia. In deep narcosis, the decrease may reach 50 to 40 per cent. A similar relation was claimed for ether, chloroform, nitrous oxide and magnesium anesthesia.

Burge assumes that narcosis is due to direct destruction of catalase by the anesthetic agent; that this results in diminished oxidation and that this produces anesthesia. He explains recovery by increased catalase output from the liver.

However, this assigns to the catalase a more important role in oxidation than is generally accepted; and Becht, 1919, throws serious doubt on the results. With a more reliable method, he found practically no change of catalase during anesthesia; if anything, there was a slight increase. The catalase was contained entirely in the corpuscles, and the slight variations may be due merely to changes in the corpuscle-plasma ratio. There is still no evidence that the catalases have anything to do with the ordinary processes of the body. More probably, they serve to destroy peroxids that might become harmful (Loew).

Fig. 22.—Alcohol on Purkinje cells. cat.—Nissl stain (after C. C. Stewart): 1, Normal; 2, alcohol for fifty minutes; 3, for fifty-four hours.

Chemic Theory of Moore and Rosal.—The evidence for the extension of the lipolytic theories to the permeability of the plasma membrane is not as complete as that for the parallelism of the narcotic action and the partition coefficient. It has been suggested (Kuschmann, 1909) that the lipid solubility is merely the necessary condition for the entrance of the narcotics; and that the real action occurring within the cell may be altogether different, i.e., chemical (Heymans and De Buck, 1905). It is most unlikely, however, that the quantitative parallelism between narcotic effect and partition coefficient would obtain if the intracellular action were based on difference properties. Nor is it plausible that the chemical effects of the chemically dissimilar lipolytic substances should act in the identical narcotic phenomena.

Interest in the chemical theories was revived by the observations of Moore and Rosal, 1915, which indicate the possible existence of loose reversible chemical combinations between certain anesthetics and proteins. F.d., with high concentrations of chloroform, its solubility in serum and tissue extracts does not obey the ordinary laws of solution; but this is probably an adsorption phenomenon, which need not have anything to do with narcosis. Cushny, 1915, finds that the exhalation of the volatile members of the alkyl series is exactly analogous to their evaporation from water solutions, indicating that anesthetic concentrations exist in the body in purely physical solutions. The precipitation of proteins by lipolytic agents requires much higher concentrations than exist in anesthesia.
Morphologic Changes.—It may well be supposed that the changes in the physical composition of the cell will produce corresponding changes in their histologic structure. Most of these would probably disappear in the process of fixation, but certain of them appear to persist. A diminution and fusion of the Nissl granules have been described by good observers after deep anesthesia (Fig. 35); other observers have not been able to confirm this, and the changes may be only artifacts. Kocher, 1916, emphasizes the numerous sources of error and the inconsistent results of such observations.

It is also stated that the dendrites of many pyramidal cells show moniliform enlargements; the alterations disappearing completely within forty-eight hours, even when caused by chloroform anesthesia of nine hours' duration. Lépine and Durat attributed anesthesia to retraction of the dendritic processes.

ALCOHOL

Ethyl alcohol is a local irritant. After absorption, it depresses the central nervous system, especially the "higher functions." It simulates stimulation, chiefly by lowering the normal restraining functions; but there may be some direct facilitation of motor processes and respiration.

Local Action of Alcohol.—Concentrated alcohol "hardens" tissues by abstracting their water and precipitating the proteins. It is therefore irritant and astringent. The effect is proportional to the concentration. Applied to the skin, it causes some redness and burning, followed by slight anesthesia. It is therefore employed as a mild rubefacient and counterirritant in sprains and other minor pains. It may be applied in 10 to 50 per cent. concentration, by friction or embrocation. It is often combined with other mild irritants, as in the Linimentum Saponis, Spiritus Camphore, Aqua Hamamelidis ("Witchhazel") and Tinctoria Arnica. The presence of considerable proportions of alcohol in other spirits, tinctures, fluidextracts, wines and elixirs should be borne in mind, both in their external and internal use.

If the alcohol is sponged on the skin and permitted to evaporate it produces a cooling effect. This is utilized in fever, and in excessive perspiration ("night-sweats") of phthisis. The cleansing and hardening of the skin is also useful in this connection, and to prevent the development of bed sores. The astringent and stimulant action promotes the healing of ulcers (25 to 50 per cent.). Breitmann, 1913, recommends its liberal use as an astringent lotion (70 per cent.) in first- and second-degree burns.

On mucous membranes, the local action produces hyperemia or inflammation according to the concentration (see the "Effects on Digestion"). Even the minor grades of this irritation produce chronic inflammation on continued use, and this tends to extend beyond the local surface, producing fatty and fibrous changes in the internal organs (see "Habitual Use"). The diuretic action of alcohol indicates that it irritates the renal cells.

Subcutaneous Injections of alcohol in concentrations above 50 per cent. are painful; especial care should be used not to inject it near a nerve.

Intravenous injections of alcohol were introduced by Schuessler for the relief of neuralgia and spasms (Oswald, 1906; Harris, 1914). They are generally effective, but are frequently followed by toxic degeneration of the nerve. They should therefore be avoided for motor or mixed nerves (sciatica), and find their best field in trigeminal neuralgia, as a substitute for the extirpation of the Gasserian ganglion (Fischer, 1907).

Caldwaler, 1915, has studied the results of various concentrations: 50 per cent. alcohol produces immediate and complete paralysis, followed by absolute histologic degeneration. The paralysis may persist for one to three years, or until regeneration is complete; in case of scar formation, there may be no regeneration. 35 per cent. causes less severe paralysis and degeneration; and 25 per cent. has but little effect in either respect.
Bactericidal Action of Alcohol.—70 per cent. alcohol is a fairly effective germicide. Concentrations above 80 per cent. and below 50 per cent., however, are almost inactive (A. Beyer, 1911; Sottile, 1912), because they do not penetrate proteins as readily (Tijmstra, 1913).

Propyl alcohol has been advocated for pre-operative hand disinfection, as being more effective than ethyl alcohol (Christiansen, 1918).

“Stimulant” Effects of Alcohol.—These are observed in most individuals, after taking “moderate” doses of alcohol—a quantity not easily expressed in cubic centimeters. The phenomena are only too well known. They are always, typically, of stimulation. The breath rate of respiration and of the heart; the blood pressure rises. The skin is reddened, with a grateful sensation of warmth and comfort. There is an increased rapidity of motion, action, and speech, which latter may acquire a stamp of brilliancy, even of inspiration. The subjective condition of the individual also undergoes a peculiar change.

Shyness, if it ordinarily exists, is replaced by self-confidence. The person under the influence of alcohol feels an unlimited confidence in his own powers and accomplishments, both intellectual and physical. He will attempt very difficult, even impossible, tasks, and feel that he accomplishes them. And he similarly overestimates the reductions of others.

These manifestations are so conspicuous and apparent, that alcohol in proper doses as been considered a typical stimulant; this opinion is still held by some eminent pharmacologists. However, the critical study of its actions tends to the conclusion that most of these actions do not depend upon true direct stimulation of the nerve-centers; that they are the indirect result of incoordination, of accessory factors of environment, and of reflex stimulations.

If the phenomena be somewhat more closely inquired into, this will become apparent at once. Of the physical phenomena, the flushing of the cutaneous vessels—to which the retention of heat must be attributed—occurs as a result of the vasomotor paralysis, restricted, it is true, to this area. The quickened pulse results partly from reflexes caused by swallowing and by irritation of the mucous membranes, partly from the increased excitement and motion; not at all from a direct action on the cardiac nervous muscular mechanism—for it is entirely absent in animals, and very brief in man if any factor of excitement be eliminated. The quickening of the respiration is also largely due to similar causes.

The psychic phenomena and their explanation in a dulling of certain mental faculties, whilst others are still practically unaffected—in a disturbance of what has been called the “normal balance of the brain.” The first functions to be lost are the finer grades of judgment, reflection, observation, and attention—the faculties which have largely been acquired through education, and which constitute the elements of the restraint and prudence which man usually imposes on his actions.

Thus, to quote a well-known example: The orator no longer considers that he may be called to account for his utterances; he allows himself to be carried by the impulse of the moment, without reflecting on ultimate consequences, and, as his expressions become bare, they acquire an appearance of warmth, of feeling, of inspiration. And not a little of this inspiration is contributed by the audience, who are usually in a similar condition of increased appreciation.

The view that alcohol increases the intellectual and physical powers of the individual is shown by actual experiment to be erroneous, and based almost entirely upon subjective conditions of the individual, his weakened faculty of judgment.

Experience soon teaches this lesson: that alcohol does not really stimulate. Persons have to undergo severe exertion, either physical or intellectual, very rarely take alcohol before or during their labor, but only when this is finished. And then not for stimulating, but really for its depressing effect; for the feeling of comfort and general well-being; which it induces. The continued use of large doses of alcohol greatly

1 No better description of these effects can be given than that of Horace: “What wonder does not burn? It discloses secrets; rouses and confirms our hopes; thwarts the coward forth to battle; eases the anxious mind; of its burden; instructs in arts. Whom has not a cheerful glass made eloquent? Who not quite free and easy from pinching poverty?”

ALCOHOL
diminishes the activity of the individual, and even moderate doses tend to have the same effect.

Another very characteristic feature, evidently resulting from this paralysis of the higher cerebral centers, is the loss of the power to control mood. There may be causeless merri-
ment or sadness, friendliness or the opposite. It is interesting to note how often alcohol
brings out the true character of an individual by this abolition of restraint: "There is
truth in wine." On the other hand, the habits of self-control, where they have been
cultivated, persist to some extent even in intoxication.

Experimental Analysis of the Psychic Effects of Alcohol.—The use of
different experimental methods has led to contradictory conclusions,
depending mainly on the interpretation of the more or less complex psycho-
logic phenomena. The most reliable data appear to be those of Dodge
and Benedict, 1915, for they aimed to use the simplest methods of a given
kind.

They found that moderate doses depress all kinds of neural processes,
more as well as sensory. This diminished efficiency is most conspicuous
in the simpler and unconscious reflex processes, i.e., those that are most
independent of the will; for a normal individual even when somewhat
alcoholized, attempts automatically to compensate for diminished effi-
ciency by greater effort. This in turn, however, is likely to lead to more
errors; for the extra effort is often ill directed, since alcohol diminishes
cautions and inhibitions.

Dosage, time and subjects.—Dodge and Benedict employed doses of 30 and 45 c.c.
of alcohol, diluted to 20 per cent. The depression reached its maximum in 1 to 2 hours;
recovery starting within 3 hours. The responses were essentially similar for abstainers
and reformed drinkers.

Quantitative Response.—The results may be arranged in progressive order from those
showing the greatest, to those of the least effects:

Reflexes.—Knee-jerk and lid-reflex: Latent period increased by 10 and 7 per cent.
Muscle shortening diminished by 46 and 19 per cent.
Threshold to Electric Stimulation.—Raised by 14 per cent.
Motor Coordinations.—Speed of eye-movements and of reciprocal finger movements
Diminished by 14 and 9 per cent.
Elaborated Reactions.—Reaction time of eye and speech organs; latent period
increased by 5 and 3 per cent.
Memory.—No change.

Kraepelin, 1892, also concluded that alcohol is purely depressive to
sensory or intellectual processes; but he believed that the generation of
motor impulses is first stimulated, but later also depressed. In the light
of the more recent work, this "stimulation" of motor processes is appar-
ently an erroneous interpretation; but this does not destroy the value of
the actual data of the extensive studies of Kraepelin; namely that the
"stimulant" stage of alcohol favors mechanical performances—the "sim-
pler reactions" of memorising, mechanical reading, repetition, at the
expense of the more intellectual processes—association, arithmetical, etc.
It favors motor impulsiveness, but produces intellectual dulness and sill-
ness, lessens thought and judgment, and resistance to temptation, and
thus leads to its abuse. The euphoria probably depends on the deceptive
feeling of facilitation and capability.

Psychic Depression.—With doses of 30 to 45 Gm. of alcohol, this lasts thirty to forty-
five minutes; with 60 Gm., one to two hours. The phenomena are somewhat analogous
to fatigue. In both, mechanical associations predominate. However, the lighter
grades of alcohol "fatigue" disappear with exercise, while genuine fatigue is relieved
by rest.

Motor Processes.—The facilitation begins at once and lasts at most twenty to thirty
minutes, less with larger doses. It is followed by depression even with the small dose
of 7.5 Gm. With 45 to 60 Gm., the initial facilitation is seen only exceptionally. However, the results depend somewhat on circumstances; in excitement, even large doses produce facilitation; and in fatigue, small doses may depress. The more mechanical the function, the more conspicuous is the facilitation. The force measured by the dynamometer is not increased, so that the rate rather than the force of motor impulses is favored. There is also evidence that the muscular contraction proper is not quickened, but that the motor impulses are started more easily.

Perception of Sensory Impressions.—This is impaired for hours, even by 1/4 oz. of alcohol (Kraepelin, 1916).

The reflexes from the frog’s skin are depressed, even with the smallest effective doses (Hyde and pupils, 1913), before there are any grossly visible symptoms.

Color-vision.—H. Schuly, 1916, finds that small doses of alcohol increase the acuteness of vision, both for red and green. Large doses diminish it.

Aplied Efficiency Tests: Mechanical Operations.—Vermont and Greenwold, 1910, found that small doses of alcohol, well within a “moderation,” do not interfere with the speed of semimechanical operations; for instance, typing from memorized passages; but that they greatly decrease the accuracy in fast work. This deleterious effect is not noticed if the task is very familiar; or if the speed is slow. Similar observations were recorded by Frankfurter. They are in line with the weakening effect of alcohol on inhibitory and cautionary reactions.

Use as Stimulant.—Even the “stimulant” doses do not increase intellectual efficiency; but they could be employed for facilitating motor functions of short duration; not so much to increase their force, but for overcoming inhibition or hesitancy; to promote decision or resolution, f.e., in speaking, in psychic dreads, etc. It would be unfavorable to attention, watchfulness or ready judgment. The stimulant dose should generally not be more than 15 to 20 Gm. of alcohol, or if a longer effect is needed, 5 to 8 Gm. in twenty-minute intervals.

Alcohol on Muscular Work.—In man, the ergographic experiments of Lombard, 1892, showed that the muscular force in voluntary contractions is not increased; but the appreciation of fatigue is lessened (Joteyko, 1904, Foerster, 1912), so that the total work may be increased. When a finger is tetanized, by electric stimulation, the total work is rather decreased (Lombard); the favorable effect must therefore be at least partly central (facilitation of cerebral motor processes). However, the voluntary response is modified by the previous state of the muscles as well as by the dosage of alcohol: Helmst, 1904, found that moderate doses (10 Gm.) at first increase the power of voluntary muscular work (to 8 per cent.), but in one-hour diminsh it to 6 per cent. below normal. Myers, 1912, reports no effects from 1 to 20 c.c.; 30 to 40 c.c. gave irregular results, notably a common primary increase and secondary decrease of the work. The increase is seen only when the muscle is not too much exhausted, but it is favored by moderate fatigue. The favorable effect therefore appears to be due partly to the direct food-value of the alcohol, somewhat as with sugar; the food effect of alcohol is more prompt, but not as efficient in the long run. The depression of the larger doses is purely central.

On frog’s muscle, minute quantities have no effect; moderate doses were said to exert a favorable action on all the features of muscular activity; larger quantities are very unfavorable (Lee and Salant, 1902). Cudler and Robinson, 1916, attribute the reported favorable effect to experimental error.

The effects on invertebrates and lower vertebrates have been studied by Fuehner, 1912.

The Effects on the Respirations.—“Stimulant” doses of alcohol may increase the rate and depth of the respirations, by reflex and central stimulation. This may aid in the therapeutic use of alcohol as a stimulant. The response, however, is variable and generally small. With narcotic doses, the respiratory center is depressed.

In Higgins’ experiments (1917) on man, 30 to 44 c.c. of alcohol taken diluted, produced little change in the rate or type of respirations (unless there was excitement). The threshold to CO₂ was sometimes lowered. The minute-volume was generally diminished, by decreased CO₂ production. The bronchioles were generally unaffected, rarely dilated.
The respiratory stimulation is especially large in fatigue, and is greater with wines and liquors rich in "bouquet," than with dilutions of pure alcohol (Bina, 1903). Wendelstadt, 1899, obtained similar results in man.

The increased respiration is partly due to the general excitement and partly to reflexes from the local irritation (Jacquet, 1863) and from the odor, etc. However, some increase occurs even in sleep, so that the factors of environment are not essential. Nor can it be affirmed that it is due solely to reflex irritation, for other irritants do not produce an equivalent effect (Bina, 1903). Moreover, an immediate increase of respiration occurs if alcohol is injected into the brain through the carotid artery (Wilmanns, 1897).

With unanesthetized animals, slow intravascular injection produced only slight respiratory stimulation, even when the injections were repeated beyond the excitement stage (Hyatt and Jensen, 1918).

With a more perfect separate perfusion of the brain and medulla, Hooker, 1917, also found that the addition of 0.025 to 0.1 per cent. of alcohol (corresponding to clinical concentrations), produces pure stimulation of the respiration. With 0.2 per cent., the stimulation was transitory, and followed by prolonged inhibition. This would correspond to coma.

It is therefore certain that the respiratory center is stimulated directly. A Fontayne, 1906, finds that large doses lessen at first the rate, and later also the volume. In cats, Pilcher, 1912, found the rate usually increased by all except fatal doses. In decerebrated cats, doses of 0.5 to 5 c.c. per kilogram, dilute or concentrated, caused so change in the respiration (Lieb, 1915).

**The Effects on the Circulation.**—These are rather inconstant, varying not only with the dose and concentration and mode of administration, but also with the condition of the individual.

**Small Therapeutic Doses** (in man, to perhaps 5 to 25 c.c. of absolute alcohol, diluted at least to 25 per cent.) produce generally (but not always) an insignificant quickening of the pulse rate, due mainly to excitement.

The cutaneous vessels are dilated, and the splanchnic vessels are somewhat constricted leading to a rise of the systolic blood pressure and a fall of the diastolic pressure. The mean aortic pressure rises slightly in most cases, but not always. The normal heart muscle is probably not affected by these doses; but the exhausted heart may be stimulated by the nutrient action of the alcohol.

The actions, taken together, alter the distribution of the blood, so that more will be contained in the surface vessels and in the arteries, and less in the splanchnic veins. The amplitude and force of the pulse; the "mass-movement" of the blood; the output of the heart; and the efficiency of the circulation in general, will be improved. The effects are not very great and not altogether constant in normal individuals; but they suffice to produce decided therapeutic effects, especially in conditions of exhaustion.

The actions reach their maximum in about half an hour, and disappear in an hour or two.

**Somewhat Larger Doses** (45 to 90 c.c. of alcohol for man, diluted) produce at first the same effects, followed in an hour or less by decreased amplitude and force of the pulse, with progressive fall of the systolic pressure, and unaltered or rising diastolic pressure. If the alcohol is taken in more concentrated form on an empty stomach, this stage may occur at once, without the preliminary improvement of the pulse. The fall of the pressure is attributable to splanchnic dilatation, replacing the constriction of the first stage. The action is therefore comparable to that of the nitrates. The effects reach their maximum in one to one and one-half hours, and last one-half to one hour.

**Toxic Doses** depress the vasomotor center and perhaps also the cardiac muscle, so that the blood pressure falls severely. The heart rate may be
slowed through central vagus stimulation, or through the depressant action of the coma; or it may be quickened by the fall of blood pressure.

Heart Rate.—The effect is greatly modified by the condition of the individual. In man, the rate is generally increased, mainly by the psychic and reflex actions (Dixon, 1907); the increase is often absent, especially if the patient keeps quiet (Zimmermann, 1856; Jacquett, 1891, Dixon).

Dodge and Benedict, 1915, always observed some acceleration, which they attribute to diminished vagus tone. With larger doses, the quickening is the rule (John, 1918; Higgins, 1917), presumably to offset the falling blood pressure. Animals give similar inconsistent results (Pilcher, 1912). The intravenous injection into non-anesthetized animals generally causes some slowing (Brooks, 1910).

General Blood Pressure.—In man, Kochmann, 1905, and Bachem, 1905, found a rise of systolic pressure with small doses. Dixon, 1907 (dose not stated) found the systolic pressure unchanged or slightly raised, the diastolic pressure lowered. This was confirmed by John, 1908. Lieb, 1915, observed practically no effect from diluted whiskey (usually 5 to 10 c.c.). When given concentrated, this produced a slight reflex rise (about 5 mm.) of the systolic and diastolic pressure, returning to normal in less than one-half hour. The return of the diastolic pressure is somewhat slower, so that the pulse pressure is decreased. The Tigerstedt formula indicates a very slight decrease of cardiac efficiency. These effects are entirely reflex, and are most pronounced when the reflexes are hyperactive; least in atonic patients and toxemics. Moderate users are more susceptible to them than drinkers. With larger doses John found a progressive fall of systolic pressure, with unchanged or rising diastolic pressure.

Anesthetized animals are obviously not suited for determining the effects of small doses of alcohol. In nonanesthetized animals, Brooks, 1910, found that the oral administration produced a slight rise, lasting five to ten minutes; administration through a gastric fistula had no effect; intravenously, there was the sharp drop, common to many drugs, followed by rapid recovery.

On the other hand, Hyatt and Jensen, 1918, found no change of blood pressure in anesthetized animals by slow intravenous injection, repeated beyond the excitement stage.

In decerebrated cats, Lieb, 1915, found no marked change in the blood pressure or heart rate, except a rise of 5 c.c. per kilogram, dilute or concentrated.

The hypodermic injection of whiskey, as that of other volatile irritants, often produces a slight and transient rise (Lieb and Herrick, 1917).

The Kidney pressure is not changed by small doses, but increased by large doses which injure the heart (Gapps and Matthews, 1913).

Blood Flow.—Alcoholic beverages of the strength of wine, administered to normal men in moderate doses, produce a brief preliminary decrease, followed by a more lasting increase of the blood flow in the hand. Both effects are vascular. Alcohol also favors vasodilator reflexes, e.g., the contralateral heat reflex (G. N. Stewart, 1915). Hanisch (1908) found that the circulation in an intestinal vessel was distinctly colored by relatively small doses of alcohol, intravenously, even when the carotid pressure was unchanged.

Vasomotor Changes.—The cutaneous vasodilation is obvious on mere inspection, and may be confirmed by plethysmograms of the limbs, and by the blood flow. Since the blood pressure does not fall in the early stages, it is evident that this dilation of the surface vessels is compensated, either by the constriction of other vascular areas, or by increased output of the heart. Both factors appear to contribute to the result, according to circumstances.

Spinal anesthesia in the early stage has been demonstrated by Dixon, 1907, who found that the volume of the intestine decreases while the blood pressure rises. General vasodilation, presumably in the more advanced stages of the action, is shown by the fact that the blood pressure is practically not increased, notwithstanding considerable increase of the output of the heart, as measured by the stethoscope (Hemmeter, 1905; Wood and Hoyt, 1905), or by the cardiometer (Dixon). If the vasomotor center is excluded by section, the injection of the alcohol causes a more marked rise of pressure (Kochmann; Wood and Hoyt), showing that the vasodilator action of alcohol must be central. (Bachem, however, found less rise after section of the vasomotor center.)

Vasomotor Reflexes.—Porter and Turner, 1915, find that alcohol may suspend vasomotor reflexes even when the general level of the blood pressure is not altered. They conclude from this that separate centers exist for vasomotor tone and reflexes.

Direct Action on Vessels.—These appear to be insignificant. On perfusion, Dixon found in mammals slight dilatation with 0.1 to 0.1 per cent., higher concentrations gave
constriction. Perfusion of the frog showed moderate constriction. In surviving arterial rings, Cow, 1911, found very slight response: transient constriction followed by dilatation. Plummer, 1905, believes that alcohol has a peripheral constrictor effect.

**Impaired Nutrition of the Heart.** — The increased output of the heart in in vitro is attested by the stethoscope, cardiometer, rise of pressure after destruction of vasomotor center, etc. Since this improvement is not usually noted in excised hearts, it can not be due to a direct action of alcohol on the cardiac muscle. Kochmann, 1905, attributes it to improvement of the coronary circulation by the general vascular changes. Dixon, 1907, brings good evidence that the food-value of alcohol plays the most important role; for he finds it most effective, in excised hearts, when the nutrient supply has been previously exhausted. Hamill, 1910, then showed directly that perfused hearts are able to metabolize alcohol.

C. C. Lieb, 1917, failed to confirm this utilisation; but here positive results are much more valuable than are negative data.

**Excited Mamalian Heart.** — The effects have been studied by perfusion with Langendorff's method, especially by Kochmann, 1904; O. Loeb, 1905; Lackmann, 1906; Kuno, 1913; Barry, 1915. Concentrations up to 0.5 per cent. are absolutely without action, according to most observers. Loeb, however, describes occasional slight stimulation; and Dixon finds increased excursions constantly if the heart has been exhausted (see preceding section). Burridge, 1917, also finds that alcohol may have either a depressant or a favorable action on the perfused heart. Lieb, 1917, alone claims that depression occurs with all concentrations above 1:50,000.

Concentrations to 0.5 per cent. also give no result, or at most insignificant and slight slowing; or weakening or arrhythmia. With concentration of 1 per cent. and higher marked depression appears; the systoles are weakened, but the diastolic excursions are not increased. The coronary vessels appear somewhat dilated, 0.5 per cent. of alcohol causes severe damage to the muscle, especially of the auricles, which are slowed and weakened, while the ventricles may be merely slowed (Barry, 1915). Four to 5 per cent. arrests the heart in diastole; the auricles stopping before the ventricle. If the alcohol is removed, the heart recovers rapidly, even from severe depression. Repeated perfusion confers tolerance (Kuno). Lieb, 1917, failed to find this rather improbable rapid stimulation.

Brandini, 1913, found the depressant effect on perfused rabbit's heart increased with rise of temperature.

During the depressant stage of alcohol or the anesthetist, the heart takes up less calcium from the perfusing fluid (Burridge, 1917).

The concentration of alcohol in the blood of living animals is said to be 0.12 per cent. in "slight confusion," and 0.7 per cent. in deep narcosis. It is therefore evident that the direct cardiac effects of alcohol play no part in either the therapeutical or toxic phenomena.

**Pressure in Pulmonary Artery.** — Dixon, 1905, and Wood, 1911, find this slightly increased, even when the carotid pressure is unchanged. Cloetta and Andersen, 1914, found the effect on the pulmonary vessels inconstant; generally dilatation, rarely constriction.

**Cerebral Circulation.** — Contradictory results were obtained by Aliprandi and Formaroli, 1905; and by E. Weber, 1909. Hirschfelder, 1915, describes dilatation of the vessels of the pia mater and retina. Berezn, 1916, also observed dilation.

**Hemolytic Action.** — Alcohol added in sufficient concentration directly to blood causes hemolysis (C. H. Schulz, 1841). This concentration is not reached in living animals but the resistance to laking agents is noticeably lowered (Liebermann; Fillinger, 1912). Continued administration increases the resistance of the corpuscles (Orban, 1913). If the relative hemolytic effect of different alcohols is compared, it is found to be proportional to their effect on surface tension, rather than to their lipid solvent action (Fiehn, 1912). J. N. Schultz, 1912, has investigated the influence of various substances (including sera in different diseases) on the alcohol hemolysis.

**Blood Viscosity.** — This is somewhat increased by the administration or inhalation of alcohol or methyl alcohol (Burton-Opitz, 1904, 1914).

**Use of Alcohol in Collapse.** — The effects of alcohol on the general circulation are utilized in the treatment of collapse and in extinguishing fever-
its usefulness as a quickly acting ("diffusible") stimulant can scarcely be doubted in the various forms of sudden circulatory collapse—syncope, anaphylactic shock, hemorrhage, traumatic shock, snake venom, strychnine, strychninism, veratrum poisoning, etc. The main element in its action is the psychic stimulation, increasing the pulse rate, the blood pressure, and the respiration.

However, the stimulation is apt to fail in the severer grades of hemorrhage and shock (Lief and Herrick, 1917). The narcotic action is also useful; the psychic centers are less easily stimulated, and the narcotized medullary centers are less subject to damage. The subsequent vasodilation is theoretically inadvisable, it is not sufficiently pronounced to have any practical significance. The reflex action being brief, alcohol acts mainly as a temporary agency remedy, to tide the patient over the immediate dangers. To re these reflex effects, 25 c.c. of whiskey or brandy should be given diluted, and preferably hot, repeated every ten to fifteen minutes, according to effect.

**Other Diffusible Stimulants.**—A similar reflex stimulation may be produced by ether, aromatic oils, camphor, or ammonia. These may be inhaled by mouth (Spiritus Aetheris; Spiritus Camphorae; Spiritus Aromaticus); or by smelling (aromatic ammonia, smelling salts; or hypodermically (brandy, ether, camphorated oil).

**Cardiac Disease.**—The actions of alcohol are scarcely available except for temporary conditions, such as acute myocardial insufficiency. In chronic lesions, small doses may suffice to lessen the worries of the patient, especially if he has been accustomed to it. The vasodilator effect may be useful in Angina Pectoris, but it is superior to strychnine. Alcohol does not influence Pulmonary Hemorrhage (E. Frey, 1909).

**Use in Exhausting Fevers.**—(Typhoid, Pneumonia, etc.). The intelligent and discriminating employment of alcohol should be useful in these conditions; its indiscriminate use would doubtless do more harm than good. The beneficial effects are probably mainly nutrient, due to the concentrated food-value of the alcohol, and to the stimulation of the digestion and absorption of other foods (see below). This not only conserves the general nutrition of the patient, but also increases the output of the exhausted organ. The pulse becomes stronger and more regular. The altered distillation of the blood by the mildest degrees of alcohol action would also be beneficial. The dilution of the cutaneous vessels removes the blood from the atonic and therefore congested internal organs, and lessens the sense of distention of the heart. It would also tend to lower the temperature, although the antipyretic effect is but small. The narcotic action of alcohol is useful by quieting the febrile excitement, thus reducing the strain on the strength of the patient.

On the other hand, if the action of the alcohol proceeds to the point of reducing splanchnic dilation and lowering blood pressure, it will exaggerate the serious circulatory abnormalities of fever. Again, in the acute, febrile stages of the "afebrile" fevers, alcohol is apt to increase the circulatory excitement, and should be avoided.

The effects of alcohol must therefore be carefully watched, to secure stimulant effects, when needed, while avoiding both the depressant and excitant stages. The individual observations on each patient can alone determine its employment: The dose may be increased or maintained so long as it improves the prominent symptoms, quiets the patient, regulates and stabilizes the circulation.
strengthens the pulse, and lowers the temperature. When it ceases to have these effects—particularly when the pulse becomes “excited,” or when the odor of alcohol remains on the breath—it should be diminished or stopped.

The amount must be governed by the previous habits of the patient; but astonishingly large quantities can often be given to fever patients without producing “intoxication” even if they are unaccustomed to its use; the febrile organism probably oxidizing the alcohol more rapidly.

Ordinarily, one may begin with ½ to 2 tablespoons of brandy in half a glass of milk, every three hours, increasing the frequency as needed. 

**Diuresis.**—Dilute alcoholic beverages (wine, and especially beer) increase the flow of urine, but the effect is mainly that of the excessive ingestion of fluid.

In man, Raphael, 1894, found that a liter of wine or beer had no more effect than the same quantity of water, and less than that of milk. John, 1908, found that the average quantity of urine in four to six hours after taking 1½ liters of water to be 3,500 c.c.; with 1½ liters of 3 per cent. alcohol, he averaged 1,800 c.c.; with the same quantity of 6 per cent. alcohol he averaged 2,000 c.c. of urine. The effect was relatively greater in a case of renal insufficiency from hypertonias; in this, 1½ liters of water gave only 845 c.c. of urine, while the same quantity of 3 per cent. alcohol yielded 4,600 c.c.

This suggests that the greater diuretic action may be due to a dilator effect on the renal vessels. Moreover, alcohol irritates the urinary passages (and is therefore contraindicated in cystitis and urethritis); this may increase the desire to micturate, and make the diuretic effect appear greater than it really is. “Gin,” which contains juniper, has more direct diuretic effect, from the renal irritation produced by the oil. Dogs fail to show more than the water-diuresis, on the oral administration of any dosage of alcohol (Januškiewicz, 1911). (Intravenous injection would arrest the urine flow, as do other hypotonic solutions.)

**Temperature.**—The ingestion of alcohol causes a sensation of warmth, due to the increased blood flow to the temperature-nerves of the stomach and skin. This sensation, however, is deceptive; for this increased blood flow to the surface and the dia phoresis increase the heat loss, so that the internal temperature tends to fall.

With small doses, this tendency may be overcome by the increased movements of the patient; but with larger doses the heat loss becomes pronounced (Pilcher, 1912), and is exaggerated by the depressant action on the temperature-regulating centers. The rise of temperature is especially great if the external temperature is cold, and also if the lost dissipation was previously low, as in fevers.

**Use of Alcohol in Chills and Exposure.**—It is evident that this would be detrimental during exposure to cold; the temporary relief and feeling of warmth is obtained at the expense of an increased loss of heat, and consequently diminished power of resistance. But if taken after the exposure, the dilatation of the cutaneous vessels favors the absorption of external heat, and also prevents the tendency to congestion of internal organs, and thereby the tendency to “catch cold.”

**Influence of Alcohol on Digestion.**—This varies with the quantity and concentration; with the state of the digestive functions; with the habits of the individual, and probably also with the flavor and extractives of the beverage. In general, moderate doses act as “condiment” or stimulant to digestion. In this the flavor and the hyperemia cooperate to increase the appetite, the flow of digestive juices, the movements of the stomach, and absorption. The action of fermenters is also accelerated.

Small quantities of alcohol, taken with meals, therefore, tend to have a favorable action on digestion. If digestion is perfectly normal, these
Effects are quite superfluous; the utilization of food, and the total time of digestion, is scarcely influenced by these doses of alcohol. In pathological conditions, however, and perhaps in overeating, the effects may be beneficial. The best results would usually be secured with wine. The alcohol would not be taken in strength greater than perhaps 20 per cent.; even this would be too strong did it remain for any length of time; but it is absorbed so rapidly that this strength would very soon reach the favorable mit.

Large quantities of alcohol, however—and especially when in concentrated form on the empty stomach—produce an irritation which surpasses the physiologic limit and interferes with the functions. This is most markedly in the habitual use, when the inflammatory changes become chronic, and extend to the portal system.

**Hunger Contractions.**—These are inhibited by alcohol, as by many other chemical and mechanic stimuli (Carison, 1911).

**Excised Intestine of Rabbit.**—The movements are mainly depressed by monovalent alcohols; very dilute solutions produce a primary stimulation (Kuno, 1914).

**Action on Ferments.**—Since alcohol is very quickly absorbed, and no great amount of it reaches the intestine, it can only influence the ferment of the stomach, and its action in pepsin is alone of practical interest. It is found that in vivo—and there is no reason to suppose that it acts any differently in vivo—1 to 2 per cent. of alcohol increases the rapidity of peptic digestion. Up to 15 per cent., it causes no perceptible retardation. With 15 to 18 per cent., the digestion is reduced by one-fourth to one-third. With 20 per cent., the digestion is strongly inhibited (Chittenden, Mendel, and Jackson, 1898).

Beers and wines have a slightly more unfavorable effect on account of the extractive material contained in them.

**Secretion of Saliva.**—The presence of alcohol, strong or dilute, in the mouth increases nearly the amount and the solids of the saliva, just as do many other substances (acetic acid, ether, etc.). This increased secretion does not take place if the alcohol is introduced directly into the stomach through a fistula or if it is given subcutaneously.

**Secretion of Gastric Juice.**—The quantity, the acidity, the absolute quantity of ferments, and the total solids (but not the mucus) are markedly increased (Chittenden, Mendel and Jackson, 1898; Chiarì, 1912). The increase occurs also if the local action of the alcohol on the stomach is excluded, as in the "Pavlov stomach" (Zito Betchuch, 1905); or if the alcohol is placed into the intestine (Chittenden) or rectum (Kast, 1900).

With oral administration, in man as well as in animals, the favorable effect obtains with concentrations up to 10 per cent.; with 10 to 20 per cent., the mucus is increased, as well as the juice. Above 20 per cent., the mucus is further increased, but the secretion is decreased.

**Pancreatic Juice.**—Giselt, 1906, claims that the pancreatic secretion is stimulated when alcohol is administered by mouth, intestine, or subcutaneously; but only if the vis is intact.

**Bile.**—Salant, 1906, found that alcohol by mouth (but not intravenously) increases the flow of bile by 50 to 350 per cent.; the solids are also increased. Increased bile secretion was confirmed for large doses by Okuda, 1915.

**Effects on Absorption.**—Alcohol itself is rapidly absorbed (see below).

It also increases the absorption of other substances under certain conditions (Riemshälder, Strychnin, 1900), but not under some other conditions (Ryan, Strychnin, 1912). Breguet, 1913, found only a slight effect on the gastric absorption of strychnin, bicarbonate or iodid. Tschekoanow, 1914, observed no increase for saccharose, iodid or NaCl. Hanakl found the absorption of phenol and iodid diminished by strong alcohol.

Alcohol intended as antidote may therefore even increase the toxicity of poisons, if both are taken by the stomach, and this is not evacuated.

**Use of Alcohol in Indigestion.**—Alcohol, in the form of wine or diluted spirits, taken with meals, is clinically of value in some forms, and harmful in others. The precise conditions have not been sufficiently defined. It would be useful as a "counterirritant" in functional "colic" and gas-
tralgia, and harmful in the presence of an acute gastritis. In chronic conditions, good results might be expected in "adynamic states," where the circulation or tone are defective—in the course or convalescence from fevers or exhausting illness, phthisis, etc. It would be harmful in hyper-acidity, and therefore in most "nervous dyspepsias." Certain wines become injurious on account of their acidity.

Champagne is also used as an aperitif. Its action in this case depends perhaps more on the carbon dioxide and cold and on the psychical effect, than on the direct action of the alcohol.

The Absorption of Alcohol.—This occurs rapidly, mainly from the small intestine, and is practically independent of the quantity.

Chittenden, Mendel and Jackson, 1898, found that 90 c.c. of a 20 per cent. alcohol disappear from the stomach of a dog in less than half an hour; and with the duodenum ligated, 100 c.c. of a 37 per cent. alcohol are completely absorbed from the stomach in three to three and a half hours. Vollmeyer, 1912, found absorption practically completed in an hour. Voeltz and Dietrich, 1915, found the absorption materially faster in habituated animals, but in either case practically completed in two and one-half hours. Nersem, 1907, investigated the relative role of the succeeding portions of the alimentary tract in the absorption of alcohol, under normal conditions. Administering 30 per cent. alcohol to dogs with fistulae at different levels, he finds that the amount absorbed at each level depends mainly upon the time during which the fluid normally sojourns at this level: Very little of the alcohol is therefore absorbed from the mouth, about a fifth from the stomach; very little from the duodenum; the greatest quantity from the jejunum, and the remaining fifth from the ileum.

Hanzlik and Collins, 1913, have studied the absorption from intestinal loops in living animals. It was rather better from the colon than from the stomach or small intestines; the length of the loop had little influence; 10 per cent. solutions were absorbed slightly better than stronger or weaker concentrations. The intestinal wall retains a certain amount of alcohol very firmly, thus apparently resisting its absorption. Voeltz, Baudrexel and Dietrich, 1912, found rather similar phenomena in the absorption of alcohol by the urinary bladder, which is fairly extensive (Nicolai and Novicka, 1912).

Excretion of Alcohol.—Only a very small proportion of the ingested alcohol is excreted, by the kidneys and lungs, generally less than 2 per cent. and probably never more than 10 per cent. (Strassmann, 1891; Benedetti, 1896). The remainder is completely oxidized in the tissues.

The proportion excreted depends upon the dose and other conditions.

It is greater if the respiration is increased as by muscular work; or if the absorption is more rapid, as when the alcohol is taken on an empty stomach (Voeltz, Baudrexel and Dietrich, 1911, 1912).

Chanel of Excretion.—This occurs mainly by the kidneys and lungs; a small amount is excreted and reabsorbed from the urinary bladder. The pulmonary excretion is fairly constant; that by the urine varies between one and one-half and 13 per cent., depending largely on the sojourn and reabsorption in the bladder (Nicolaus and Novicka, 1913). The milk may contain a small amount if large quantities are ingested, but not with ordinary doses (Klingemann; Koldewijn, 1910; Schottmüller and Schum, 1912). The maximum amount would be too small to affect sucklings (Voeltz and Paechter, 1913). It is also excreted into the cerebro-spinal fluid (also acetone and chloroform, Halé, 1911). This has been proposed as a test for alcoholic psychoses (Selig, 1913; Vorkaseter and Neve, 1913, caution against hasty conclusions).

Lentz and Daniel, 1915, find that after ordinary alcoholic intemperance, it appears promptly in the cerebro-spinal fluid, and persists there for an average of ten days. The excretion curve is similar to that of the urine. It is not excreted in the sweat or feces (slight traces by intestinal loops, Hanzlak and Collins, 1913).

The excretions do not contain an appreciable amount of acetone or other intermediate decomposition products (Masch, 1914).

Percentage of Alcohol in Blood.—According to the old work of Schulius, 1866, the blood is said to contain 0.12 per cent. in the stage of slight confusion, and 0.27 per cent. in deep narcosis.
ALCOHOL

Schweitsheimer, 1913, found that symptoms may begin with 0.02 per cent., and are generally quite pronounced with 0.05 per cent. A liter of wine containing 10 per cent. of alcohol may raise the concentration in the blood to 0.1–0.15 per cent. Larger doses take longer to have their effect.

According to Widmark, 1915, the concentration, in man, is about the same in the blood and urine. It is not affected by the concentration in which the alcohol is administered, but it is higher if the alcohol is taken fasting than after meals.

Course of the Alcohol Concentration in the Blood.—Schweitsheimer, 1913, finds that the concentration in the human blood corresponds with the degree of intoxication. With have accustomed to alcohol, the maximum concentration in the blood was reached 1 1/2 hours after a liter of wine containing 10 per cent. of alcohol. The concentration then remained nearly level for 5 or 6 hours. The alcohol had practically disappeared in 12 hours.

With habitual drunkards, receiving the same dose the maximum concentration in the blood was reached more promptly, but did not rise as high, and was maintained for only hours; and the final disappearance from the blood was also more rapid.

Existence of Alcohol in Normal Tissues.—A trifling quantity of alcohol appears to be produced in the tissues in the course of normal metabolism. Its presence was claimed by W. H. Ford, 1872, and confirmed qualitatively by Landsberg, 1904. Reach, 1907, finds that fresh rabbit’s muscle contains to 0.0017 per cent. of alcohol; the liver may contain 0.02 to 0.14 per cent. Voeltz and Dietrich, 1913, recovered a total of about c.c. c.c. c.c. from normal dogs. Dakin believed that this “normal” alcohol is not formed in the tissues, but by intestinal fermentation; but Taylor, 1919, finds it even after the removal of the entire digestive tract. Schweitsheimer, 1913, claims that normal human blood contains about 0.01 per cent. of alcohol. In drunkards, the concentration may rise to 1/24 per mille; but after the ingestion of alcohol the excess disappears more rapidly from the blood of drunkards than from non-habituated individuals.

Distribution of Ingested Alcohol in Tissues.—Vollmering, 1912, found that soon after absorption the ratio was blood > liver > muscle > brain. Later, the brain contained the most. Fatty tissue was slow to take it up, but retained it longer. Voeltz and Dietrich, 1912, found 5 to 12 per cent. still present in the body fifteen hours after doses of to c.c. per kilogram; to 4 per cent. had been excreted by the respiration, 0.4 to 4 per cent. by the kidneys, and 95 per cent. had been oxidized. Messner, 1913, could not demonstrate destruction of alcohol by emulsions of tissues, or by blood in vitro.

The Fate of Alcohol in the Tissues; Effect on Metabolism.—Over 98 per cent. of the ingested alcohol disappears in the body, being completely oxidized to carbon dioxide and water (Atwater and Benedict, 1902); probably with acetic acid as an intermediate stage. By the chemical energy thus liberated (about 7 calories for Gm. of alcohol, or 4 calories for c.c. of whiskey) alcohol can perfectly replace carbohydrates and fats in the diet, and is a typical non-nitrogenous food. It is even superior to most other foods in one particular, viz., in that it does not require digestion. By its poisonous side actions, however, it may at first cause an increased nitrogen excretion in individuals not accustomed to its use; but this action disappears in a few days, and it then excretes nitrogen like any other food.

When added to an ordinary diet, the CO₂ excretion, the oxygen consumption, and the output of heat are not materially changed (Higgins, 1917). The alcohol therefore leaves the other constituents of the diet from decomposition, and the body shows a corresponding gain in weight. If it is added to a diet deficient in carbohydrates or fats, the metabolism is the same as if an inodynamic quantity of these foods were added. It serves carbohydrates in man even when large amounts of sugar are supplied (Toedel and coworkers, 1913). It can be used up in muscular work (Krüger, 1913). In dogs receiving 2 c.c. of alcohol per kilogram, this supplies about 40 per cent. of the energy (Voeltz and Dietrich, 1915). The literature of this subject is summarized by Rose, 1902, Pfugrer’s Archiv, 86: 307.

By observing the respiratory quotient, Higgins, 1916, showed that in man, with doses of 30 c.c. of alcohol, appreciable quantities begin to be burned in five to eleven minutes after administration. Sucrose, lactose and levulose gave similar results: whereas glucose and maltose began to be oxidized only after twenty to thirty minutes.

The oxidation of alcohol is completed rather slowly; with c.c. per kilogram, it requires about eighteen hours (Voeltz and Dietrich, 1913).
In man, the combustion of 30 c.c. requires about 8 hours; of 45 c.c. 12 hours (Higgin, 1917). It is not materially faster in habituated individuals, as claimed by Pringsheim, 1908.

Likewise, liver emulsions from habituated animals do not destroy alcohol faster than those from non-habituated animals (J. Hirsch, 1916). The destruction is said to be hastened by fever. Increase of external temperature is said to lessen its oxidation and to promote its excretion (thus 66 per cent. oxidized at 16°C; 92 per cent. at 36°; Voitz and Baudreux, 1913).

Alcohol can also be utilized in the form of rectal injection. Thus, T. M. Carpenter, 1917, found the respiratory quotient (in man) generally lowered in 2 to 3 hours after the injection of 25 c.c. of alcohol diluted to 5 or 10 per cent.

**Blood Cadilose.—**In dogs, this is usually increased by gastric administration of alcohol, presumably through increased output by the liver. Intravenous injections diminish the catalase content by direct destruction (Burke, 1917).

**Absorption of Nitrogen Metabolism.—**Mendel and Hilditch, 1920, have investigated the effects of moderate quantities on man and dogs. Giving, in man, large quantities, corresponding to 96 c.c. of 95 per cent. alcohol (500 calories), divided into six doses per day, with constant diet, they found no pronounced disturbance in the alimentary utilization of food. These doses spared protein; the partition of the urinary nitrogen was unchanged, except that the purin excretion, both endogenous and exogenous, was increased. Larger doses caused a loss of nitrogen and a relative increase of urinary ammonia.

With smaller doses (40 c.c. of rum, three times daily) and in individuals accustomed to its use, Hammers, 1916, found no increase of uric acid.

Stehle, 1915, found no increase in the excretion of endogenous uric acid. Winterstein, 1914, claims that alcohol increases the gas-metabolism of the spinal cord of pigs. **Subacute Alcoholic Intoxication.**—Salant and Hinkel, 1916, found that this caused, in well-fed dogs, a moderate diminution of the total urinary nitrogen and sulphur, a much greater decrease of the inorganic sulphates and phosphates; a tendency to retention of chlorides; a diminution of indiesan; and an increase of neutral and ether sulphur.

**FOOD-VALUE OF ALCOHOL.**

Whilst there can be no doubt that alcohol is an excellent food, in the sense of being a source of energy, other factors must be taken into consideration. The increased nutrition may itself be detrimental to the body, either by preventing the complete combustion of metabolites (which may be connected with the origin of gout), or by leading to an abnormal deposition of fat. A still more potent objection to considering alcohol as a generally useful food lies in its toxic action, especially its psychical effects. Alcohol should therefore be employed as a food only when a sufficient supply of energy can not be obtained from an ordinary diet, for instance, in digestive disturbances, or when the demands of the organism are unusually large, as in fever.

The proverbial obesity of persons addicted to the overuse of weak alcoholic liquid (in which the nutrient effect is less obscured by the toxic actions), is a striking illustration that too good a nutrition is not necessarily beneficial. That alcohol lessens the oxidation of metabolites is shown by an increased excretion of uric acid and ammonia nitrogen at the expense of urea (Paton and Eason, 1901; Mendel and Hilditch, 1916). This points to a modification of the functions of the liver.

Excessive doses of alcohol are always detrimental to nutrition, lessening both assimilation and dissimilation. The effects resemble those of the anesthetics.

**Alcohol in Diabetes Mellitus.—**Alcohol would be expected to act favorably as an easily digestible food, supplying the place of the sugar, and diminishing the excretion of mannitol on proteins, and thus lessening the risk of acidosis. This expectation has been partially verified: Benedict and Findlay, 1906, found that the replacement of 30 to 50 gms. of food-fats by isodynamic quantities of alcohol lessened the excretion of sugar, acidosis, and nitrogen. O. Neubauer, 1906, also reports it as useful.

On the other hand, Higgins, Peabody and Fitts, 1916, found that alcohol (100 to 180 c.c. of whiskey per day) did not prevent acidosis in normal persons on carbohydrate-free diet. Mosenthal and Harrop, 1918, also found that alcohol was unable to replace isodynamic quantities of protein or even fat in conserving a nitrogen balance.
Excessive quantities, however, can not be expected to exert a favorable action, and the toxic effects will predominate. Salat, 1906, fed rabbits on alcohol alone, and found no increase of hepatic glycogen; nor did large doses retard the disappearance of stored glycogen.

Use of Alcohol in Convalescence and Debility as an "Analeptic," Restorative" or "Stimulant."—The value of alcohol in these conditions is supported by long experience. Its action must be quite complicated. In the absence of organic lesions a great deal may be expected from improving the symptoms. This, like nursing and hygiene, increases the comfort and well-being of the patient, and starts him on the way to improvement. Alcohol meets these indications in an excellent manner: the feeling of well-being caused by it, the sense of capability, the removal of worry, the enjoyment in the act of taking it, the rest and sleep induced by its narcotic action, its food-value and its beneficial effects upon digestion, all concur in its action. To this may be added its slight but certain effects upon the vascular system—the altered distribution of blood, the diminished resistance to the heart—which may be of benefit in some cases. For these purposes, the alcohol should be taken well-diluted, as light aires or beers.

Use of Alcohol in Depressed Psychical States.—(Hypochondria, Melancholia, Neuralgia, and other obscure nervous diseases.)—This relieves the patient, by its mild narcotic and euphoric action—but the temporary relief is generally obtained at the expense of a permanent alcohol habit, and is therefore not to be advised.

Use of Alcohol as a Hypnotic.—Alcohol, especially in the form of beer, taken at night and in the absence of excitement, is a fairly efficient hypnotic; but its usefulness is limited by the danger of chronic alcoholism. The hypnotic dosage corresponds to 45 to 60 Gm. of alcohol.

CONTRAINDICATIONS TO ALCOHOL

These may be briefly resummarized as: Danger of habit; states of excitement; athenic stage of fevers; irritation of the alimentary or genitourinary tract.

ACUTE ALCOHOL POISONING

With excessive doses, the "stimulant stage" passes progressively into the narcotic, anesthetic, and paralytic stages. The narcotic stage may be said to exist when the symptoms of lessened psychic activity assume prominence. Sensation and motion become impaired. Speech is thick and muttering, the gait uncertain, the special senses are blunted. Drowsiness sets in. The face, which was flushed, may become pale. Vomiting occurs. Consciousness and sensation and muscular tone are gradually lost completely. This constitutes the anesthetic stage.

In the paralytic stage proper, the symptoms are those of beginning medullary paralysis; the respiration is slow and stertorous; the pulse scarcely discernible. Skin cold and cyanotic. Pupils generally dilated. Reflexes abolished. The temperature falls severely. The odor of the breath is diagnostic.

If very large doses have been taken on an empty stomach, these paralytic symptoms may set in at once.

Death is relatively rare. It may occur within half an hour, or the coma may grow deeper and terminate in paralysis of the respiration or the heart, or in pulmonary
edema; generally within twenty-four hours. If the coma lasts beyond thirteen hours, recovery is exceptional. Death may also occur later, either from prolonged coma; or after a protracted debauch, as the result of gastric irritation and debilitation.

The acute fatal dose is probably variable. In analogy with animals, it would require about a pint of whisky; and cases of death from such quantities are recorded (Lewin).

**Recovery.**—The coma—if the intoxication has progressed so far—passes into natural sleep, often with sweating. On awakening there follows a series of symptoms pointing mainly to *acute gastric catarrh*, and perhaps to functional neuritis; and grouped by the Germans under the name of "Katzenjammer." Headache, coated tongue, loss of appetite, irritable stomach, diarrhea, muscular pains, etc.

The *kiel*, after severe alcoholic poisoning, may show effects resembling those of contusions or burns; edema, blisters, extravasation of blood, and gangrene. Bedsores are especially common. These effects may perhaps be due to injury to the capillaries, or neurites.

The *treatment of acute alcoholism* consists in evacuation of the stomach preferably by apomorphin, which acts also as a hypnotic; and the administration of stimulants, caffeine or strychnin. The subsequent headache and nervousness are met by bromids and caffeine. Sodium bicarbonate lessens the gastritis.

**THE ANTAGONISM OF ALCOHOL AND CAFFEIN**

This has been studied by Pilcher, 1913, on cats. The combination of small doses of alcohol and caffeine result in an antagonistic effect, but the combination of larger (half-fatal) doses results in greater depression and greater fatality than if either drug were used alone. The ordinary doses of caffeine would tend somewhat to decrease the severity and hasten the recovery from severe, but not fatal alcohol poisoning. With fatal doses of alcohol ordinary doses of caffeine would have no effect, and larger doses would be detrimental.

**THE HABITUAL BUT MODERATE USE OF ALCOHOL**

*It may be considered as probable that a certain amount of alcohol (variable in individual cases) may be taken daily without any demonstrable permanent injurious effect. But it stands equally certain that it is as dispensible to the organism as nicotine or caffeine, and that it must be looked upon purely as a luxury. The injury done by such use of alcohol lies chiefly in the fact that it is so apt to lead to the use of immoderate amounts.*

**Lessened Resistance.**—Perhaps the only positive evidence of injury from small doses of alcohol is in this direction: Hunt, 1907, found that the long-continued administration of small quantities of alcohol to mice or guinea pigs increases their susceptibility to the fatal action of acetanilide. This is attributed to a derangement of metabolism which hastes the decomposition of the non-toxic nitrile into the cyanid. It is not produced by methyl alcohol, chloral, etc. Laitiner, 1907, also claims that very small doses (0.1 c.c. per kilogram, daily) suffice to render the erythrocytes less resistant to hemolysis; and also lessen the resistance to infectious diseases. He asserts that this lessened vitality is transmitted to the offspring.

Mueller, 1904, Wirgin, 1905, and others have found that the formation of salicylic acid is lessened, if rabbits are kept mildly intoxicated for several days after the injection of an antigen.

For human subjects, Reich, 1015, also claims diminished resistance of erythrocytes to hypotonic solutions, and slight decrease of the bactericidal action of serum against typhoid bacilli. The effects, however, varied greatly, so that it is difficult to estimate their importance. Phagocytosis was not affected.
ALCOHOL

CHRONIC ALCOHOLISM

The excessive habitual use of alcohol leads to effects which may be grouped together under the name of chronic alcoholism, and which depend in part upon the irritant action of the alcohol, in part upon specific injury to the neurons.

**Gastro-intestinal Irritation.**—The first effects are local, and depend largely upon the concentration of the spirits. They consist of a catarrh of the whole alimentary canal, progressing from the pharynx downward. They are characterized by the usual symptoms of catarrhal gastroenteritis: sense of appetite, gastric distress, irregularity of stools, craving for spices, etc. The chronic catarrh leads to malnutrition and emaciation when strong spirits are used. It also appears to constitute a predisposing factor in carcinoma of these organs. In the case of excessive beer-drinking the abnormally over-distention of the stomach leads to chronic dilatation.

**Degenerative Changes in Internal Organs.**—The continued presence of alcohol in the body sets up a series of irritant and degenerative phenomena in various other organs with which it comes into contact. These changes consist in fatty infiltrations, cellular degenerations, and hyperrophy of connective tissue.

The necrotic changes in the tissues cells must be attributed to the continued irritation from the constant presence of the alcohol; and to this must be added the interference with circulation due to the changes which alcohol causes in the blood vessels. These are the direct irritant action of alcohol on the cells, and the impaired circulation—re inseparably connected in the production of the degenerations. Of these, the fatty is the most common, since alcohol, by its combustion, prevents the normal consumption of fat. Connective-tissue formation results as the ordinary consequence of necrosis of the parenchyma.

These changes are proportional to the concentration of the alcohol. Since this is naturally greatest in the liver, kidneys and blood vessels, these organs show the action most and most prominently. In the liver, again, the periphery of the lobules is mainly affected. Chronic alcoholism is probably the most common cause of hepatic cirrhosis (perhaps half the cases; but only 5 or 6 per cent. of the alcoholics develop cirrhosis; Baumgarten, 1908).

McJunkin, 1917, however, points out that the evidence of the alcoholic factor in the causation is not quite clear; probably the action is indirect. He failed to obtain cirrhosis in animals by any method of administration. Other observers obtained discordant results (A. L. Gruver, 1916; Littauer). The positive data are perhaps spontaneous (rabbits),

Next in point of time comes the action on the blood vessels. This is of especial import, since it contributes materially to the degenerations in other organs. The principal changes are in the intima; there are fatty degenerations, loss of elasticity and atrophy.

These may lead to ruptures (apoplexy, etc.).

The degenerative changes in the kidneys lead to nephritis, with cirrhosis, albuminuria, diminished secretion of urine, secondary weakening of the heart, etc. The heart itself, however, in common with skeletal muscle, shows primary fatty degeneration. This, together with the atheroma, etc., leads to hypertrophy and dilatation of the heart, and later to dropus, etc. The heart rate is generally rapid. The fatty changes in voluntary muscle lead to muscular debility, especially in beer-drinkers, in whom there is more material for fat formation. Gout is a common sequel of moderate alcoholism.

The respiratory organs show a chronic catarrhal inflammation of the passages, and disposition to fatal pneumonia. Changes in the skin—vascular ecchymoses, acne rosacea, disposition to furuncles and carbuncles—may be counted among the earlier actions.

In experimental chronic alcoholism, in rabbits, produced fatty changes in the heart, liver and kidneys, and cellular infiltration of the pia (Lissauer, 1914). Hepatic changes occur also on intravenous injection (Schaaf, 1913). In the heart, Otto, 1914, found generations of ganglion cells, atrophy of muscle, and scar tissue. Large single doses 1 As a result of an extensive study of anatomy material, Cabot, 1900, disagrees with the common opinion that alcoholism is a cause of arteriosclerosis.
(4 c.c. per kilogram) may also cause changes. Single small doses do not leave any lesion (v. Otto, 1914).

These various anatomic lesions of important organs result in a pronounced lowering of the "powers of resistance," and a high mortality with infectious diseases, operation, etc. It appears that the amount of antitoxic complement is lessened.

Nervous Phenomena.—These differ from the preceding in that they are partly functional.

Ten to 30 per cent. of the cases of insanity are attributed directly to alcoholism; but Heron, 1912, found the proportion of mental defects as high in the recent, as in old cases of alcoholism. Epilepsy, which is a hereditary nervous disease, is 70 times as frequent in alcoholics as in the general population. These facts indicate that alcoholism is the effect, rather than the cause, of mental degeneration.

However, alcohol may cause various types of acute delirium and mania.

On the part of the motor system there are tremors and late convulsions and paralyses, the latter partly the result of peripheral neuritis.

It is difficult to exaggerate the importance of habit and repeated impressions on the psychic activities. The constant repetition of the features of alcoholic excess could not but produce in this manner a permanent mental degeneration. But associated with this functional feature are marked anatomic changes, due to the same causes as similar changes in other organs; and, lastly, it must be remembered that alcohol has a specific action on the nerve cells.

Among the anatomic lesions which have been observed are: Chronic meningitis with thickening; serous effusions into ventricles; softening; tendency to hemorrhage and apoplexy. Histologically, shrinkage and alterations in the staining properties of the cells (Fig. 24) and changes in the dendritic processes have been observed.

Clinically, the first effects are shown by diminished activity of the individual. This occurs even with very moderate doses. (Nice, 1912, found the activity of white mice, as recorded by a revolving cage, to be reduced by one-fourth through chronic alcoholism.) Later there is a diminished acumen of the special senses and of the restraining powers, leading, the former to disturbances of vision, the latter to degeneracy and dementia, often suicidal. It is a noteworthy fact that by far the greater proportion of insane asylums and prisons were addicted to the excessive use of alcohol.

Children of Alcoholic Parents.—The influence of alcoholism of the parents on their offspring is still an unsolved problem, the data as well as opinions being so contradictory that no definite conclusions can be drawn.

Miss Eldeston and Karl Pearson, 1910, in a statistical study covering 3,600 school children, found no real evidence of either physical or mental deterioration (death rate, mean weight and height, general health, mental and visual defects). They conclude that the danger of alcoholic parents lies in the transmission of the hereditary defects which caused the parental alcoholism. At the other extreme, von Bunge, 1909, claims that chronic alcoholism on the part of the father renders the daughter incapable of efficient lactation, and that this incapacity, as well as a tendency to tuberculosis and caries of the teeth is transmitted to subsequent generations. But if this danger were as great as it is painted, it is difficult to account for the comparatively vigorous populations among whom chronic alcoholism has been fairly common for many centuries, or for the fact that some mothers still nurse their children.

Bertholet, 1900, finds that the testicles of chronic alcoholics generally show atrophy of the parenchyma, and increase of interstitial tissue, with corresponding decrease and abnormalities of the spermatogenesis. This would lead to more or less impotence. Ivanow, 1913, reports that the addition of 2 per cent. alcohol in urine has practically no effect on the motility of spermatozoa; 12 per cent. has little effect; with 15 per cent. there is marked impairment. Contact for thirty minutes with 10 per cent. alcohol does not hinder their fertilizing action, and the fertil is normal.

Arlitt and Wels, 1917, claim that in animals the spermatic tissue reacts before any other to the daily administration of alcohol.
 Exposure of the ova or spermatocoea of the fish fundulus to alcohol before fertilization produces impaired and abnormal development (Gee, 1917). Of course, the concentrations and other conditions of such experiments are so peculiar that they have little meaning for the human problem.

Pearl, 1916, found the progeny of fowl treated with ethyl or methyl alcohol or ether rather stronger than the controls, although fewer eggs were hatched.

Stockard, 1912, finds that chronic alcoholism, induced in guinea pigs, either parent, diminishes fertility and causes most of the embryos to die before or shortly after birth. The offspring is often defective, sometimes with gross deformities. This degeneration is transmitted for at least three generations; in fact, it rather increases (1914). Stockard also found (1909) that alcohol and other anesthetics cause various morphologic defects in fish embryos, but this of course is a very different matter. Whitney, 1913, found that cultivation of ratifers in 1/4 to 1/2 per cent. alcohol lessens their resistance to copper, the injury increasing with successive cultivations; but if the alcohol was withdrawn, the normal resistance was recovered in the second generation. With these animals therefore the alcohol has no direct influence on the germ-plasm. With female pigeons, the daily inhalation for one to two hours of nearly paralyzed doses of alcohol, for two to four months, reduced the size of the egg-yolk quite materially (Riddle and Bassett, 1916).

McDowell, 1919, observed lowered efficiency in the solving of maze and similar problems by the non-alcoholic offspring of heavily alcoholized rats.

While it is not proven that ordinary alcoholism has a direct influence on the germ-plasm, it is certain that the embryo is exposed to the influence of the alcohol, since this passes readily through the placenta, and exists in the same concentration in the fetal blood as in that of the mother (Nicolous, 1903). This may be supposed to cause a more or less persistent lowering of the resistance, and account for the high mortality among the children of alcoholics; the usually poor hygienic surroundings would contribute to this result. Moreover, the children will inherit the degeneracy which induces alcoholism in the parents. The statistics of prisons and asylums indicate a tendency to psychic and moral degeneracy amongst the descendants—epilepsy, idiocy, insanity, disposition to crime and to alcoholism. It is not decided whether the defective alcohol inheritance causes a degeneration induced in the parent by alcohol, or the degeneration underlying the abuse of alcohol. The latter is more probable.

Other Intoxicants. Alcohol is not the only member of the hydrocarbon series which has been abused as an intoxicant. Ether, chloroform, chloral, paraldehyde and even turpentine and gasoline have their devotees. Their effects, in so far as they have been studied, correspond closely to those of alcohol.

Treatment of Chronic Alcoholism. This follows the same principles as with other drug habits. The first essential is the complete withdrawal of the drug. This may be facilitated by scopolamin (see under "Morphin Habit"). A diastase may be created by the addition of some nausea (apomorphin), but the effect of this deception is usually not lasting. Suggestion may be very useful. The local action of the alcohol may be replaced by capiscum or ginger, the stimulation by beef-tea; the depression may be met by caffeine, the insomnia by bromid. The prospects of cure are better than with morphin or cocain; but the patients will often relapse.

Delirium Tremens. This peculiar manifestation occurs in drunkards when their forces are unusually weakened—by extraordinary excess, or by the suppression of their usual allowance of alcohol; by absence of food; exposure; overexertion; trauma; hemorrhage; operations; psychic shock; or in any serious illness, especially in pneumonia. Premonitory symptoms of restlessness, tremor, insomnia, and anorexia last usually a couple of days. They pass into excessive tremor, persistent insomnia, violent and talkative delirium and terrifying specific hallucinations of sight (often small animals), touch, and sometimes hearing. It usually runs its course
in a few days, ending in prolonged sleep. Acute anhydramia has been reported (Kaiser, 1912). The treatment aims to support the strength of the patient by allaying the gastritis and giving light but nourishing food. The insomnia, restlessness and excitement should be treated on their first appearance, by moderate doses of sedatives and hypnotics; such as bromid (1 Gm. every one to four hours; chloral at night (not over 1 Gm., since large doses have caused death); veronal (1 Gm.); paraldehyde (3 Gm.); morphin; or scopodol (o.5 mg.). Ergot has been advocated, and the statistical study of Ransom, 1909, seems to be in its favor, although it is not conclusive.

Petechial hemorrhages in the gastric mucosa are very common lesions in necroses of delirium tremens patients. They exist without any evidence of acute inflammation, and must be due to a direct toxic action on the vessels (E. F. Hirsch, 1910). The pulmonary capillaries may contain fat emboli, as in other convulsive conditions (MacCallum).

PECULIARITIES OF ALCOHOLIC BEVERAGES

Common experience teaches that the effects of the various alcoholic beverages differ in minor details. These differences are due to the concentration of the alcohol, extractive matter, and to the presence of esters and higher alcohols. However, the scientific data are scanty and unsatisfactory.

Beer owes its hypnotic qualities somewhat to the lupulin of the hops as well as to the alcohol. Some wines are also hypnotic, while others—the majority—are exciting. The diuretic action of gin is largely due to the essential oils contained in it.

Absinthe produces hallucinations and finally epilepsy. The Mexican drink, "pulque," produced by the fermentation of the juice of the maguey plant, produces an alcoholic intoxication in which the thought and language are low, the patient is boisterous and quarrelsome, and, it is said, generally unhappy.

The stronger spirits contain, besides alcohol, substances which may pharmacologically be divided into two groups: the "oceanic ethers" that give the bouquet (flavor), which add to the stimulation and have no other marked action; and those that have a deleterious effect. The latter—which are commonly called impurities—are largely destroyed by age. The most abundant is amyl alcohol (fusel oil).

The action of these "impurities" as far as studied is, upon the whole, similar to that of alcohol itself, but more toxic. However, the whole subject is in dispute. (The literature is abstracted by R. Foerster, 1910.)

Friedenwald, 1911, found that, with intravenous injections into rabbits, the toxicity of alcoholic liquors, wines and beers was higher than would correspond to their alcohol content. The small value of these results is illustrated by the fact that they would place the toxicity of pure 10 per cent. alcohol considerably above that of 38 per cent. The aldehyds have a strongly irritant action on mucous membrane—as shown by formaldehyde or acrolein (allyl-aldehyde—the vapors of overheated fatty oil). Furfural, which was formerly believed to modify the intoxication, does not appear to do so. Larger doses are convulsant (Laborde, 1888).

Artificial liquors are made by the admixture of ethers and essential oils to alcohol. Their action is not uniform, but it is generally believed to be more irritating locally, and more injurious to the brain.

PREPARATIONS—ALCOHOL

Alcohol Dehydratum (Alcohol Dehyd.), U.S.P.; Alcohol Absolutum (Alcohol Absol.), B.P.—Not less than 99 per cent. by weight of C₂H₅OH. Very hygroscopic.
ALCOHOL

"Alcohol, U.S.P.; Spiritus Rectificatus (Sp. Rectifi.), B.P.—Not less than 92.3 per cent. by weight, 94.9 per cent. by volume, U.S.P.; 90 per cent. by volume, B.P., of C₂H₅OH. Colorless, volatile liquid, of characteristic odor and burning taste. Freely miscible with water, ether, chloroform, etc.

Dilution.—Since a condensation occurs on mixing alcohol and water, the percentage of the resulting product can not be deduced by the formula per cent. + (v + v). Tables for making the commonly needed percentages by the dilution from the official alcohols are given in the U.S.P. (pages 532 and B.P. (pages 565 and 559).

Alcohol Dilution (Alcohol Dil.,) U.S.P.—A mixture of equal volumes of official alcohol and water, containing 41 to 42 per cent. by weight or from 48.5 to 49.5 per cent. by volume of C₂H₅OH.

*Distilled Spirits.—These include whisky (Spir. Frumenti), distilled from the mash of fermented grain and aged for at least two years; 44 to 55 per cent. of alcohol by volume; average proof, 13 c.c. 45. Brandy or Cognac (Spir. Vini Gallici), same per cent. Of about the same strength are the other spirits, which are less used in medicine. Holland Gin, distilled over juniper berries; Common Gin, often containing turpentine; Rum from molasses; Arrack from rice, etc.

Mistura Spiritus Vini Gallici.—Four ounces each of brandy and cinnamon water, two yolks of eggs, and 1/2 ounce of sugar.

WINES

These are made by fermenting the expressed juice (must) of the grape. If this contains the skins of dark grapes, the wine will be red; if made from light grapes, or from the juice of dark grapes without skins, it is "white," i.e., an amber color.

A wine which contains much alcohol (15 to 20 per cent.) is "generous"; one poor in alcohol, "light"; one containing much sugar, "sweet"; poor in sugar, "dry." If it contains CO₂, it is sparkling; if tannin, "rough" or "stringent"; if acid tartarates, "acidulous." The last two ingredients may interfere with digestion if the wine is habitually used.

The most important wines are:

Sherry (Vinium Xerizum): Dark amber, dry, little acidity (Madeira, Marsala, Tokay, Xhlaga, are similar, but more sweet)
Port (Vinium Fortense): Deep purple, rather sweet and rough.
Claret (Bordeaux): Red, dry, with some degree of acidity and astringency.
Champagne: Pale amber, sweet, sparkling.
Riesling and Muscat: Pale amber, dry, slightly acid.
Cvelawka: Amber, dry, rather acid (or sweet)

Unfermented Grape Juice (i.e., must, preserved by heat or an antiseptic) can scarcely be considered a medicinal agent.

Other Fermented Liquors.—

From Apple: Cider, From Pear: Perry, 5 to 10 per cent. (by weight).
From other fruits,

Malt Liquors.—These contain alcohol, CO₂, sugar, and usually hops. The color varies from pale amber to dark brown, the difference being due mainly to charring of the malt. Lager beer is made by slow fermentation at a low temperature; porter, ale, and stout by rapid fermentation at a higher heat. Their alcoholic strength is as follows:

Ale, Porter, Stout, and Export Beer 5 to 6 per cent. by weight.
Lager Beer 2 to 3 per cent.

By fermenting milk, a pleasant alcoholic liquid, "Kwiss," can be obtained, which contains 3 per cent. of alcohol.

HIGHER ALCOHOLS

In acute intoxication, the toxicity of the alcohols increases with the size of the molecule, as shown in the following table (Baer):

| Methyl, CH₃OH | 65 | 0.8 |
| Ethyl, C₂H₅OH | 78 | 5.0 |
| Propl, C₃H₇OH | 98 | 2.0 |
| Butyl, C₄H₉OH | 107 | 3.0 |
| Amyl, C₅H₁₁OH | 131 | 4.0 |
MANUAL OF PHARMACOLOGY

This (Richardson's law) applies also to the individual tissues: sensory and motor nerves, epithelium, muscle, ova, heart (Kuno, 1913). It is quite conceivable that the late actions may differ more markedly from those of ethyl alcohol; as they do, f.s., in the case of methyl alcohol.

ISO-AMYL ALCOHOL

The main constituent of "fusel oil," is more violent than ethyl alcohol in its acute and subacute actions (Salant, 1909) and the after-effects are more pronounced; but its admixture up to 1 per cent. produces very little difference in acute alcoholic intoxication (Baer, 1898).

METHYL ALCOHOL

General Statement.—The extensive use of this substance (Wood Alcohol, Columbian Spirits) in the arts (as a combustible, solvent for shellac, etc.) and as an adulterant of alcoholic beverages and medicines has given rise to numerous cases of poisoning. The acute symptoms resemble ordinary alcoholic intoxication. The main differences are in the stronger local irritation and in the more protracted and more serious after-effects, the coma lasting several days and often terminating in death. A very important feature is the frequent occurrence of incurable blindness from retrolubar neuritis and retinitis. This may occur after taking 10 c.c., but the individual susceptibility varies greatly. The effects are produced by the purest samples, and are therefore due chiefly to the methyl alcohol itself, although they may be exaggerated by the impurities (acetone, etc.) which are usually present. Methyl alcohol should never be applied to the body, externally or internally. Its presence in foods and drugs is prohibited by law. Protection against the inhalation of its vapors should be enforced in the trades. The treatment of poisoning by methyl alcohol includes evacuation, stimulants, heat, and morphine to allay suffering.

Etiology.—The practical seriousness of methyl alcohol poisoning is illustrated by the fact that Buller and Wood found 153 cases of blindness and 122 deaths recorded up to 1904, although the existence of the danger had only been recently recognized. A wholesale poisoning occurred among the inmates of a Berlin municipal lodging house (Stadtmann and Magnus Levy, 1912; Review of series of papers, Year Book, Am. Pharn. Assoc., 1912, 1:304-307; Baskerville, 1913), has abstracted the cases in the literature. About 81 million gallons are produced annually, and 2 million people are engaged in trades where it is employed (Wilbert, 1915.) Adulterated eucalypt and bay rum, etc., have often proved toxic when used externally. The vapor of methyl alcohol (varnish) is dangerous if ventilation is insufficient (recent Bibliography, J.A.M.A., 1913, 60:1227). The inhalation is also highly toxic to animals, the effects agreeing with those in man (Tyson and Schoenberg, 1914). Considerable absorption occurs when the air contains 0.2 per cent. (A. Loewy and Heide, 1914.)

General Symptoms.—These begin with gastrointestinal disturbance, abdominal pain, general weakness, nausea, vomiting, vertigo, headache. The symptoms of ordinary alcoholic intoxication supervene, with delirium, restlessness, unconsciousness, collapse and coma. The pupils are usually dilated and iridescent; nystagmus may be present. Dyspnœa and cyanosis are marked. The temperature is subnormal. Death is very much more frequent than with ethyl alcohol. It occurs in coma, from respiratory paralysis, in a few hours to three days. The fatal dose is probably from 100 to 300 c.c. The postmortem lesions show irritation of the stomach, duodenum, kidneys, and bladder. Continued use leads to fatty degeneration of the liver.

Late Symptoms.—Sometimes the symptoms are deferred for several days and then prove rapidly fatal. Delirium may set in after the acute symptoms have subsided. Cystitis is a frequent sequel. The most important sequel, however, is the optic injury. The symptoms are bilateral and consist in scotoma, dimness or total blindness; the pupils are dilated and insensitive to light. The loss of vision may start in a few hours, or be delayed several days; it generally becomes complete; subsequently there is some improvement, which in most cases, however, finally relapses into total blindness (Buller and Wood, 1904; other reports summarized by Woods, 1912). The
anatomic changes consist chiefly in hyperemia and edema of the fundus and destructive inflammation of the optic nerve or retinal elements or both, followed by their atrophy (Tyson and Schoellkopf, 1914). The effective dose varies greatly: 50 c.c. has caused blindness in some cases while 90 c.c. has failed to do so in others. Permanent impairment of vision occurs in something like half of all cases of poisoning (for other toxic amylopectins, see "Nicotin"). The pathologic changes in rabbits are described by Kasava, 1913.

The cause of the peculiarities of methyl alcohol poisoning has not been satisfactorily explained. In animals, the acute toxicity of methyl alcohol is about 10 per cent. less than that of ethyl alcohol (also for rottlers, Whitney, 1912), but the subacute toxicity is markedly greater. The symptoms develop more slowly, even on intravenous administration and are much more protracted: While the ethyl alcohol coma lasts only six to twenty-four hours, that of methyl alcohol lasts three to four days. This protracted action leads to cumulative effects: Pohl, 1837; Reif, Hunt, 1902; Langnard, 1913; and Sollmann, 1921, found that the daily repetition of sublethal doses is more fatal with methyl than with ethyl alcohol. Birch Hirschfeld demonstrated a similar cumulative action on monkeys. "Tippling" has also been found especially dangerous in man.

Excretion and Fate.—The protracted and cumulative action is connected with the slow excretion. Voeltz and Dietrich, 1912, found after 2 c.c per kilogram that during two days about 21 per cent. were excreted unchanged by the lungs. 3 per cent. by the urine, 39 per cent. had been burned, and 37 per cent. were still in the tissues. Nicloux and Placet, 1913, found it present in the blood and brain after five days. The brain, however, is not an important storage organ; the alcohol being more soluble in water than in fats (Pohl, 1910).

The concentration in the blood is about the same as in the urine (Chabanier and Ibarra-Loring, 1910). The slow destruction would explain the cumulative; but there may be an additional factor: While ethyl alcohol is oxidized completely to CO₂ and H₂O, methyl alcohol is oxidized mainly to formic acid (Pohl, 1890). This is excreted rapidly by the urine, but gives rise to acidosis (increased ammonia excretion, Krol, 1913), and this may be responsible for the symptoms. v. Fellenberg, 1915, claims that methyl alcohol is readily formed from the pectin of fruit and vegetables, pectin yielding from 0.1 to 12 per cent. of methyl alcohol. He asserts that this is not harmful, being practically completely burned in the body; whereas if the methyl is mixed with ethyl alcohol, as in liquors, the combustion is incomplete, and harmful results from relatively small doses. Confirmation should be awaited.

Impurities.—The best commercial wood spirit contains about 95 per cent. of methyl alcohol; the common varieties 75 to 90 per cent.; some samples only 35 to 40 per cent. The impurities consist of acetone, methyl acetate, ethyl alcohol, ether, emulsifying products, etc. (Baskerville, 1913). It has been suggested that these are responsible for the peculiar toxicity (Mueller, 1915; Robert, 1910). However, most investigators have found no essential difference between the ordinary and the purest obtainable products (Hunt, 1902; Buller and Wood, 1904; Ahrends, 1910; Sollmann, 1921); nor do any of the impurities produce the characteristic effects (Baskerville, 1913).

ACETONE (DIMETHYL-KETONE)

Acetone, U.S.P.; CH₃CO·C₂H₃, is used as a solvent for fats, resins, rubber, etc.; for the preparation of oleoresins. It is a rather feeble narcotic, causing considerable dyspnea (Albertoni, 1884). Hypodermically (guinea pigs) it is much more toxic than methyl alcohol (Khany, 1912). It is excreted mainly by the lungs. The citrine excretion in fasting dogs is diminished by caffeine and cocaine (Cervello and Greigli, 1914).

DENATURED ALCOHOL

Alcohol for industrial uses is mixed with various nauseous substances, to unfit it for consumption, and thus secure exemption from the internal revenue tax. The standard formulas contain 55 to 95 per cent. of grain alcohol, 2 to 10 per cent. of wood alcohol, and 5 per cent. of benzene or of pyridin bases. A few other formulas are authorized for special technical purposes.

The use of wood alcohol for denaturing industrial alcohol is to be deprecated, since prolonged exposure to vapors from alcohol containing only 4 per cent. of methyl alcohol has given toxic eye symptoms (J. M. Robinson, 1918). Poisoning by denatured alcohol (containing 1 per cent. of wood alcohol) has become quite common in Russia since the prohibition of grain alcohol. Visual disturbances occur, generally after three to four months, or with large doses (Eleonskain, 1916).
ETHER AND CHLOROFORM GROUP

General Statement.—Ether, chloroform and other volatile hydrocarbons are employed mainly for producing surgical anesthesia. They depress successively the psychic centers, then probably the basal ganglia and cerebellum; then the spinal reflexes, first the sensory, and then the motor functions of the cord, probably from below upward; and finally the medullary centers. The most highly evolved functions are affected first. Chloroform also has a direct depressant effect on the cardiac muscle and is generally more dangerous. Locally, they act as irritants.

Discovery of Surgical Anesthesia.—The use of narcotics for lessening the pain of operations dates back to antiquity; however, the discovery of the means to achieve complete and safe anesthesia is an accomplishment of the nineteenth century (1842 to 1847). The credit for this discovery must be divided between several investigators: Humphrey Davy for the definite suggestion; C. W. Long for the independent discovery but inadequate publication of ether anesthesia; Horace Wells for the successful use and publication of nitrous oxide; Jackson and Morton for the successful public demonstration of etherization; Flourens and Simpson for the introduction of chloroform.

The Egyptians probably employed narcotics. The Assyrians are said to have strangled the children before circumcision, producing anesthesia by the aid of CO. This method was revived by Valverdi in Italy early in the seventeenth century. The Chinese used hashish. All kinds of narcotics were given during the middle ages, especially opium and drugs containing hyoscin (such as the legendary “mandrake,” Mandragora officinalis). The recent “Scopolamin-Morphin-Anesthesia” is an interesting reversion to this ancient method, which became obsolete when the vastly superior halation anesthesia was discovered.

Sir Humphrey Davy in 1799 announced the anesthetic properties of nitrous oxide (laughing gas) and suggested: “As nitrous oxide, in its extensive operation, appears capable of destroying physical pain, it may probably be used with advantage during surgical operations in which no great effusion of blood takes place.” Unfortunately, the suggestion was not acted upon at that time.

Dr. Crawford W. Long, of Jefferson, Ga., administered ether as a surgical anesthetic in 1842, but neglected the adequate publication of his discovery.

Dr. Horace Wells, a dentist of Hartford, Conn., witnessed an exhibition of “laughing gas” in a public lecture by Colton in December, 1844. He noticed that one of the subjects was insensible to pain; acting on this hint, he had a tooth extracted under its influence on the next day. The operation was a complete success. He introduced the gas into general dental practice in Hartford, and gave the matter wide publicity, without reservation. The intoxicating action of ether being well known, he tried this with Dr. Macy of New York, early in 1845, but thought it inferior to the gas.

There can be no question that Wells discovered anesthesia independently, and that he introduced it successfully into practice; and he seems to have been the first to realize fully the importance of the discovery. Unfortunately, an attempted public demonstration in Boston in January, 1845, failed partly and was met with ridicule.

The successful demonstration of ether by Morton threw nitrous oxide completely in the shade for many years. Wells was greatly disappointed, became insane and committed suicide (Truman Smith, 1858). "An Examination of the Question of Anesthesia." The use of the gas was revived about 1861 by Colton (whose demonstration he started Wells), and by 1868 it was extensively used in dentistry. It has since been reintroduced into major surgery, and has thus vindicated the claims of Wells.
he gave a perfect demonstration at an operation by Dr. J. C. Warren, at Massachusetts General Hospital. The complete success of this operation achieved the introduction of anæsthesia into surgery. Morton obtained a patent in November, 1846. This step, and the methods which he was said to have employed to obtain it, raised much opposition. His life was embittered by the controversies, and he died of apoplexy. Jackson, the third party to the unfortunate contention for priority, also became insane.

The use of anæsthetics spread rapidly, and related substances were tried: Chloroform was used on animals by Flourens in 1847, and in the same year, on the independent suggestion of McWaldie by Simpson of Edinburgh, on man. Flourens in the same year also called attention to ethyl chlorid. It was used surgically by Heyfelder in the next year, but then neglected till 1855.

The first fundamental scientific work on the action of anæsthetics was published by Snell, 1851. Ether was discovered by Valerius Cordus, 1540; chloroform independently by Liebig, Soubeiran and Guthrie, 1831.

Stages of Anæsthesia.—The main actions of alcohol, ether, chloroform, chloral, and the numerous other hydrocarbon or lipolytic narcotics are qualitatively similar; but they show practically important differences in severity, rapidity, duration and sequela. The successional effects may be divided into "stages." Hewitt, *ibid.*, classifies these as (1) analgesia; (2) light anæsthesia; (3) deep anæsthesia; (4) bulbar paralysis. Since the effects pass without abrupt transition from one stage to the other, any classification is arbitrary. In the following, they will be divided merely into the pre-anæsthetic, anæsthetic and paralytic stages. In surgical practice, the normal course of anæsthesia is generally "complicated" by asphyxial phenomena, traumatic reflexes, hemorrhage, etc.

Pre-anæsthetic Stage.—This sets in with a comfortable feeling of warmth, spreading over the whole body; but soon associated with a distressing sensation of suffocation, especially if ether is used and the access of air is limited, as in the "closed" methods. The local effects make themselves felt by prickling and smarting of the nose, throat and conjunctiva, with hypersecretion of mucus, tears and saliva. The suffocation, as well as the direct effects of the anæsthetics, result in more or less excitement and struggling, and sometimes convulsions, especially in hysterical patients. The reflexes are at first rather exaggerated, later somewhat depressed and less purposive. Tonic muscular spasm, general, or of the jaws, glottis or respiration may occur. The sensation becomes disturbed: the sensibility is impaired after the first few inhalations. Stimulation evokes responses, but without pain. This "primary analgesia," while the patient is still conscious, may be used for short operations, especially under chloroform and nitrous oxide.

The thoughts become confused, with hallucinations (noises, etc.), sensation of stiffness, and want of muscular control. The patient loses self-control and indulges in loud incoherent talking, laughing, singing, etc.; passing gradually into unintelligent muttering. These initial excitement symptoms vary greatly in duration and intensity in different patients. Alcoholic may exhibit violent delirium and even mania. Vomiting (probably central), retching, and coughing may occur. The face is flushed; the pupils at first dilated, then gradually constricted; the pulse rapid; the blood pressure increased; the respiration somewhat quickened and at times irregular, sometimes suspended if the vapor is too strong.

The Anæsthetic Stage.—This is the stage which it is aimed to produce and maintain. It is characterized by complete paralysis of the brain and of the motor reflex centers of the cord, and usually some depression of the medullary centers. Consciousness, sensation, and most reflexes are lost—
the corneal reflex being among the last. Consequently the muscles are lax. The smooth muscles are not usually affected, but there is sometimes a relaxation of the sphincters. The pulse is full and soft, the rate rather slow with chloroform, slightly faster than normal with ether; the blood pressure being lowered by chloroform, normal or rather raised by ether. The respiration is regular and deep, often softly snoring or stertorous; rather rapid with ether. The temperature falls in consequence of the lessened muscular activity and increased heat loss. The pupils are somewhat small and respond sluggishly to light. The face is pale with chloroform, often cyanotic with ether.

The medullary depression does not reach a dangerous degree if the administration is carefully done. But with prolonged anesthesia the pulse tends to become progressively weaker; the respiration becomes shallower and the temperature lower—it may fall as much as 5°C. This is due to parallelism of the function of temperature-regulation.

The paralytic stage is characterized by progressive paralysis of the medulla. This stage must be carefully guarded against.

All reflexes disappear. The respiration becomes shallow, irregular, labored, and then ceases. The skin is cold and pale, and covered with the clammy sweat of the “agony.” The pupils are widely dilated. The pulse becomes slow and weak, and ceases normally after the respiration.

Recovery of Patient from Normal Anesthesia.—The rapidity of the recovery is inverse to the duration of the administration. The first change after the withdrawal is usually in the respiration, which becomes quieter and less stertorous. Then the lid reflex and deglutition movements reappear. The pupils generally grow smaller, but dilate easily. The breathing is disturbed by swallowing, coughing, retching and actual vomiting, usually just before consciousness returns. This is commonly succeeded by sleep, lasting several hours. Thirst and gastritis persist for some time.

Individual Functions.—The proper administration of anesthetics requires a detailed knowledge of their effects on the important individual functions in the successive stages.

Respiration.—This is influenced, not only by the direct action of the anesthetic, but also by the patency of the respiratory channels; by local and distant reflexes; the state of the circulation, etc. In the early stages, if local irritation is avoided, the respiration is generally somewhat deeper and quicker from stimulation of the respiratory center. Most commonly it is apt to be irregular, especially if the administration is started abruptly on account of the struggling, choking sensation and local irritation. The latter may produce temporary expiratory stoppage by a trigeminal reflex (Kraitscher, 1870); but in man, this reflex is not usually so strong or lasting. The “choking” is especially pronounced with ether. Reflex closure of the larynx may produce asphyxia under chloroform (Bernard). With chloroform also spasmodic arrest of respiration may sometimes occur, especially in vigorous subjects, and is probably a common cause of the early deaths. This is less likely to occur if dilute vapors are employed.

As the patient passes into anesthesia, the breathing becomes regular and noisy; with ether, the depth and rate may at first be increased; with chloroform they are decreased, partly by the low blood pressure. The respiration is mainly diaphragmatic. The snoring and the louder “snore” are generally produced by the vibration of the tongue against the pharyngeal wall. “Stridor” is laryngeal, due to paralysis or spasm of the vocal
Ether and Chloroform Group

665

cords or obstruction of the glottis by mucus. As anesthesia deepens, increase of concentration usually makes the respiration temporarily deeper, quicker and more stertorous, and *vice versa*. Cheyne-Stokes respiration is not uncommon with chloroform, but exceptional with ether, because the CO₂ tension is high.

**Reflex Respiratory Changes.**—These occur even during full anesthesia but are most marked if the anesthesia is light. The respiration is usually stimulated by the operative procedures, and these may provoke coughing, deglutition, retching, stertor, or spasmodic inspiratory or expiratory arrest. Operations during partial anesthesia are therefore dangerous.

**Laryngeal Reflex.**—When a fresh portion of ether is poured upon the cone, the irritation of the more concentrated vapor causes the patient, so long as he is partly conscious, to hold the breath momentarily. The disappearance of this reflex is a valuable index of surgical anesthesia (Briggs).

With the approach of the paralytic stage, the respiration becomes more stertorous (softly snoring with chloroform), irregular, dyspnæic, and stops; paralysis of the respiratory center being the usual mode of death in deep anesthesia. Chloroform has a more pronounced paralytic action than ether; the paralysis may also be due to very low blood pressure.

**Reflex Inhibition of Respiration.**—Deep etherization depresses or abolishes all augmentary reflexes, but intensifies those that produce inhibition. For instance stimulation of the different vagus or superior laryngeal fibers causes only short arrest of the respiration in normal animals. As etherization deepens, the arrest becomes longer. With deep anesthesia, not much beyond the surgical limit, the arrest is so long that the resulting asphyxia kills the heart (F. C. Mann, 1918).

**Factors in the Respiratory Effects.**—The understanding of the several factors concerned in the respiratory effects is essential to the intelligent conduct of anesthesia. The factors are classified by Y. Henderson and Scarbrough, 1910, as follows:

1. The Threshold of Excitability for Carbon Dioxide.—This is elevated (i.e., the excitability is depressed) by morphin, chloroform, and deep etherization. It is lowered by light etherization, by the acidosis of deficient oxygenation; and by fear.

2. The Carbon Dioxide Content of the Blood. —This acts as a stimulus to respiration. It varies inversely as the respiratory ventilation.

3. The Threshold of Excitability for Afferent Impulses.—This is raised (i.e., respiration is depressed) by deficiency of carbon dioxide (acapnia); and by morphin, chloroform, and ether. It is lowered by fear.

4. The Intensity of afferent impulses, especially pain and psychic impressions.

5. Inhibitory cerebral impulses, such as the fortitude of the patient.

The several anesthetics act differently on these factors: Morphin raises the threshold for carbon dioxide; it has less effect on the threshold for afferent impulses. It quiet's respiration.

Chloroform raises the threshold more for afferent impulses than for carbon dioxide. Ether may lower the carbon dioxide threshold, whilst the afferent threshold may be elevated. Hence, ether tends to increase respiration (Fonteyne, 1906), so much so that in dogs it may cause fatal acapnia (Henderson). Most other fatalities occur in the pre-anesthetic stage; the respiration almost always failing before the heart (Cunningham and Anderson, 1906). This tendency may be neutralized by morphin. The respiratory excitement during the early stages of anesthesia has a similar tendency; it lowers the carbon dioxide content of the blood and thus tends to subsequent failure of respiration. Good surgical anesthesia obviates the development of acapnia by preventing pain.

Excessively deep anesthesia paralyzes respiration by raising the threshold of the respiratory center, and by diminishing the production of CO₂. The paralysis is essentially central, although a curare action on the phrenic nerves may play a minor part (Githens and Meltzer, 1914).
Anesthesia before pain prevents acapnia by lessening the afferent hyperpneic impulses. The induction of anesthesia after pain is more dangerous, because the lowered excitability during hyperpnea is apt to lead to acapnia (Henderson, 1910). The acapnia also damages the heart, so that it succumbs more easily to chloroform (Catiehart and Clark, 1913).

Stoppage of Respiration is Therefore Most Apt to Occur With Uneven Anesthesia (Henderson, 1911).

Irritation of Respiratory Passages.—Both anesthetics, but especially ether, produce irritation, with reflex phenomena, increased flow of saliva and mucus, and sometimes inflammatory after-effects. The hypersecretion is especially marked with ether; chloroform produces only a slight increase during induction, and practical arrest during full anesthesia. Emphysema, bronchitis and advanced tuberculosis are therefore special contraindications to ether. The increased flow of saliva and the anesthesia of the larynx are apt to lead to aspiration pneumonia (Hoelscher, 1868). Pneumonia may also be due to direct irritation; it is not known which has the larger share. It is much more common with ether than with the other anesthetics. It has been attributed to impurities, especially peroxides (Bruns, 1895; Smith, 1913). Excessive mucous secretion may also produce acute suffocation by inudulation. The tongue during anesthesia is apt to fall against and close the glottis. These accidents are largely obviated by proper position of the head.

Coughing, retching and vomiting sometimes occur immediately after starting the administration; or later, during imperfect full anesthesia, especially with ether, being partly due to the swallowing of mucus. Their occurrence indicates that the anesthesia should be deepened. The approach of vomiting is heralded by swallowing movements. If it can not be averted, the head should be turned to the side and the opposite shoulder raised.

X-ray examinations on dogs reveals marked diminution of gastric tone under chloroform or ether (Baron and Barsony, 1914).

Bronchial Muscle.—Excised tracheal muscle is relaxed by ether, constricted by chloroform, in vapor-concentrations such as occur in anesthesia (Trendelenburg, 1912). In intact animals, however, chloroform produces slight dilation (Dixon and Brodie). It excised lung (pulsee pig), temporary dilation is produced by ether, chloroform and urethane (Baehr and Pick, 1913).

Blood-gases in Chloroform Anesthesia.—The gas exchange is decreased; in the excitement stage by hyperpneic acapnia and mechanical obstruction; in the anesthetic stage by depression of the center (V. Henderson; Buckmaster and Gardner, 1910). The production of CO₂ during anesthesia is only one-half to two-thirds of the norm. The CO₂ content of the blood was increased from 15 to 16 per cent., the oxygen content reduced from 15:6 to 8.1 per cent. (Gardner and Buckmaster, 1910). The blood is therefore darkened. Chloroform seems to diminish the oxygen capacity of the blood for the diminution of oxygen occurs even with artificial respiration. Gangitano claims that this lasts for twenty-five days.

The gas-metabolism of the brain is depressed by 60 to 90 per cent., proportional to the depth of the narcosis. With ether, the CO₂ falls less than the oxygen; the reverse is true of morphin (Alexander and Cerna, 1913). In norm fibers, direct exposure to low (stimulant) concentrations increase CO₂ production, while anesthetic concentrations depress it (Tashiro and Adams, 1914).

Ether on Circulation.—In the early stages, the pulse rate and blood pressure are increased by the reflexes, excitement and incipient asphyxia. During anesthesia, the effects are similar to those of alcohol, stimulant rather than depressant: the cutaneous and cerebral vessels are dilated (also with chloroform, Berezin, 1910), the intestinal constricted (Derozak, 1909), the pulse rate is increased to 80 to 110, and the blood pressure
(Fig. 264) is practically unchanged, or somewhat above normal in man (Blaauw, 1911). The face is reddened. The pressure in the pulmonary artery rises even if the carotid pressure remains unchanged (Wood, 1911). There is generally some venous congestion, especially with the "closed" methods (asphyxiation). The threshold to vagus stimulation is raised (Jackson and Ewing, 1914).

These indifferent or favorable actions on the circulation persist through the stage of surgical anesthesia, even if this is prolonged for hours. (However, Muns, 1916, claims that after about an hour of continued ether anesthesia, there is seen a marked and progressive arterial dilation of central origin.) In the paralytic stage, the vasomotor center is gradually depressed: the pressure falls very slowly, the face becomes pale, while the heart remains practically perfect even when the respiration ceases. It can therefore usually be revived effectively by prompt artificial respiration. Fatty feeble hearts, however, may be affected more severely.

The vascular effects are central; the cardiac changes are mainly the indirect results of the vascular disturbance; the heart-muscle (Bock) and the vagus excitability remaining unchanged. Concentrations of ether which injure the heart directly can be reached only in perfusions.

**Fig. 265.—Anesthetics on circulation.**

A. Ether on blood pressure (dog). The animal is very slightly anesthetized at the beginning of the tracing. The ether is pushed at (a). There is practically no effect on the blood pressure, even after ten minutes (b). B. Chloroform on blood pressure (dog). The inhalation is begun at (c) and pushed. The pressure falls, without any material change in the heart (central vasomotor depression). The anesthetic is withdrawn at (d). The respiration is very shallow. Artificial respiration is started at (e) and stopped at (f). The original pressure is gradually recovered. C. Ether chlorid on blood pressure (dog). The inhalation is continued from (a) to (b). The effects are very similar to those of chloroform.

*Toxic Circulatory Effects and Concentration in Blood.*—These have been investigated in cats by Schram et al., 1916. With normal cats, concentrations of 0.13 to 0.14 per cent. of ether in the blood lower the blood pressure considerably by action on the vasomotor and vagus centers; but the heart-muscle is not affected by this concentration. Even with the fatal concentration (0.17 per cent.), the heart is scarcely damaged, although the circulation is depressed before death.

If artificial respiration is performed, cardiac arrest occurs with 0.25 per cent. of ether in the blood. This also is not essentially due to direct injury of the heart muscle; for
by dividing the vagi, the minimal fatal concentration becomes 0.31 per cent. If low blood pressure is excluded (by the Starling arrangement), it becomes 0.44 per cent.; and if the nutrition of the heart is maintained (by Langendorff perfusion), the concentration rises to 0.553 per cent. before the heart is arrested.

Asphyxial Effects on the Circulation.—Slight mechanical interference with the respiration rather improves the respiratory movements and the circulation by stimulating the medullary centers. Severer grades produce venous congestion, extensive bleeding from severed vessels, etc. Profound asphyxia leads to extreme cardiac dilation by paralysis of the vasomotor center and heart.

In light ether anesthesia, 12 to 16 per cent. of CO₂ in the air raises the blood pressure, but slows and weakens the heart. These actions are much less pronounced in deep anesthesia (Cathcart and Clark, 1913). The secretion of cerebro spinal fluid is increased by the anesthetics and CO₂ (Dixon and Halliburton, 1913). Vasomotor Center.—Anesthetic doses of ether produce no direct effect, or moderate stimulation. The stimulation is probably largely asphyxial, from respiratory depression (Pilcher and Sollmann, 1912).

Anesthetics in "Shock."—In partial shock, ether depresses the circulation more profoundly; for instance, etherization to disappearance of the conjunctival reflex lowered the blood pressure of a "shocked" animal from 65 to 30 mm. The use of nitrous-oxid oxygen mixture (5:1) does not produce this depression. In any case, deep anesthetic, and rebreathing methods, should be avoided in shock (Cannon, 1919).

Effects of Chloroform on the Circulation.—These are much more serious than those of ether. Even in smooth anesthesia, the pressure falls markedly (Fig. 26B) by central vasomotor depression. Slight faults, especially early in the administration, may produce sudden permanent arrest of the heart. "A.C.E. Mixture" and Ethyl Chlorid (Fig. 26C) act similarly.

In normal chloroform anesthesia, with carefully graduated administration, the pulse and blood pressure in the pre-anesthetic stage are somewhat irregular, but generally increased and the face flushed, similarly to ether. As anesthesia is reached, or shortly after, the blood pressure declines progressively (Lenz, 1853; English Chloroform Commission; Blood in man); in an hour it may have fallen to one-half, in two and one-half hours to one-third the normal level (Rosenfeld, 1860). This fall of pressure is primarily due to depression of the vasomotor center. The vessels are dilated, but constrict on stimulation of their nerves (Scheneissos, 1869). The depression of the center can be shown directly by the perfusion method (Sollmann and Pilcher, 1912). The dilatation involves mainly the splanichic area (onometer, Embley, 1902; increase of blood flow, Pick, 1890). The skin becomes pale and cold. The cerebral vessels contract, the pulse is slow and soft but regular, the heart beating efficiently when the vasomotor paralysis is complete (no response to asphyxia, Knoll, 1878). The respiration also remains regular and efficient. The vasomotor depression is not necessarily harmful to the patient, unless it be excessive or prolonged.

With prolonged anesthesia, or with the approach of the paralytic stage, the heart is injured more or less by the direct action of the chloroform, as well as by the low blood pressure and asphyxia. It is also very probable that degenerated heart-muscle is more subject to these injuries. Ordinarily, however, the vasomotor paralysis dominates the circulatory phenomena until death, the heart beating after the respiration has stopped (Hyderabad Commission, 1889 and 1890), although it may not be able to maintain a circulation.
With *faulty administration* the events are quite different. Excessive concentration of the chloroform vapor, particularly when the anesthesia is incomplete, stops the circulation before the respiration (Fig. 27). This is the usual mode of chloroform death (Lancet, Commission, 1893).

If the heart is exposed, it may be contracting feebly, even after the respiration has stopped, so that literally the respiration stops first; but these feeble beats can not propel the blood, so that, in fact, the circulation usually fails before the respiration.

![Figure 27](image)

**Fig. 27.—Accidents of anesthesia; A. Reflex stoppage of heart; blood pressure, dog. Ethyl chlorid is inhaled at (a). The heart and respiration stop promptly (trigeminus-vagus reflex). They resume spontaneously after two minutes. B. Direct paralysis of the heart, preceded by universal rise. Ethyl chlorid inhalation, blood pressure, dog.**

The cardiac arrest may be due, in individual cases, to direct or reflex vagus stimulation, to asphyxia, or to direct paralysis of the cardiac muscle; or generally perhaps to a combination of these factors. Reflex circulatory disturbances are most dangerous in incomplete anesthesia where the reflex response is active; and in very deep anesthesia, when the low blood pressure may make even slight reflex changes fatal.

**Laryngeal-reflex Syncope.**—Desouby and Magne, 1914, confirmed that brusque chloroform inhalation produces complete arrest of heart and respiration in dogs and rabbits. However, if absorption of the chloroform is prevented, the arrest is temporary, and followed by rise of blood pressure from splanchnic constriction. In the usual fatal result therefore the toxic action of the absorbed chloroform plays an important part in preventing recovery from the reflex arrest.

**Vasomotor Center.**—The preliminary stimulation is partly due to a direct action of the chloroform, for it occurs when this is confined to the cerebral circulation (by perfusing this from the vessels of a second, chloroformed animal; Gaskell and Shore, 1893); in part, the rise of pressure is also reflex and asphyxial. The vasomotor center becomes depressed quite early; *f*4, the normal vascular compensation against the head-down
position is destroyed (L. Hill, 1807). It does not become completely paralyzed until much later (W. Magendie, 1823). In our own experiments, Pick and Sollmann, 1915, confirmed that the vasomotor center is depressed directly during chloroform anesthesia. Indirect stimulation may, however, occur in the nasal cavity when asphyxia is induced by respiratory distress. When the center becomes suddenly anemic by rapid fall of blood pressure or cardiac arrest. Under such conditions, the center may be violently stimulated, with or without preceding depression.

Chloroform abolishes the effect of depressor reflexes at higher levels of blood pressure than normal (Pick and Sollmann).

In an intermediate stage of chloroform anesthesia, stimulation of the vasomotor center lowers blood pressure, since chloroform disturbs the reciprocity of antagonistic nerves so that afferent stimuli produce only inhibitory effects; chloroform causing the reverse effects to occur. The chloroform vasodilation may therefore be due to the reversion of the normal pressor impulses of the center. Asphyxia, however, still causes vasoconstriction (Bayliss, 1908). When the vasomotor paralysis is complete, asphyxia does not raise the pressure.

The typical fall of blood pressure occurs with all methods of anesthesia. Direct Action on Vessels.—Perfusion of excised organs with chloroform solutions produces a constrictor effect in some organs, a dilator effect in others, especially the kidneys (Scheaffer and Scharlieb, 1904; Embley and Martin, 1905; Filehne and Biberfeld, 1906; Campbell, 1911). The required concentration, however (0.1 per cent.), is almost twice as great as that which kills the heart and paralyzes respiration (0.06 per cent.); so that this peripheral action can play no part in chloroform anesthesia (Sternberg and Sowton, 1904).

Early Stages of Heart.—Most fatalities with chloroform occur during the induction of the anesthesia, by sudden arrest of the heart. Experimentally, the heart will often resume if the vagi are promptly divided. In these cases the arrest is due to stimulation of the vagus center. This may be reflex, due to nasal, laryngeal, tracheal or pulmonary irritation by the chloroform vapor (Dastre; Morat; Brodie and Russell); but it may also occur through the paths which are eliminated, or an intravenous injection (Embley, 1901); thus indicating direct stimulation of the center. Its excitability is exaggerated by high concentrations of chloroform (about 2 per cent.), by morphin, and by asphyxia. Dye anesthesia also adds to the vagus hyporeacility, thus explaining why these accidents generally occur at the start. The administration of atropin would prevent this form of fatality completely.

There is, however, another factor; for a normal heart can not be stopped permanently by vaga stimulation, direct or reflex; with a chloroform heart permanent arrest is easily produced (Embley; Desobry and Magne, 1914). It follows therefore that the high concentration of chloroform vapor must have injured the heart. This increased sensitivity of the heart may be fatal apart from the vagus: A. G. Levy, 1911, finds the cat's heart in early chloroform anesthesia very sensitive to high blood pressure (epinephrin), death in this case being not avoidable by vagotomy or atropin. This condition disappears in deeper anesthesia and was not seen with ether.

Socin, 1914, showed that chloroform also renders the excited heart less resistant to venous engorgement or increased arterial resistance; i.e., that it dilates more easily. Similarly, excitement may stop the heart of lightly chloralized cats (Sollmann, 1908). Embley, 1915, finds that early chloroform death with cats is frequently due to ventricular fibrillation. With dogs, this was never witnessed, except as a terminal result of good blood pressure.

Hering, 1910, also finds the tendency to early death, in dogs and cats, parallel to excitement. The arrest is generally due to ventricular fibrillation from excessive excitability of the heart.

Henderson, 1914, is inclined to attribute these early fatalities mainly to asphyxia. Direct Cardiac Depression by Chloroform.—This was demonstrated on the excised frogs' heart by Clemens, 1850; on the exposed mammalian heart by Snow, 1872.

The excited mammalian heart (Langetorf method; Sherrington and Sowton, 1912) shows strikingly the difference between chloroform and ether. The chloroform depression occurs very promptly (within two minutes) and with much lower concentrations than are required for the vessels. It consists in a lessened force of the contractions, the rate being but little altered. The auricles are less affected than the ventricles. The effect is proportional to the concentration of the chloroform, and independent of the absolute quantity and of the time of perfusion. The heart recovers at once when the chloroform is removed, unless the concentration was excessive (0.15 per cent.), in which case fibrillary contractions appear and recovery is impossible. Ether has much less action, and alcohol is practically harmless even when 2 per cent. is present.
ETHER AND CHLOROFORM GROUP

Burridge, 1917, finds that alcohols, ether and chloroform may produce either depressant or stimulant effects on perfused hearts.

The quantitative difference in the cardiac depressant action of these narcotics is illustrated by the results of Dieballa, 1894, on perfused frog's heart: If the fatal dose of chloroform be taken as 70, that of ethyl bromide would be 121 of ether 48; of alcohol 192.

That the heart may be directly depressed by chloroform in the intact animal was shown by Sneijens, 1858, who found that the blood pressure fell even if vasodilatation was largely excluded by clamping the aorta. Bock employed the same principle more perfectly, with the same results. This method involves high concentrations of chloroform.

Ordinary concentrations also weaken the heart somewhat (lessened systolic amplitude and rapid dilatation; Mac-William, 1890; Embley, 1902); but this may possibly be the result of the fall of blood pressure. However, the concentration of chloroform in the blood which is required for anesthesia (0.015 per cent.) is not very far removed from that which paralyzes the heart (0.06 per cent.; Fohl, 1891), so that there is probably some direct cardiac depression even in "safe" anesthesia, and the margin of safety is quite small. Levy and Lewis, 1912, also found that low concentrations of chloroform produce marked cardiac irregularity (idiopathic ventricular contractions) in cats. Hecht and Nobsel, 1913, observed disturbed conduction, sometimes to complete auriculoventricular dissociation. In some experiments this could be removed by vagotomy or atropin, but in others it could not, indicating an action on the bundle. In perfused hearts, and doubtless also in living animals, the depressant action of chloroform is greatly increased by CO₂ and therefore by asphyxia (Sherrington and Sowton, 1906).

The pressure in the pulmonary artery falls, through the cardiac and respiratory depression (Wiggers, 1911).

With frog's hearts, the depressant effects of anesthetics can be antagonized by calcium (Burridge, 1912).

Actions on Blood.—These are not important in ordinary anesthesia. Ether and chloroform, at satisfactory concentrations, produce hemolysis when added to shed blood; and an insignificant degree of this action seems to occur during life: examination of the blood shows a polychromasia, due to diminution of the plasma. The hemoglobin is, however, reduced. Some corpuscles are destroyed entirely, others lose only part of their hemoglobin. Since a diminution of hemoglobin to 50 per cent. is dangerous, it is never safe to use anesthetics on patients showing only 60 per cent. of hemoglobin (Da Costa and Kalischer, 1912).

It is conceivable that this hemolysis explains partly the anemia and icterus which are sometimes seen; but these may also be caused by hepatic changes.

Coagulation Time of the Blood.—This is shortened by ether anesthesia. Chloroform and chloral have no effect if the coagulation time is normal; but lengthen it if abnormally short. Mendenhal, 1913, suggests that these changes are due to disturbed interaction of the liver and adrenal glands.

When added directly to blood, complex effects are produced on coagulation. Chloroform and ether render antithrombin ineffective. Ether also weakens the thrombin action; chloroform does not, nor does it convert prothrombin into thrombin. The quantities used were much higher than in anesthesia (Minot, 1915).

The specific gravity of the blood is somewhat increased during anesthesia and for several days after (Sherrington and Copeman). Buck, 1914, describes marked decrease of the globulins after about two hours of chloroform or ether anesthesia. The viscosity of the blood is slightly increased in deep, diminished in light anesthesia, but not to an important degree (Burton-Optiz, 1913). The osmotic pressure is a trifle increased by the molecular concentration of the dissolved anesthetic (Carlson and Luckhardt, 1908).

The clotting time of the blood is increased by ether; chloroform has this effect only when the animal has been on a fat-rich diet (Bloor, 1914).

Disappearance of Fibrinogen.—Prolonged chloroform narcosis diminishes or abolishes the coagulability of the blood. This change is noticeable after thirty-five minutes of anesthesia. In extreme cases the fibrinogen may be completely absent. This effect is connected with the injury to the liver, similar to that of phosphorus, and is not produced by ether. The coagulability recovers with the repair of the hepatic lesions (M. Doyon, 1913; Whipple, 1914).

The cholesterol content of the blood does not show any significant changes in surgical ether anesthesia (F. C. Mann, 1916).

Blood Catalase.—This decreases during the administration of ether, by direct destruction; and increases during recovery, through increased output of catalase by the liver (Burge, 1917).
Temperature.—Chloroform and ether cause about an equal fall of temperature.
In ordinary operations on man the fall is from 1 to 4°F., averaging about 2.5°F. (H. A. Hare, 1888); much more in prolonged operations on animals. It is not markedly increased by the ordinary dosage of morphin. The fall is due mainly to increased heat loss, from the narcosis of the temperature regulation, aided by the cooling action of the vapor and by exposure. It can be prevented by external heat (the room temperature should be above 26.5°C. = 80°F.) and by keeping the skin dry (S. G. Davis, 1909). These precautions are important, since chilling favors the occurrence of shock and of postanesthetic pneumonia. Warning the vapor has been advocated (Gwathmey, 1908; Pembrey and Shipway, 1916); but the loss of heat from this source would be insignificant (Boothby, 1913).

Reflexes.—The gradual abolition of all spinal reflexes produces complete muscular relaxation in the anesthetic stage—an important surgical advantage over nitrous oxid or cocain anesthesia. The relaxation and reflexes are also valuable for judging the depth of the anesthesia, for the reflexes vary with remarkable uniformity according to the concentration of the anesthetic in the blood (van Leeuwen) and even according to the concentration in the air (Mann, 1918). There are, however, rare exceptions. The order in which the reflexes disappear is not the same for chloroform and ether, indicating that their actions are not strictly alike (van Leeuwen, 1916).
The reflexes disappear in a rather definite order. Among the last to disappear are the corneal, laryngeal, pharyngeal, rectal, vesical, peritoneal and genital. The patellar reflex persists very late. The movements of paralysis agitans cease during anesthesia as they do in sleep. With chloroform, the depression of the reflexes is strikingly parallel to the chloroform content of the blood. No initial stimulation of reflex excitability is noticeable (van Leeuwen, 1913).

The Sensory Component is Depressed Before the Motor Component.—In the early stage sensation is blunted while motion is unimpaired or indeed increased. The psychical condition is similar to alcohol, but the facilitation of motor processes is early obscured by the sensory depression (Knappel, 1892). In the deeper stages, the sensory cells of the spinal cord are paralyzed before the motor cells: If chloroform is restricted to the upper half of the cord, so that this will not react to reflexes from the upper extremities, it will still respond to impulses from the unpoisoned sensory cells of the lower end (Bernstein). The response to direct stimulation of the cord disappears first from the sensory posterior columns (Flourns, 1849). Eventually, however, the motor cells also become inexcitable.

Forbes and Miller, 1916, conclude (from the action-currents) that the efferent impulses are blocked before they reach the cerebral cortex.

The cerebral motor cortex is also depressed; but loses its excitability only in very deep anesthesia (Hitzeig, 1853).

Ether as an Intoxicant.—The resemblance of the earlier effects of ether to those of alcohol has led to its use as an intoxicant. It is said that either drinking is a common form of dissipation in Ireland. The effects are produced, and pass off, more promptly than with alcohol (Discussion and literature, J.A.M.A., 64: 168, 1915).

General Protoplastic Poisons and Local Irritants.—The anesthetic, on direct application, narcotize all cells, of the lower organisms, as well as of the higher. This is preceded, at least in some cases, by evidences of stimulation. The concentration required for irritation is greater than that reached from systemic administration. At the place of application, however, the irritation is quite marked. Chloroform is more irritant than
with equal concentrations, and can be employed as a rubefacient in vesicant.

irritation is due largely to conglutination of the protoplasm. The cause of this the various members. In the case of alcohol it rests upon withdrawal of water, especially all proteins are affected; chloroform has a more marked action upon it (especially myosin), and ether upon albumins (especially egg-albumen).

-local Action on Nerves.—Direct application of solutions or vapors of the volatileics to a nerve lowers its conductivity and excitability, changes the polarization (Alcock, 1900; Bethe, 1906), and abolishes the action-current (Forbes, and Selton, 1916). The sensory fibers succumb before the motor (Longuet). The conduction of the nerve is lowered, as well as its excitability; for if a nerve is exposed to ether vapor, stimulation at the proximal end ceases to be effective much sooner at the distal end. The excitability is recovered if the ether is washed off in 10 min. chloroform, recovery is more difficult. The concentrations required for peripherical effects are greater than can exist in living animals; the motor and sensory nerves remaining excitable even in profound anesthesia; nor is the conductivity during life (Forbes, McIntosh and Selton, 1916).

oils of a nerve diminishes its CO₂ production materially. Lower concentra-

-chloroform, recovery is more difficult. The concentrations required for peripherical effects are greater than can exist in living animals; the motor and sensory nerves remaining excitable even in profound anesthesia; nor is the conductivity during life (Forbes, McIntosh and Selton, 1916).

-ons of the sense organs.

-sense organs are excited (Githens and M ALTER, 1914).

-is stimulated by small concentrations, is arrested by higher

-amburger, 1911). The stimulation is perhaps due to asphyxia, since cyanid and dioxide produce the same effect (Hamburger, 1913).

-surgical ether anesthesia, a local effect acts slowly, usually after one to two hrs. It concerns mainly the polymorphous, but the other forms are also in-

-appears to be due to stimulation of the bone-marrow. The phagocytic activity is increased, even after four to six hours of anesthesia (F. C. Mann, 1916). The reactions abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abolish protoplasmic movements; cause plasmolysis; suppress movements of the Sensitive Plant (Mimosa pudica), etc. Small amounts of the narcotics abol
Cutaneous Irritation.—The evaporation of the volatile anesthesia cools the skin. Local anesthesia by freezing may thus be produced (as "Ethylic Chlorid"). With ether and especially chloroform, the cooling is succeeded by a burning sensation and rubefaction. If evaporation prevented, this may proceed to vesication. Chloroform is therefore used as an active counterirritant (linimentum chloroformi, U.S.P.; Chloroform 30, Soap Liniment 70; B.P.: Chloroform 50, Camphor Liniment 50). The irritant action on mucous membranes is even more violent.

Gastro-intestinal Tract.—The inhalation of the anesthetics generally leads to nausea and vomiting, probably partly central, partly due to local irritation and to the swallowing of mucus. Etherization somewhat slows the passage of food through the alimentary canal (Cannon, 1911). Passage of the intestines occurs commonly after laparotomies; but this is mainly due to the operative procedures (Cannon), although Y. Henderson, 1909, states that ether acapnia may also produce this result.

The oral administration of ether and especially chloroform causes considerable gastric irritation. In milder degree this produces a carminative and anodyne effect, which is useful in colic and dyspepsia (Spiritus Aetheris, 5 c.c., 15; Spiritus Chloroformi, 2 c.c., 1/2; Aq. Chloroformi, 15 c.c., 4 1/2). Spiritus Aetheris is also employed as a reflex "diffusable stimulant."

If ether is taken into the stomach, it is rapidly volatilized and larger quantities destroy the organism, sometimes so much as to interfere with respiration; it may even produce rupture of the organ. It also causes considerable local irritation, and consequently a temporary leukocytosis.

Hypodermic Injection of Ether.—This is employed (1 to 2 c.c.) as a rapid stimulant in collapse. Like other similar irritants, it tends to produce a slight and transient rise of blood pressure, but it falls in the severer grades of hemorrhage and shock, and in anesthesia (Lieb and Herrick, 1917).

Pupils.—These furnish valuable information of the efficiency of the reflexes and asphyxia; and therefore of the depth and course of the anesthesia. They are dilated in the excitement stage, with the light reaction moderately decreased. This dilation cedes with the approach of anesthesia. In man there is an actual constriction; the light-reaction is diminished or abolished; the eyes are turned inward and upward as in sleep. The constriction persists throughout the anesthetic stage and into recovery. With ether, the diameter averages 3/8 to 2/3 mm.; with chloroform, 2 to 3 mm. If the anesthesia deepens they usually dilate; with lighter anesthesia they become smaller. However, their behavior is easily modified by reflexes, respiratory embarrassment, etc.; and should be occasionally ascertained by intentionally changing the depth of anesthesia. Constricted pupils usually mean that the anesthesia is light. Dilation may either mean deep anesthesia, asphyxia, or reflexes with light anesthesia. If the corneal reflex is present, dilation should lead to more rapid administration; in the absence of reflexes, to lighter administration. Sudden and extreme dilation generally signifies dangerous asphyxia. Morphin and atropin interfere with these reactions.

The effect of anesthesia is identical with that of sleep and is due to the abolition of the cerebral impulses which normally inhibit the constricor tone of the ocular muscle center. Asphyxia, on the other hand, increases this inhibition (Braunstein, 1854).

The Pupillary Reactions of Animals.—These are somewhat different; all show dilation in the excitement and asphyxial stages, and the abolition of the light-reflex during anesthesia; but the anesthetic miosis is witnessed only occasionally in dog
ether and Chloroform Group

Ether and Chloroform in Animals.

In cats or rabbits. In these animals the pupils assume a median position. The lung's pupill is not affected by anesthesia (Nakazawa, 1910).

The Cornual and Conjugational Reflex.—These disappear very late, as in all modes of death. C. Bernard found that the conjunctival reflex disappears before the corneal in other anesthesia and in asphyxia; whilst the corneal reflex disappears first in death by cold or strychnine.

Absorption and Excretion.—Chloroform and ether, like most other chemically indifferent vapors and gases, are absorbed almost instantly from the lungs, and excreted promptly and almost quantitatively by the same channel. A small part is probably excreted by the urine. Absorption from the stomach and rectum is also very prompt, and may be utilized for anesthesia.

Retention.—The percentage of the anesthetic in the expired air at first much less than in the inspired. It begins to rise after ten minutes (Brodie and Widdows, 1906). This shows as actual retention of the anesthetic, which is reflected by the percentage in the blood (Buckmaster and Gardner, 1907). Harcourt, 1906, states that at the end of half an hour of anesthesia, about one-third of the administered chloroform has remained in the body; this time this little further retention occurs.

The excretion of volatile anesthetics through the lungs is a merely physical process, analogous to their evaporation from aqueous solutions. It depends more upon their solubility and affinity for water than on their boiling-point (Cushny, 1910).

The cerebro-spinal fluid also contains small quantities of chloroform when this is inhaled (Hald, 1911).

Destruction of Chloroform in the Body.—A small amount of chloroform is decomposed in the tissues, with the production of chlorine (excreted by the urine; Zeller, 1883), and carbon monoxide. The quantity of the latter is too small to produce any effects. This decomposition occurs also in shed blood (Nicolour, 1910).

Concentration of Anesthetic in Inspired Air.—The anesthetics exist in the blood and tissues mainly, if not solely in physical solution: they are therefore absorbed and excreted by the alveolar blood in proportion to their concentration in the alveolar air, until the whole system of air-blood-tissues is in equilibrium. Since the exchange is rapid, the quantity of anesthetic in the tissues at any given moment depends essentially on the concentration (partial pressure) of the anesthetic vapor in the inspired air (P. Bert). The action is determined essentially by this concentration and only in a minor degree by the absolute dose of the anesthetic. A knowledge of the concentrations is therefore important.

The effective concentrations for the inspired air have been determined experimentally, mainly on animals; but they agree for all mammals, and according to available data, also for man (Bert, 1884; Dresser, 1892).

Boothby, 1916, finds the "anesthetic tension" (the partial pressure of ether vapor which maintains anesthesia indefinitely, after it has been established) as 47 mm., equivalent to about 6.7 volume per cent.

With ether, light operative anesthesia can be maintained with about 6 per cent. (volume) of ether vapor (18.5 mg. per 100 c.c. of air); deep narcosis (abolition of reflexes) requires 10.5 per cent. volume. The fatal concentration is 11 per cent. For chloroform, the corresponding concentrations are, fee light anesthesia, 1.35 volume per cent. (6.8 mg. in 100 c.c. of air); deep narcosis, 1.65 per cent.; fatal, 2 per cent. (Kochmann, 1914). The anesthetic zone between the minimal anesthetic and the fatal dose is much wider for ether (viz., 5 per cent.) than for chloroform (0.65 per cent.). This is one reason for the greater safety of ether. Another difference is that the deep anesthesia can be maintained almost indefinitely with ether, whilst chloroform kills within one or two hours (Rosenfeld, 1896). The
time factor therefore plays a part especially with chloroform (also on account of the postanesthetic degenerations). On the other hand, the coincidental rise moment may be above the fatal limit, since the absorption, although rapid, is not instantaneous.

The above figures are those of Kochmann and his pupils. The older experiments generally gave lower numbers, probably due to analytical errors. Thus, Spenser, 1894, stated the effective volume per cent. of ether as 3.5 per cent.; fatal, 6 per cent. For chloroform, Rosenfeld, 1890, named 1 per cent. as anesthetic, 1.65 per cent. as fatal. The various results are collated by Kitchell and Stange, 1893.

Concentration of Chloroform in Practical Anesthesia.—For inducing anesthesia, 1 per cent. chloroform vapor is insufficient; 2 per cent. is generally effective; less than this must be used in pathologic conditions, but requires a longer time to establish narcosis. Even 3 per cent. may be necessary in exceptional cases. The maximum limit of safety is placed at 2 per cent. by Waller; at 1 to 1.5 per cent. by Embley. Therefore, as soon as anesthesia is reached, the concentration must be gradually reduced to 1 per cent., and after half an hour even lower (Alcock, 1909; Levy, 1910).

Even perfectly adjusted mixtures are not absolutely safe. In practice the inconveniences of exact vapor mixtures are generally held to outweigh their advantages. However, the above figures are fairly approximated in the ordinary methods of administration. The air under the ordinary mask has been found to contain generally from 1 to 2 per cent. of chloroform, and with rapid application, up to 9 per cent.

Concentration of Anesthetics in Blood and Tissues.—This has been investigated especially by Nicloux, 1906 to 1907; Tisot; Mansion and Tisot, 1906; Sicard, 1906. According to these, the arterial blood contains, with complete anesthesia of chloroform, 0.03 to 0.05 per cent. (0.04 to 0.06 according to Buckmaster and Gardner); of ether, 0.13 to 0.4 per cent. At death, the chloroform concentration averages 0.08 per cent. (0.06 per cent., Pohl; 0.04 per cent., Buckmaster and Gardner); ether, 0.16 to 0.17 per cent. The concentration in the venous blood is somewhat lower, since the anesthetic is given off to the tissues. This difference is of course especially large before equilibrium is reached. The left heart is therefore exposed to a higher concentration than the right especially if the anesthetic is “puffed” (Pohl, 1891).

The dangerous concentrations of ether in the blood have been determined for cats by Schram, van Leeuwen and Made, 1916. 0.13 to 0.14 per cent., corresponding to deep anesthesia, cause marked fall of blood pressure by action of the vasomotor center and vagi. 0.17 per cent. is fatal unless artificial respiration is used.

With artificial respiration, 0.25 per cent. is fatal if the vagi are active; 0.31 per cent if they were paralyzed.

0.24 per cent. is fatal to the isolated heart-lung preparation and 0.5 per cent. to the perfused heart. The perfused heart is but little damaged by 0.17 per cent., i.e., the concentration that is fatal to intact cats.

During good anesthesia, the ether concentration in the gases of the peritoneal cavity reaches about 4 per cent. (Y. Henderson, 1918).

The distribution of the chloroform in the tissues is related to their content of lipoid matter (Frison and Nicloux, 1907); especially of cholesterol and lecithin, in which chloroform is more soluble than water. Blood therefore absorbs considerably more chloroform than does salt solution; and the percentage is two or three times greater at eight times the red corpuscles than in the plasma (Pohl, 1891; Nicloux, 1906; Buckmaster and Gardner, 1907); twice as great in brain (0.027 per cent. at death) than in liver or muscle (0.026 per cent.). Adipose tissue is a curious exception, since it contains no more than muscle. Waller, 1904, states that only 15 per cent. of the chloroform when added to blood can be recovered. With ether, which has a relatively smaller affinity for lipoids, the percentages in all the tissues are practically equal (Nicloux). It should be added that Guenter and Hochscher, 1906, contradict these statements of the French observers, and claim that there is no difference in the percentage of chloroform in the blood, brain, liver and kidney; provided that the inhalation of a given concentration is kept uniform until equilibrium becomes established.

Elimination.—When the anesthetic is discontinued, the greater part disappears very rapidly from the blood: Within five minutes, the percentage of ether or chloroform has fallen to one-half. The final elimination is more gradual. With ether, there are traces in two hours but not in four hours. With chloroform, the concentration falls to only 1% seventh in three hours, and traces are present even in seven hours (Nicloux).

Ether on Urine Flow.—This is distinctly diminished during the anesthesia (e.g., Hawk, 1911; Ginsberg, 1912; MacNider, 1913), presumably by the altered circulation and perhaps
also by the irritation. (Kemp, 1899, described contraction of the renal vessels with diminished kidney volume; but according to Buxton and Levy, this occurs only in over dosage, and then as a part of the general circulatory disturbance.) As soon as the anesthesia is terminated, the flow increases, the output being above normal for several days. The specific gravity is also increased. This diuresis is proportional to the duration of the anesthesia (W. H. Thompson; Hawk, 1908, 1911, dogs; Pringle, Maunsell and Pringle, human, 1905). In surgical patients, the urine output is often diminished by restriction of the water-intake (Epstein, Reiss and Branower, 1910).

Ether on Nitrogen Excretion.—This is diminished during the anesthesia (Pringle, 1905); it is then increased for twenty-eight to forty-eight hours, depending but slightly on the duration of the anesthesia. The total increase may amount to 45 per cent., but a generally smaller, and therefore much less than with chloroform (Hawk, 1908).

Amino-Acid of Blood Serum.—In dogs, this is not materially influenced by ether anesthesia. However, there is a slight decrease after 1½ minutes, especially if the amino acids had been raised by meat-digestion (E. L. Ross, 1910).

Anesthesiatics on Gasous Metabolism.—In animals there is first a temporary fall; then a rise, with higher concentrations. In plants, anesthetics produce a rise, followed by fall (Ostertout, 1918).

Ether Glycosuria.—Ether anesthesia sometimes causes temporary hyperglycemia and glycosuria (animals, Hawk, 1904; Shaffer, 1913; human, Roehricht, 1905). They occur also on intravenous injection (King, Moyle and Haupt, 1913). They are due to increased hepatic glycogenolysis, for they do not occur if the liver is excluded from the circulation (King and co-workers, 1913); and are more intensive in well-fed dogs than in fasting (Hawk, 1911). They occur after division of the splanchics (King, etc., 1915), but only to a slight degree (Keeon and Ross, 1919). Atropine reduces the hyperglycemia considerably (Ross, 1919).

Ether and nitrous oxide also increase the glycosuria and D + N ratio in phlorihzin diabetes, the extra sugar being derived from glycogen, probably through tissue-ashphyxia (Sanum and Woodyatt, 1915).

Hawk, 1911, attributes the ether glycosuria to dyspnea. Grube, 1911, believed that the cooling was the factor; but Ross and Hawk, 1911, show that the rise occurs due to fall of temperature. Ross and McGuigan, 1915, claim a direct action of the ether, and that asphyxia and excitement are not essential.

Diastolic Activity of the Blood.—This is increased parallel to the rise of blood sugar (Killian, 1917).

Renal Irritation.—Postanesthetic albuminuria occurs in about one-fourth of ether anesthetics, and about one-third of chloroform (Wunderlich). Tube casts are also common. With previously sound kidneys, the renal irritation usually disappears in a short time. In patients with chronic nephritis there may be fatal suppression of urine; but patients with some albuminuria are often etherized without bad effects. Chloroform is apparently somewhat more injurious than ether, but the difference is not very marked.

Acetonuria is also very frequent after ether or chloroform anesthesia (E. Becker, 1895; Beely, 1906; Marshall and Rowntree, 1916; ethyl chloride, Telrold, 1906; even after local cocain, Gundrum). With ether, it is not much influenced by the duration of the anesthesia; fasting may be a factor (Chalfant, 1913). It is more common with the close than with the open methods of administration. Children are more susceptible. Illustratory has been advised as prophylactic.

Acidosis.—Inhalation anesthesia, whether by ether, chloroform or nitrous oxide, tends to reduce the reserve alkali (bicarbonate) of the blood (Menton and Crile, 1915). The reduction is greatest with chloroform (Morris, 1917).

With clinical ether anesthesia, compensated acidosis occurs in 30 to 85 per cent. of routine operations; uncompensated acidosis in 15 to 20 per cent. The average reduction in plasma-bicarbonate is equivalent to 50-115 c.c. of CO₂ per 100 c.c. (Reimann, 1919). The bicarbonate substances of the blood are increased, accounting for at least 60 per cent. of the bicarbonate decrease, and perhaps for all (Reimann and Bloom, 1915). Killian, 1917, claims that the oral administration of sodium bicarbonate, 20 grams per day, corrects not only the diminished alkali reserve, but also the hyperglycemia,
It would be especially indicated if the CO₂ capacity of the plasma before operation is less than 56 c.c. per 100 c.c. of blood. Belman and Bliss (1923).  

Pheny!thalein Output.—The "functional capacity" of the kidney, as measured by this test, is generally somewhat decreased by ether anesthesia. The effect is the greater the longer the anesthesia has been in operation. An increase in the output is low, returning to normal in twenty-four to forty-eight hours. Exceptionally, there may be no decrease, but even an increase; or the decrease may be very great. It has no relation to albuminuria. All shock and collapse conditions lower the phenlthalein output (R. H. Miller and Cabot, 1915; Epstein, Reiss and Branower, 1916). Whipple and Sped, 1915, also found the phenlthalein output lowered after ether, paraldehyde, chloral, chloride, chloriform or alcohol anesthesia. They observed that Eck's fistulas produced lowered output, as also phosphorus, and therefore attribute the effect to disturbance of liver function.  

Anesthetics in Experimental Nephritis.—In dogs rendered polycythemic and glycosuric by tubular uranium nephritis, MacNider, 1913, found chloriform anesthesia much more damaging than ether. In full-grown animals, chloriform promptly arrested the urine flow, so that it would not respond to diuretics; it made the histologic lesions much more marked. The damage was much less in young animals. Ether produced but little effect even in adults. (Young puppies are remarkably tolerant also to the other dangers of chloriform; Whipple, 1912.)  

Chloriform on Urine Flow.—In man this diminishes steadily during anesthesia (Bovee, 1909). Animals also usually show this decrease, due to the low blood pressure with diminished kidney volume (Thomson and Kemp, 1899). Thompson, 1906, often observed increased diuresis in the early stages, and invariably after recovery.  

Chloriform on Nitrogen Metabolism.—Chloriform anesthesia increases the total nitrogen excretion (especially in carnivorous animals), and the ammonia, allantoin, diaminoco-acids, polyphosphate, creatine and organic sulphur. It decreases the excretion of urea and of monoamino-acids (Strassmann, 1886; Salkowski, 1886, Noel Paton, 1894; Vidal, 1869; Rostoki, 1907; Howland and Richards, 1909; Lindsay, 1911). The increase persists for some days and may amount to 300 per cent. These changes indicate an increased destruction but incomplete oxidation of the proteins. They are similar to those of phenlthalein, and probably depend on the hepatic lesions.  

The chloride excretion is increased during and after the anesthesia.  

Chloriform Glycosuria.—This is quite common in ordinary anesthesia. The disturbance is probably analogous to either (hyperglycemia; E. L. Smith, 1911) but more profound. There is some dispute as to whether other reducing substances besides dextrose are present (Hawk, 1911). Chloriform diminishes the tolerance to galactose and lactose, as shown by Mardel and Kowitt, 1915).  

Delayed Chloriform Poisoning (Postanesthetic Toxemia).—The prolonged administration of chloriform is often followed by fatty degeneration of the liver, heart, kidneys; leading to profound toxemia, vomiting, prostration, icterus, and coma, which is often fatal. These results are very exceptional with ether. Postanesthetic toxemia is especially common with children; and in patients with acetonauria, diabetes, hepatic disorders (Hildebrandt, 1913), cyclic vomiting, rickets or wasting diseases.  

Symptoms.—The importance of late chloriform poisoning seems to have been first recognized by Bevan and Favill, 1905; although cases had been reported previously. The symptoms start after ten to one hundred and fifty, generally twenty-four to forty-eight hours; the intervening time being indistinguishable from the normal course. They consist in profuse, sometimes incessant vomiting, first bilious, then blood-stained; excitement and delirium, alternating with apathy and prostration; dilated pupils; rapid pulse; icterus; unconsciousness deepening into coma. Death occurs in four to five days (Herb, 1911).  

The blood generally shows retention of non-protein nitrogen, urea and amino acids, similar to phosphorus poisoning, though less intensive (E. K. Marshall and Rowett, 1915).  

Anatomic Lesions in the Liver.—These consist in extensive vacuolization, fatty degeneration, swelling and necrosis of the cells, especially about the central veins (Nodnagel, 1866; Unger and Junker; Wells, 1906; Howland and Richards, 1909; Whipple and Sperry, 1909; Herb, 1911). The icterus, the disappearance of fibrinogen from the blood; the diminution of liver lipase with increase of plasma, kidney and muscle lipase (Quinan, 1915); the delay of the biliary excretion of phenolstearichlorphthalein (Whipple and pupils, 1913); the changes in metabolism; and the occasional occurrence of leucin.
and tyrosin, must be referred largely to the hepatic lesions, and are analogous to acute yellow atrophy and to phosphorus poisoning. H. G. Wells suggests that they are due to checking of the synthetic processes, whilst the autolytic activity is unimpaired (Quinau). Large doses of the heart-muscle (orthazine, 4-aminophenol, cyanide, thallol) in animals which recover, the liver changes tend to return to normal, even when there has been extensive necrosis (Whipple and Sperry, 1909). Mosiman and Whipple, 1912, found that puppies and fetsi are less subject to the hepatic necrosis; and that pigeons, frogs and terrapin seem to be immune.

**Influence of Experimental Conditions on Chloroform Hepatitis.**—W. C. Davis and Whipple, 1919, found that a practically uniform degree of hepatitis can be induced by 1 1/2 hours of light chloroform anesthesia in dogs that had fasted three days. This served as the standard:

**Diets.**—Starvation renders dogs much more susceptible. More or less marked protection is conferred by feeding with sugar or carbohydrates; skim milk or casein; brain substance. Meat is but slightly protective; fat not at all. These observations suggest that patients who are to take chloroform should receive liberal quantities of carbohydrates and milk.

The protective action of sugar was also asserted by Gnahm, 1919, and has been confirmed by Simonds, 1919.

**Hepatitis and Diet on Metabolism.**—Chloroform hepatitis is accompanied by increased nitrogen excretion, which is greatest in fasting animals; and by the rapid disappearance of hepatic glycogen. Both effects are prevented by feeding sugar, but not by fat. Davis, Hall and Whipple, 1919, suggest that the sugar acts by conserving protein destruction products.

**Influence of Drugs.**—Davis and Whipple, 1915, obtained no protection from alkalies. Epinephrin and quinin appeared somewhat protective, the epinephrin, however, only after a day. The addition of other liver-poisons did not markedly modify the effects of the chloroform.

**Histologic Changes in Other Organs.**—These are also important. Fatty and degenerative changes are seen in the epithelium of the straight and convoluted tubules of the kidneys (Howland and Richards; Apperly, 1912); in the pancreas (Whipple and Sperry); in the suprarenal cortex and ether glands of internal secretion (Scagelone, 1912). Involve doses of the heart-muscle (orthazine, 4-aminophenol, cyanide, thallol) in the sympathetic ganglia, the heart, the heart-muscle has been described (Straussmann, 1898). Small hemorrhagic foci exist in the gastro-intestinal tract, mesentery, pleura and pericardium (Herb). These histologic lesions can be produced, especially in young dogs, by chloroform anesthesia lasting two hours (Whipple and Sperry, 1909; Whipple and Hurwitz, 1911). Repeated chloroform anesthesia, with rabbits, produces degenerative changes also in the central nervous system and brain (Auerbach and Meissner plexus. So do many other poisons, but not ether (Lissauer, 1914).

Cragin and Hull, 1911, point out the similarity of the late chloroform phenomenon to alcoholic and suggest that chloroform would be much more injurious than ether in this condition.

McCrudden, 1912, finds that chloroform is more apt to produce fatty changes of the heart's heart after nephrectomy. Ether does not do this.

**Relation to Acidosis.**—Lesions resembling delayed chloroform poisoning occur in many intoxications, among others in acidosis. Graham, 1913, assumes a causative relation. He points out that the oxidation of chloroform and other analogous halogen compounds may lead to the production of HCl, and believes that this would produce acidosis, and thus the degenerative changes. It has never been shown, however, that such oxidation actually takes place in the body, especially to a degree that would overcome the very efficient defense mechanism neutralizing acidity. It is also difficult to explain away the observations of similar degenerations after chloral, urethane, ether, phosphorus, etc., which certainly are not oxidized to acids.

Davis and Whipple, 1919, failed to confirm some of Graham's data, and point out the possibility of technical errors.

**Treatment of Anesthetic Acidosis.**—W. H. Morris, 1917, finds that the depletion of reserve alkalai is largely prevented by the preliminary administration of sodium bicarbonate (15 to 20 Gm. in the 36 hours preceding the anesthetic—sufficient to make the urine alkaline).

**Experimental Hepatic Cirrhosis.**—This occurs after repeated administrations of chloroform (Mertens, 1896; Herter and Williams, 1902). It is favored by the presence of bacterial infections and may then proceed to acute yellow atrophy (Opie, 1910).

**Intravenous injection of ether** (large doses in rabbits) causes destruction of liver tissue, with extensive thrombus formation (prevented by leech extract). The mechan-
is evident altogether different from ordinary chloroform degeneration (L. Loeb 1905; Loeb and Meyen, 1910).

Repeated Anesthesia on Growth.—Schapiro, 1906, found marked retardation in young cats anesthetized every morning and evening for forty-eight days. When this was discontinued the animals caught up, at least partly with the controls. The effect therefore has no practical importance.

Other After-effects of Anesthetics.—These are mainly due to the irritant action, and may therefore occur with either anesthetic. They may be recapitulated as:

*Gastric Irritation, Nausea and Vomiting.*—Almost universal; vary with duration of anesthesia; less with open methods.

*Tympanites.*—Especially after abdominal operations; the anesthesia is only contributory.

*Renal Irritation.*—About equally frequent with either anesthetic.

*Aspiration Pneumonia.*—More frequent after ether.

**CHOICE OF THE ANESTHETIC**

This is determined by the particular conditions of the patient and of the operation. Safety should be the first consideration; but the depth and duration of anesthesia, the comfort of the patient, and the convenience of the operator are also very important. The principal anesthetics which deserve consideration are: General Anesthesia by ether, chloroform, nitrous oxide, or ethyl chloride, with or without morphin and scopolamin; Spinal Anesthesia; and Local Anesthesia.

**For short operations,** local anesthesia by cocain or similar drugs, or by freezing should be preferred. Where these are not practicable, nitrous oxide or ethyl chloride are used. Nitrous oxide is the safer. It is practically devoid of danger in short anesthesia.

**For longer operations,** the advantages of general anesthesia outweigh the disadvantages, as compared with spinal anesthesia. Chloroform is far more dangerous than ether or nitrous oxide; although with practical experience the acute dangers may be greatly reduced. The chief immediate risks are in the induction period. The danger of postanesthetic toxemia makes its employment in prolonged operations almost criminal.

**Advantages of Chloroform.**—Its continuance in practice is due to its convenience for patient and operator: Its action is much more rapid than that of ether; it induces the most profound anesthesia and relaxation; it does not have the disagreeable taste, causes less suffocation, less excitement, and less postoperative nausea and vomiting. These disagreeable features of ether can be largely avoided by proper administration (preliminary gas, and open-drop method). At their worst, they are not enough to offset the dangers of chloroform. These should only be risked in emergencies; when prompt anesthesia is imperative; in brain surgery; atemoma and aneurism, where the lowered blood pressure is advantageous; and possibly on the battlefield to increase speed and lessen bulk. It has no advantage over ether in renal disease, and but little in respiratory diseases.

**Specific Contraindications to Chloroform** are: advanced heart disease, Graves' disease, hemorrhage, prolonged operations, and the conditions which favor acidosis.

**Chloroform in Obstetrics.**—It is quite generally believed that the use of chloroform in childbirth is relatively safe (J. Hill, 1916). This is explained partly by the lesser apprehension of the patients, and partly by the light degree of anesthesia or rather analgesia, which ordinarily suffices.
for deep anesthesia, it is doubtless quite as dangerous as for other patients, and presents the added disadvantage of delaying labor and thus favoring postpartum hemorrhage. The analgesic dosage does not cause serious delay. The anesthetics pass into the fetal circulation (Jung, 1914); and prolonged anesthesia is probably as injurious to the child as to the mother.

Chloroform Analgesia.—A light chloroform anesthesia is used to dull the excitability of the central nervous system, in pain or insomnia; and to check convulsions, as those of tetanus, tetrazus, or eclampsia. It is especially useful in the onset of these conditions; then the convulsions are fully developed it must be used cautiously, to avoid asphyxia.

For the production of the light anesthesia, chloroform is preferred to ether, since it is more easily vaporized, and its effects are more easily controlled.

A very deep degree of anesthesia is employed in reducing dislocations, to relax the use of the opposing muscles.

Ether is probably safer.

Fixed Dose Self Inhalation Chloroform Analgesia.—A single dose of 5 c.c. of chloroform, poured on cotton and inhaled from the hand, produces a very effective analgesia, with slight confusion, but without unconsciousness, nausea or dangerous effects. The action is complete in five minutes and lasts about 20 minutes. The method has been used successfully for painful dressings and short operations (Sollmann, 1918).

Ether Analgesia by Oral Administration.—This has been employed for similar purposes. The action is more lasting, but not always as efficient. The dose consists of an ounce of a 50 per cent solution of ether in liquid petrolatum, sandwiched between two drinks of port wine. The petrolatum is intended to act as an automatic regulator for the vaporization and absorption of the ether vapor (Gwathmey and Kasner, 1917).

Ether and nitrous oxide are practically equally safe in ordinary cases. Ether has several advantages: it is more easily administered; it gives more complete relaxation, less asphyxia, and less rise of blood pressure; so that the condition of the respiration and circulation are more nearly normal. Its administration is simple and does not require as much experience; ether being perhaps the safest anesthetic for long operations. The disagreeable features of its administration can be practically avoided by skillful administration. The advantages of nitrous oxide appear especially in the cases in which ether is specifically contraindicated.

Contraindications to Ether.—The irritant action contraindicates its use (and also that of chloroform) in renal disease, and in acute respiratory disease (colds, bronchitis). In these, nitrous oxide is preferred, although ether is often employed without damage. Chronic respiratory disease is not a contraindication, unless there is actual dyspnea (emphysema).

Children are especially subject to ether irritation, resulting in respiratory embarrassment and choking. Ether favors bleeding, especially in parts in contact with the vapor; it is therefore not popular for operations of the mouth and larynx. In brain tumor or atheroma, ether and especially nitrous oxide may produce apoplexy; local or spinal anesthesia should be preferred. Advanced heart disease makes all anesthetics more dangerous. In this respect, ether and nitrous oxide are about equal; both should be preferred to chloroform. The danger is proportional to the myocardial degeneration, rather than to the valvular lesion: With fair compensation, ether can be used safely; indeed, the circulation may be rather improved during the anesthesia. In advanced fatty degeneration, it is better to employ local or spinal anesthesia. In hot climates, above 95°F., ether is not so rapidly that its use by the ordinary methods is difficult.

Nitrous Oxid.—This is the safest anesthetic for short operations. If the anesthesia lasts longer than an hour, it becomes somewhat more dangerous than ether even in the hands of experts; and much more dangerous if experience is limited (Bevan, 1915). It is more pleasant to
take; it causes no irritation, and but little excitement or gastric disturbance. It has little or no influence on immunity. There are practically no after-effects. According to Crlle, it lessens the tendency to shock. It is especially preferred for short operations, and for excitable and nervous patients. Old individuals are good subjects.

Disadvantages.—On the other hand, the muscular relaxation is less complete; it causes more or less asphyxiation and abnormal rise of blood pressure; it is expensive; and it requires special apparatus and special experience for its successful administration. It is not appropriate for children under three years, since their thorax is too feeble to withstand the asphyxia. Obese or anemic patients are also unsuited to all anesthetic methods which interfere with respiration.

Statistics of Anesthetic Mortality.—No reliable statistics of sufficient extent can be available until the reporting of all anesthetics, good and bad, is compulsory. Even then, the ratio of "bad risks" will be indefinite. The existing statistics therefore give only a rough idea of the relative danger; but since they agree fairly well, they are worth considering. Modern American statistics are given by Gwashney, 1912. According to the various compilations, the acute mortality for chloroform is given as 1:1,200, 1:2,075, 2,500, 5,000, 3,000, 3,500, 7,500, 5,000; a fair estimate would seem to be 1:3,5,000. This does not take account of the delayed deaths. For ether, the figures are 1: 5,000, 10,000, 14,000, 15,000, 16,500, 16,500, 23,000; the average would be perhaps 1:15,000.

For A.C.E. mixture, the ratio is 1:5,370; for ethyl bromid, 1:5,200; for ethyl chlorid, 1:3,000; 7,000; for nitrous oxid in short operations (dentistry), less than 1:5,000,000.

Anesthetic Mixtures.—The attempts to blend the actions of anesthetics by mixing them have been unsuccessful, mainly because the ingredients do not volatileize with equal rapidity (Snow). The composition of the inspired anesthetic is therefore absolutely uncertain. As a rule, the concentration of the chloroform increases during the administration. The administration is further complicated by the different sequence of the disappearance of the reflexes from chloroform and ether (van Leeuwen, 1916). These mixtures are therefore at least as dangerous as chloroform, and should be condemned (Kochmann, 1903).

The principal mixtures of this type are the English A.C.E. mixture, introduced by Harley (A; C3; E); Billroth mixture (A; C; E); C. E. mixture of Heselt (C; E); Schacht mixture (benzoin x: C3; E); other mixtures containing ethyl chlorid or bromid, etc., have also found advocates. The alcohol and benzine of these mixtures were intended mainly to raise or lower the boiling-point, but benzine is not indifferent. The investigators of Schaefer and Schlich, that the addition of 20 per cent. of alcohol to chloroform practically prevents the fall of blood pressure, needs confirmation. However, there seems to be some combination between ether and chloroform; for on mixing equal volumes (25 c.c.) the temperature is said to rise 4 C. (Marcelet, 1912).

Synergism of Ether and Chloroform.—Analysis of the concentration of the anesthetics in the blood show that mixtures of the vapors do not exhibit a potentiated effect, but rather imperfect summation of action. Earlier work with imperfect methods gave contradictory results: Honigmann, 1890; and Kionka and Kroening, 1905, apparently obtained considerable potentiation; while Madelung, 1910, and Buerger, 1910, found only simple summation and Dammkoehler, 1913, obtained different results for different depths of anesthesia.

Combination with Aliphatic Hypnotics.—This gives rather complex results (Barker, 1913); ordinary hypnotic doses, combined with inhalation, rabbits: with ether, chlorid and barbital do not materially lower the vapor concentration required for light anesthesia; but reduce that for deep anesthesia by 50 per cent., and paraldehyde even by 75 per cent. The zone of safety is normal. With chloroform, chlorid and barbital also reduce the deep-anesthesia concentration, but still more the fatal concentration: so that the danger is greater. Paraldehyde acts as with ether, so that its use would be advantageous.

1 The proportions of all the mixtures are by volume. A, stands for alcohol; C, for chloroform; E, for ether.
Mansfeld and Hamburger, 1913, believe that ether actually potentiates with chloral or morphin, by favoring their distribution into the nervous system.

Sequence Anesthesia.—A more rational method of combining the advantages of anesthetics is to employ them in sequence; particularly to induce anesthesia by the pleasant and promptly acting nitrous-oxid-oxygen inhalation, and to continue it with ether. This probably presents the nearest approach to an ideal anesthesia.

Chloroform was formerly used for the preliminary anesthetic, but presents considerable danger. Ethyl chlorid may be employed successfully. Nitrous oxid without oxygen is practically useless, because the ether is not rapidly absorbed, and the physico or return of consciousness, and the concentrated vapor is apt to cause sudden laryngeal spasm (Cunningham and Anderson, 1908). Hewitt endorses the sequence of C. E. mixture (to two to six minutes), with the gradual addition of ether, by the open method. Changing from full ether anesthesia to chloroform is especially dangerous (Hewitt).

**Morphin, Scopolamin, Atropin and Strychnin Preliminary to Anesthesia.**—One or several of these drugs are often injected hypodermically, half an hour before starting the operation. They lessen the anxiety of the patient and avoid some of the dangers of anesthesia. The doses as given below may be combined.

**Morphin** (10 to 15 mg., 1/6 to 1/8 gr.) is most effective in lessening apprehension, excitement and struggling. Labbé and Guyon, 1872, were the first to use it clinically. It makes anesthesia prompter and smoother. It reduces materially the quantity of anesthetics, and thereby the gastric, pulmonary and toxic after-effects. The patient does not awaken so early. Since the morphin narcosis involves an entirely different mechanism, the side effects of both are probably relatively smaller. On the other hand, morphin depresses the excitability of the respiratory center, and the miosis interferes with the pupil danger signal; morphin is contraindicated in pulmonary disease, in semicomatose patients, or when the operation would involve bleeding into the air passages. On the whole, the marked advantages appear to outweigh the disadvantages, although many anesthetists condemn its routine use.

Morphin reduces the concentration of ether or chloroform vapor required for light anesthesia, but not that for deep anesthesia or death. The margin of safety is therefore widened considerably—50 per cent. for chloroform, 50 per cent. for ether (Stange, 1913; Kochmann, 1914). However, the respiration must be carefully watched with chloroform, for this also shows dangerous potentiation (Wolff, 1913; W. Straub, 1913).

**Atropin** (0.3 mg., 1/400 gr.) stimulates respiration and is therefore often added as a corrective to the morphin. It also diminishes the reflex vagus stoppage of the heart by chloroform, and ether salvation and bronchorrhées, thereby lessening the occurrence of ether pneumonia. The atropin mydriasis and tachycardia interfere with the use of the pupil and pulse as danger signals. On the whole, its use is advisable; but the above dose should not be exceeded on account of occasional idiosyncrasies.

**Scopolamin** (0.5 mg., 1/240 gr.) is often substituted for the atropin. It has the same peripheral actions on the pupil and glands, but greatly lessens the narcotic effects of morphin. On the other hand, it predisposes to pronounced vasodilatation, so that the pressure falls as deeply in ether anesthesia as with chloroform (Mayor, 1908). Moreover it sometimes intensifies the respiratory depression of morphin to a very dangerous degree. This danger is so serious that its use is not advised. Bevan,
1025, who opposes it strongly, believes that it also increases the percentage of vomiting and of bladder paresis.

The combined action of morphin or scopolamin with the hydrocarbunc narcotics is far more than simple addition (Knell, 1907; Hauckro, 1910; Lindemann, 1910; Hammerschmidt, 1910). Malewing, 1910, and Rappaport, 1911, find that one-half to two-thirds of the ordinary concentration of anaesthetics suffices. Buegel, 1911, proposed a receptor theory in explanation; but this is not generally accepted. Fischner, 1911, found that the lipotropic narcotics change the lipoid solubility of morphin, and thus presumably favor its penetration and action.

Scopolamin alone does not reduce the concentration of chloroform or ether required for light anesthesia, but lessens somewhat that for deep anesthesia. Scopolamin and morphin together resemble morphia; except that they do not increase the zone of safety. The anesthesia is deeper, however; and this may be practically important (Ladwig, 1911; Jochmann, 1914).

Breslau. There is given practically only simple summation with morphin or the atypical narcotics (Klumker, 1913).

Strychinin (1 to 2 mg. to 0.5 gr.) has been suggested when respiratory failure is feared (Fothergill). Its usefulness is doubtful.

Cocainization of the nasal mucosa has been employed to avoid the trigeminal vagus reflex.

PREPARATION OF PATIENT FOR ANESTHESIA

The patient usually receives a cathartic (castor oil) twenty-four or thirty-six hours before the operation, and an enema on the morning. An interval of at least five hours should have elapsed since the last meal, which should not have been too heavy. These precautions are to prevent the discharge of the contents of the alimentary canal during the anesthesia. He should be carefully examined for cardiac, renal and pulmonary disease. He should then be placed in such a position as to interfere to the smallest possible extent with respiration; the head preferably low and turned to the side. The clothing should be loosened and all foreign bodies—false teeth, etc. removed from the mouth.

To prevent the local action of the anesthetic on the face, it is well to anoint the mouth and nose with petrolatum. Care should be taken to have the patient close his eyes.

THE ADMINISTRATION OF ANESTHETICS

Inhalation is superior to all other methods in the convenience of its application, and in the facility with which the depth of anesthesia can be regulated to suit the needs of the moment. It must be remembered that this depends solely on the concentration of the anesthetic vapor. This could be regulated either by using exactly dosed mixture of anesthetic and air, or more simply, and on the whole more efficiently, by watching closely the condition of the patient. The response of the respiration, pupils and other reflex changes in the concentration of the vapor must be studied. The concentration can be increased either by pouring the anesthetic more rapidly; by applying the mask closer to the face; or by limiting the supply of air. With either anesthetic the mask should at first be kept fairly away from the mouth, until some narcotic effect is obtained, to lessen the feeling of choking from the concentrated vapor. The patient should be encouraged to breathe quietly and regularly. Counting is a good expedient for this purpose. If the patient holds his breath, struggles or coughs during the induction of the anesthesia, the concentration should be reduced, never increased. Rapid and deep breathing lessens the concentration of the anesthetic by dilution and cooling. Slow and shallow breathing gives more concentrated vapor. Warming the anesthetic liquid also increases its evaporation and concentration (Snow).

Management during Recovery from Anesthesia.—The patient should not be left until he is fairly conscious, since vomiting, inspiration of mucus, etc., might cause asphyxia. No nourishment should be given for at least four hours. If vomiting is persistent, a tumbler of hot water, with a teaspoon of bicarbonate may be given. Recovery is usually more speedy and satisfactory if the patient is placed on his side.

Special apparatus for supplying measured concentrations can be constructed (Dreuck, 1897; Geppert, 1899; Klonka, 1907; and 1899; Kochmann, 1907; Jackson, 1910, etc.), but they are complicated and cumbersome. (A simple form is that of A. Y. Harcourt, Suppl. Brit. Med. J., 1903, p. 143.) Another objection to standardized mixtures is the changes with which they produce anesthesia. It is certain that much stronger mixtures may be borne for a short time, and are quite safe in starting the anesthetic.
Regulation of Anesthesia.—Most important is the fact that no mechanical device can replace the sense of responsibility, the constant watchfulness, and the quick reasoning of the experienced anesthetist. Anesthetization is not a physical experiment where the factors can all be foreseen, but the condition of the patient is apt to vary from moment to moment, and must be taken into account. The state of the respiration must be carefully watched: if the patient holds his breath, the mask must be held farther away, since the next respiration will be an especially deep one. When the respiration becomes slow and shallow, this signifies that a sufficient amount has been taken, and that the quantity may be lessened. The aim is to give no more than is necessary just to keep the patient anesthetized. On the other hand, care must be taken to keep him thoroughly under the influence, for excitement, struggling, stoppage of respiration, shock and overdosage are much more common under partial or uneven anesthesia. Since the respiration and circulation react one upon the other, so that no change could occur in the latter without being noticed in the former, and since most accidents occur from stoppage of the respiration, it may be sufficient to watch this alone, as is advised by some. But as it is of the highest importance to discover beginning failure of the one or the other at the earliest possible moment, the anesthetist cannot be considered as doing his duty unless he carefully observes both. The argument that watching the circulation distracts the attention from the respiration should not hold: the anesthetist must learn to keep his attention fixed upon both.

Closed and Open Methods of Administration.—The anesthetics may be administered with (open) or without (closed) free access of air. In the closed method, the patient rebreathes more or less from a permanent mixture of vapor through a fairly air-tight mask or cone. In the open method, he breathes air freely through a mask (the usual chloroform mask), on which the anesthetic is poured. The closed methods are more rapid and economize the anesthetic; but from other standpoints they are rather objectionable. The open methods avoid the asphyxial effects, and are therefore pleasanter, safer, and less subject to after-effects (mucorhea, vomiting, etc.). The apparatus is also simpler and more easily sterilized. The closed methods deserve preference, except for very short operations, or when rapid anesthesia is important. The closed method, however, is also capable of refinements. Henderson, 1915, advises a closed method with ether vapor, claiming that this is scarcely more unpleasant than nitrous oxide, and produces less nausea, vomiting, gas pains, etc., than other methods. The skin should be kept pink, neither pale (acapnia) nor dusky (asphyxia).

Isolation of Carbon Dioxide.—Y. Henderson and Haggard, 1918, advise post-anesthetic inhalation of air containing 1 to 8 per cent. tension of carbon dioxide, to contract the general depression which otherwise persists for several hours after profound other anesthesia. This expedient usually stimulates the respiration; and in this manner promotes the more rapid elimination of the ether. The blood pressure is restored more promptly, and the patient is said to be practically normal in half an hour. The frequency of nausea and vomiting also appears to be diminished; and the originsators believe that gas pains and intestinal atony are prevented. On the other hand, it must be remembered that these concentrations of carbon dioxide may not be harmless.

Administration of Ether by the “Cone” Method.—A special mask is used, which admits only a limited amount of air. About a tablespoonful is poured in the mask, and repeated as needed. The fact that the re-
quired concentration of ether is much greater than with chloroform, leads to the temptation not to admit sufficient air. This must be care-
fully guarded against, or asphyxial symptoms may result simply from a
deficient supply of oxygen. Concentrations of ether above 7 per cent.
irritate the mucosa so strongly that in imperfect anesthesia, they cause
reflex coughing, closure of the glottis and suffocation (Dreser, 1893).

To obviate the asphyxia it has been advised to administer oxygen with the ether
(Guy, Goodall and Reid, 1911); but this is superfluous, especially if the drop method
is used.

Ether by the “Drop” (“Open” or “Perhalation” Method).—This
avoids to a very great extent the irritation, suffocation and excitation of
ordinary ether anesthesia. This advantage more than compensates for
the disadvantages, the relative slowness, waste of ether, saturation of the
room, and refrigeration of the inspired air. In this method, the ether is
dropped rapidly (about 150 drops per minute), over the entire surface of
an open (chloroform) inhaler, covered with some eight layers of gauze,
and held an inch from the face. If the mask is closely applied, the vapor
concentration may rise to 9.3 to 12.8 per cent.; never above 12 per cent.
(The method was originated by L. H. Prince, 1895.)

Danger of Open Lights.—The vapor of ether being highly inflammable
and explosive, this anesthetic should not be used with the actual cautery
or by an open light. The flame may leap over considerable distance,
especially if there are drafts. If the use of an open light is unavoidable,
it should be placed high above the patient, since ether vapor is heavier
than air.

Chloroform is not explosive; but if used with an open light, it is partly
oxidized into phosgen gas (COCl₂, carbonyl chloride), chlorin and hydro-
chloric acid, which cause considerable irritation—cough, dyspnea, collapse
(Langenbeck, 1888). Fatality to the spectators has been reported (see
Gerlinger, 1902).

The decomposition of chloroform may be illustrated by the equation:

\[ 4\text{CHCl}_3 + 3\text{O}_2 = 4\text{COCl}_2 + 2\text{H}_2\text{O} + 2\text{Cl} \]

\[ \text{COCl}_2 + \text{H}_2\text{O} = \text{CO}_2 + 2\text{HCl}. \]

The inhalation of the burned chloroform vapor by rabbits produces dyspnea, pul-
monary edema, and sometimes death (Stobwasser). The toxicity of phosgen was shown
by R. Mueller, 1910: The inhalation by rats of a 0.025 per cent. volume vapor caused
death in twenty minutes; half this concentration was severely toxic. Anatomic changes
were found in the lungs, kidneys, and heart.

Administration of Chloroform.—This is dropped on a few layers of
gauze, supported by a frame, and held some little distance from the face.
The rate should under no circumstances exceed 50 per minute, and usu-
ally should not be over 12. After the anesthetic stage has been induced
6 drops per minute will usually suffice. This is better than to remove the
mask altogether and reapply it with a larger dose when the patient shows
signs of recovery.

Self-inhalation of Chloroform.—It is often necessary to keep patients lightly under
the influence of an anesthetic when no skilled assistant is available, as in obstet-
ric practice. Here a method suggested by Brunton is useful:

The inside of a tumbler is covered with blotting-paper. A few drops of chloroform
are poured on, and this is given to the patient, with directions to hold it an inch from her
mouth and inhale. This works automatically, for as the patient becomes narcotized by

686 MANUAL OF PHARMACOLOGY
ETHER AND CHLOROFORM GROUP

While allows her hand to drop, and so removes the tumbler; and as soon as she becomes conscious and sensitive to pain, she will replace it.

The quantity of anesthetic which is required for an ordinary operation is very vari-

Some 40 c.c. of chloroform, or 150 c.c. of ether, by the ordinary method, or 250 c.c. of ether, by the drop method, are about the smallest quantities for an hour's anesthesia.

The operation is done as soon as the breathing becomes irregular.

**Methods of Administration.**—The anesthetic may also be administered by any of the following methods, but these demand special experience, and dily special apparatus, and therefore have a more limited field.

1. **Inhalation**—This method is the one most commonly used, and is applicable to all operations of a general nature. The anesthetic is administered by means of a mask, hood, or simple inhaler, either as a single dose or as a series of smaller doses. The gas is usually administered by means of a chemical agent, such as soda lime or calcium oxide, which absorbs the carbon dioxide from the inspired gas. The anesthetic is then delivered to the patient through a respirator or a nosepiece. The respiratory rate is usually reduced to a few breaths per minute, and the patient is maintained in a state of unconsciousness.

2. **Intravenous Injection**—This method is rarely used in modern practice. It involves the injection of a small amount of anesthetic into a vein, usually in the arm, to produce a rapid and profound anesthetic effect. It is particularly useful for short procedures, such as those performed under local anesthesia. The anesthetic is usually a solution of chloroform or ether in saline, and the injection is made slowly to avoid hypotension.

3. **Mucous Membrane Injection**—This method is used to produce topical anesthesia, usually in the form of a drop or spray. It is commonly used for procedures that require local anesthesia, such as dental or ear, nose, and throat procedures. The anesthetic is applied directly to the mucous membrane, and it produces a rapid and localized effect.

4. **Intramuscular Injections**—This method involves the injection of a small amount of anesthetic into a muscle, usually in the arm, to produce a rapid and profound anesthetic effect. It is particularly useful for short procedures, such as those performed under local anesthesia. The anesthetic is usually a solution of chloroform or ether in saline, and the injection is made slowly to avoid hypotension.

5. **Intraspinal Injections**—This method involves the injection of a small amount of anesthetic into the spinal canal, usually in the lumbar area. It is used to produce a rapid and profound anesthetic effect, and is particularly useful for procedures that require spinal anesthesia, such as those performed on the lower extremities or the abdomen.

6. **Intracisternal Injections**—This method involves the injection of a small amount of anesthetic into the cisterna magna, usually in the occipital region. It is used to produce a rapid and profound anesthetic effect, and is particularly useful for procedures that require spinal anesthesia, such as those performed on the lower extremities or the abdomen.

**CAUSES OF DEATH UNDER ANESTHESIA**

These must be thoroughly understood in order that accidents may be avoided. They may therefore be recapitulated. They differ according to the stage of anesthesia, the character of the operations, and the conditions under which they are performed.
diseases of the patient, and other conditions. On this account, the clinical accidents are rather different from the usual laboratory experiments.

**Death not Always Due to Anesthetic.**—It is incorrect to attribute every death upon the operating table to the effects of the anesthetic; for patients died upon the table when anesthetics were yet unknown.

One such case was of considerable importance in the history of anesthesia. When Simpson was about to try chloroform on a patient for the first time, the orderly who was carrying the bottle fell and spilled the chloroform. No other being obtainable Simpson proceeded to the operation, which was for hernia, without anesthetic. The patient died with the first cut. Had the chloroform been given in this case and the same accident had happened, its introduction into practice might have suffered a long delay. Other similar cases are not unknown: A patient was to be operated and demanded chloroform. His condition, however, was so low that the surgeon feared to grant his wish, and to calm him held a cloth without chloroform before his face. Scarcely had the patient made four inhalations—of air—when he was dead. In preanesthetic days, the French surgeon Desault drew his fingers over the perineum of a patient to mark the line of incision, when the patient suddenly gave a cry and was dead. And many similar cases of sudden death from the violent mental impression might be mentioned, besides deaths undoubtedly due to traumatic shock. Even at the present day, patients often exhibit “psychic shock” when operated under local anesthesia, so that it is a general practice to precede this by morphia (Strassmann, 1898).

It is true that the public nowadays has largely lost the great fear for operations and that anesthetics lessen the danger of traumatic shock. But neither is excluded, and there is no doubt that many deaths attributed to anesthetics have their cause elsewhere.

**State of Patient.**—Healthy, vigorous patients are not the safest risks in anesthesia, but rather the relatively feeble and phlegmatic: These are less subject to excitement, struggling and muscular obstruction of respiration, and they require less anesthetic. Nervous, apprehensive patients and alcoholic subjects are always difficult to anesthetize. “Status lymphaticus” and Graves’ disease predispose to acute circulatory failure from trivial causes, fright, excitement, etc. **Respiratory catarrh** tends to obstruction of respiration by mucus, especially if ether is used. Acute pulmonary diseases predispose to asphyxia; advanced heart disease to circulatory failure.

**Death During the Induction of Anesthesia.**—This is common with chloroform, rarer with ether. The usual sequence of events is sudden suspension of the respiration from acapnia or muscular spasms; the asphyxia leads to cardiac dilation, vagus stimulation, and finally asphyxial failure of the heart. The failure is especially rapid with chloroform, because this adds the direct cardiac action of the drug. In light chloroform narcosis, the cardiac muscle is hyperexcitable; and any excitement is apt to induce ventricular fibrillation and death (G. Levy, 1913; this excitability disappears in deep anesthesia). The respiration may resume temporarily after the heart has stopped, but the heart itself can not usually be revived. Failure of the circulation therefore commonly precedes the final arrest of respiration and is the real cause of death.

In the case of ether, similar fatalities are rarer, but may occur early or somewhat later—in either case due to faulty administration during incomplete anesthesia. The error may have been committed an hour before actual death: In light ether anesthesia, the excitability of the respiratory center is increased. If this state is prolonged by excessively slow, incomplete or intermittent anesthetics (f.i., in throat operations), acapnia results. When the anesthesia deepens and the center becomes depressed, the acapnia (deficiency of CO₂) leads to arrest of respiration and injury to the heart (Henderson, 1911).

Respiration by ether is less dangerous, because the more vigorous heart generally beats until the respiration has resumed. Experimentally, the heart may also be stopped reflexly by vagus stimulation, but clinically this seems to be exceptional. In any case, the phenomena
occur with little warning. The danger signs are sudden dilation of the pupils, pallor, and change of facial expression.

Too high concentration of the vapor is the immediate cause of these actions. Fright, excitement, struggling, irregular respiration and idio-synecrasy are contributing factors. Crying in children is especially dangerous. These accidents are avoided by beginning the administration with very dilute vapor, and increasing the concentration gradually. Morphin helps to prevent acapnia and fear. Atropin eliminates the vagus reflex.

**Death in deep anesthesia** is usually due to paralysis of respiration, generally with more or less involvement of the circulation. With ether, the circulation is usually fairly good when the respiration stops. The arrest may be due to exaggerated response to inhibitory reflexes, especially from the vagus or superior laryngeal (Mann).

With chloroform, there is a progressive fall of blood pressure, then failure of the respiration, and finally cessation of the heart; but the pulse is generally imperceptible before the respiration stops. These late accidents are caused by maintaining the concentration of the vapor too high; and since the paralytic phenomena develop gradually, with ample warning, these deaths are generally due to inexperience of the anesthetist. The danger signals are: increasingly shallow or irregular respiration; very slow or very rapid pulse; cyanosis; dilation of pupil. These accidents may be avoided by carefully watching for these signs, by maintaining the anesthesia evenly (see "Report of Anesthesia Committee," J.A.M.A., 1912, vol. 58, p. 1908), and no deeper than complete muscular relaxation and absence of the sensitive reflexes.

The autopsy in acute chloroform or ether deaths shows nothing beyond the ordinary phenomena of death by asphyxia—heart distended, veins congested, etc.

**POISONING BY SWALLOWING CHLOROFORM**

This usually produces immediate vomiting and sometimes defecation, followed by narcosis (Schoenhof, 1914). The acutely fatal dose is not known; an ounce or more would be dangerous. Recovery may be succeeded by fatal gastritis or icterus and the other phenomena of late chloroform poisoning. The treatment would be as for inhalation. Gastric lavage with oil has been advised (Wirth, 1909).

**TREATMENT OF ACCIDENTS**

**Minor Accidents.**—The tongue may fall back and interfere with respiration, as denoted by noisy breathing. If this occurs, "place the index finger of each hand upon the corresponding corona of the hyoid bone, while the middle fingers rest upon the angle of the jaw, and then press forward and upward, the same force serving to extend the head upon the neck; if this fails to open the glottis, by means of a tenaculum, thrust far back into the base of the tongue, draw it forward" (H. C. Wood).

If much mucus accumulates, it should be removed with a cloth (Mayor suggests the dental saliva siphon).

**Serious Accidents.**—These should be treated with the first warning of danger: The anesthetic should be stopped at once. The head of the patient should be lowered to give the medullary centers and heart the full benefit of any remaining circulation. A few rhythmic compressions of the digastrium may be tried, but if these do not succeed quickly, artificial respiration by any of the methods should be begun at once. This prevents asphyxia and eliminates the poison. The cardiac region should also be compressed strongly at the rate of 40 times per minute, since this aids the action of the heart and supplies a mechanical stimulus. A liter of
saline solution, and 1 c.c. of 1:1,000 solution of epinephrin may be at the same time injected into the cardiac end of an artery. The combination of these measures often succeeds when the heart has actually stopped beating (Cripe and Dolley). The chances of success are proportional to the promptness with which they are applied. Gunn and Martin, 1915, recommend the combination of intrapericardial injection of epinephrin with cardiac massage. This is generally successful even when the heart is arrested and either measure alone would fail.

Of drugs, strychnin, or caffeine, by virtue of the stimulation of the respiratory and vasomotor centers, are useful if given in time—i.e., while they may still be absorbed. Digitalis is too slow in its action. Oxygen is of uncertain advantage. Reflex stimulation by the inhalation of ammonia is sometimes remarkably effective; as is scatic stimulation. Hypodermic injections of ether which have been used in man, might be supposed to act in the same manner. But clinical observers condemn their use, and experiments on animals show that the stimulus is too weak to produce much effect. On the other hand, it would tend to deepen the narcosis. The administration of brandy or nitroglycerin is similarly useless, though not quite as harmful. Paralysis of the phrenic nerve or of the heart has also been advocated, but appears to be prompted more by the desires to do something than by any rational view of the object to be accomplished. Stimulation of the phrenic, to be sure, causes contraction of the diaphragm and inspiration, and if done intermittently, would take the place of artificial respirations. But it possesses no advantage over the latter, and besides the fact that the time required to adjust the apparatus might be much better utilized, there is apt to be stimulation of the vagus—a most undesirable feature.

With regard to faradisation of the heart, there is no more effectual way known if killing this organ than electric stimulation (by the production of delirium cordis), and the only reason why more harm has not been done by this senseless procedure is that the electricity, as it is ordinarily applied, does not penetrate through the chest walls.

Epinephrin in Light Chloroform Narcosis.—While epinephrin may be very valuable in deep narcosis, it is apt to cause dangerous arrhythmia in light chloroform anaesthesia. This may be prevented by atropin, or section of the vagi; but if the arrhythmia has already started, atropin only adds to the danger (Nobel and Rotheberger, 1914).

IDIOSYNCRASY

This doubtless occurs, in analogy to alcohol; however, the actual concentration of ether required to induce and maintain anaesthesia is about the same, whether the patient is refractory or otherwise (Boothby, 1914). The great practical difference in the reaction of patients consists mainly in the manner of "taking" the anesthetic. They are therefore most conspicuous in the induction of anaesthesia, which is for instance peculiarly difficult in alcoholic patients. (Boothby, 1913, attributes their resistance to deep breathing, blowing the ether off the mask.) Morphinists are said to be relatively insusceptible. Patients with Graves' disease may react badly. A patient may tolerate one anesthetic better than another.

After the anesthesia is established, there is but little evidence of "peculiar" reactions, except such as may be foreseen in heart disease. Fatal accidents should therefore not be lightly ascribed to idiosyncrasy. The postanesthetic toxemia, however, are undoubtedly influenced by the disposition of the patient.

Mansfield (1905) claims that starved animals are much more susceptible to chloral, paraldehyde, and morphia, but not to alcohol, amyl hydrate, or urethene.

IMPURITIES

The impurities which may occur in ether and chloroform mainly by decomposition, are rather unimportant. They contribute to the local irritation, but probably not to the dangerous effects. Chloroform fatal-
ties seem to be as frequent with the "pure" chloroform as with that not specially treated.

Henderson, 1914, considers poor ether as more excitant, disposing to acapnia.

The impurities of ether are due to the presence of moisture, which leads to complex oxidations. Among the products are hydrogen peroxide, and most commonly the irritant aldehyde. Brun, 1891, concluded from clinical observation that the ether impurities are mainly responsible for the bronchitis (R. B. Smith, 1913). Ether should therefore be used in sealed containers. Partly filled glass bottles are especially detrimental (Baskerville, 1912, 1912).

The impurities of chloroform are also due to oxidation, accelerated by light and acids. The product varies with the conditions. The most constant are the irritant phenol (carbonyl chlorid) and hydrochloric acid. Chloroform should be preserved in sealed, dark glass bottles and should contain 1 per cent. of alcohol, which acts as a reducing substance.

ORIGIN OF CHLOROFORM

It has been claimed that the effects of chloroform differ somewhat according to whether it is prepared from acetone or alcohol. Wade showed that the acetone product is purer; the alcohol product contains a little ethyl chlorid, which might increase the anesthetic effects (Regnault, 1900). Hewitt, however, could discover no difference in the immediate or after-effects. Hale, 1915, also could detect no constant difference in the fatal concentration for mice and fish, for chloroform samples of different age and origin.

INDUCTION OF ANESTHESIA DURING SLEEP

This question is of some medico-legal importance. Cases are reported, but it must be difficult, and consequently rare. False accusations of criminal assault are often based on the mental confusion of the patient while in the induction stage.

RELATED ANESTHETICS

The production of narcosis is a universal action of all members of the aliphatic series which are fat-solvents, and which are absorbable into the tissues. Accordingly, a large number of the more volatile "lipopholic" hydrocarbons may be used to produce anesthesia; whilst the less volatile are employed as "hypnotics," to produce sleep.

Ethyl Chlorid.—This is the only one of the related anesthetics which is practically useful. On account of its great volatility, the anesthesia appears and disappears very promptly, and is therefore especially adapted for minor surgery. It has the same dangers as chloroform: relatively small doses may cause sudden stoppage of the heart, though less frequently than chloroform. Larger doses paralyze the heart-muscle directly; and are even more dangerous than chloroform, because of the extreme suddenness and rather insensible signs (E. D. Brown and Large, 1903; Embley, 1906; Maxx, 1907; Wood, 1910; Seiffert, Nebenwirk., 1915, p. 35). Its main advantages consist in the rapidity with which anesthesia is induced; in the consequent absence of struggling, excitement, and unpleasant sensation; in the very prompt and complete recovery. Its administration is often followed by headache, nausea, vomiting, and sometimes collapse. The muscular relaxation and abolition of reflexes are incomplete, and a little experience is required to recognize the proper time for operating. It has occasionally failed in alcoholic patients.

It may be administered by spraying it on a chloroform mask. This method is so wasteful that a special mask is to be preferred, allowing its administration in gas form, and restricting the admission of air. It has also been used by pouring a small amount into a closed mask. These methods utilize a partial asphyxia; they consume from 5 to 10 percent for operations (Large, 1906).

Administering ethyl chlorid by his special closed-circulation apparatus, D. E. Jackson, 1916, finds its effects to be intermediate between nitrous oxide and ether. The concentration of ethyl chlorid in the blood and tissues during narcosis has been investigated by Caneus and Nicloux, 1908; and E. Frey, 1912.
The main use of ethyl chlorid is for local anesthesia, freezing the tissues by a fine spray of the liquid; the tube being held about 3 feet away. The impossibility of dissecting the frozen tissues restricts its use to simple incisions (opening boils); the analgesia is imperfect, and the thawing rather painful.

Ethyl Bromid and Ethyl Iodid.—These resemble ethyl chlorid closely, differing only quantitatively, according to their volatility (Weber, 1906). The more common ethyl bromid is used for short anesthesia or rather analgesia. It must not be pushed to the disappearance of reflexes, since the respiration is paralyzed about the same time. The zone of safety is therefore very narrow. Pain is abolished before consciousness, and the operation must be made before consciousness is entirely gone. The proper time for operating is somewhat difficult to choose, and the drug is very dangerous in unskilled hands. With experience, the danger seems to be slight. The proper amount (for adults, 8 c.c.; for children not more than 1 c.c. per year) is poured on a folded sheet or cone, and administered to the exclusion of air, until the proper degree of anesthesia is reached. It is then removed. It is only suitable for short operations (tonsillectomy, etc.). The administration requires twenty to forty seconds; the anesthesia lasts about two minutes. Recovery occurs at once.

After a bottle has been opened, the contents can not be used again, as they deteriorate rapidly. The drug must not be confused with Ethylhen bromid (CHI,Br), which is very poisonous.

Bromoform (CHI,Br) is not sufficiently volatile to be of use as an anesthetic. It is employed as an antispasmodic in whooping cough, but is of very doubtful value (2 c.c.—5 minims, dropped on sugar. Practically insoluble in water, soluble in alcohol).

Carbon tetrachlorid ("Tetra," CC), is used as a non-explosive fat-solvent, and for drying the hair in shampooing. The vapor has given rise to serious poisoning (J.A.M.A., 1909, vol. 43, p. 726). Waller and Velay, 1900, state that it is more poisonous than chloroform. Lehmann, 1911 (who also investigated other aliphatic chlor derivatives) found the vapor nucrotic, but not excessively toxic. Industrial poisoning in rubber factories is described by Hamilton, 1915.

This was employed in the airplane industry as a solvent for cellulose acetate, but has been displaced largely by less dangerous solvents. Its inhalation produced hepatic degeneration, with symptoms analogous to phosphorus or chloroform poisoning (Alice Hamilton, 1917, bibliography).

Aml Curese is also a cellulose solvent. It causes local irritation, but is not a dangerous systematically (Hamilton, 1917).

Acute Poisoning is quite rare and produces effects similar to those of chloroform.

Acute Poisoning is the more common. The symptoms may not appear for several hours, and may develop quite slowly so that several stages may be distinguished. The effects have a pathological basis in irritative changes throughout the body. The symptoms begin with disturbed sensation (headache, formication, vertigo, etc.) and gastro-intestinal catarrh. In the second stage there is irritability, excitement, hysterical manifestations, etc., and signs of marasmus. The third stage shows central paralytic or epileptic features, and peripheral neuritis. Ataxia has been reported. The marasmus is pronounced. Degenerative histologic changes are found in blood (hemolytic, leucocytosis, anaemia; no methemoglobin formation), nerve cells and dendrites, liver (vacuolization), kidneys, and lungs. Death does not occur until very late. (A more extensive description is given on page 46 of the first edition.)

The fluid or vapor causes conjunctivitis and other local inflammatory changes in the eye. Continuous exposure, even to small quantities, may produce a toxic blindness, similar to that produced by tobacco (Haas and Heim, 1912).
**Ether and Chloroform Group**

*Linimentum Chloroformi* (Lin. Chlorof.), U.S.P.—30 per cent. of Chloroform in soap minims.

*Sp. Chlороf., U.S.P., B.P.—6 per cent., U.S.P.; 5 per cent., B.P. Dose, 2 c.c., 30 minims. U.S.P.; 0.2 to 1.2 c.c., 5 to 10 minims, repeated; single, 2 to 2.5 c.c., 30 to 50 minims, B.P.

(Tr. Chlороf. et Morph., Co., B.P.—See Index.)

**Bromoformatum** (Bromof.), U.S.P., CIBA.—A heavy liquid, resembling chloroform, lightly sol. in water, miscible with alc., chlorof., eth., and fixed or volatile oils. Slightly soluble, not inflammable. *Dose*, 0.2 c.c., 3 minims, U.S.P. (maximal, 0.5 c.c., 8 minims), on sugar or dissolved in alcohol and glycerin. Used in pertussis, but probably without value. Side actions, Seifert, Nebenwirk., 1915, p. 216.

**Carbon Disulphidum**, B.P., CS₂—Ether, U.S.P.; Ether Pur., B.P.; Ether (Sulphuric Ether).—Contains about 1 per cent. of ethyl oxic, (CH₃)₂O, and about 4 per cent. of alcohol. Light volatile fluid. Sp. gr. 0.713 to 0.716; U.S.P.; 0.720 B.P. Boils at 35°C. Characteristic fuming. Highly inflammable; vapors explosive. Sol. in water (1:12) and in all proportions of alc. *Dose*, 1 c.c., 15 minims, U.S.P.; to 2 c.c., 15 to 30 minims repeated; single, to 4 c.c., 45 to 60 minims, B.P.

Ether for anesthesia is to be dispensed only in small, well-closed containers and is not to be used as an anesthetic after the original container has been opened twenty-four hours.

**Spiritus Etheris** (Sp. Ether., U.S.P., B.P. (Hoffmann's Dropa)—33 per cent. in coloh. *Dose*, 0.5 c.c., 1 dram, U.S.P.; 0.8 to 2.5 c.c., 20 to 40 minims repeated; single, to 6 c.c., 60 to 90 minims, B.P.

Sp. Etheris Co., "Hoffmann's Anodyne," is an antiquated preparation of about the same strength and dose as the spirits, containing additional ethereal products (eternal oil").

**Ether Acetis** (Ath. Acet.), B.P., C₂H₅C₂H₅O₂.—*Dose*, 1 to 2 c.c., 15 to 30 minims, repeated; single, to 4 c.c., 45 to 60 minims, B.P.

**Ethyl Chloridum** (Ethyl Chlor., U.S.P.; *Eikyl Chlor., B.P. (Monochlor-ethane), *CH₃Cl.—Colorless, extremely volatile liquid, of sharp, sweet taste, and peculiar odor, inflammable. Boiling-point, 12 to 15°C. Sparsily sol. in water, readily in alc. or th. Dispersed in special glass or metal tubes. Used for freezing and for general anesthesia.

**Eikyl Bromid**, C₂H₅Br.—General properties resemble the preceding. Boiling-point, 85 to 90°C. Should be protected from light and heat. Used for short general anesthesia.

---

**Aliphatic Hypnotics**

Sleep is one of the earlier phenomena of light narcosis, and can therefore be induced by small doses of any of the aliphatic narcotics. With many of these, however, the hypnotic stage is too brief, passes too easily into general anesthesis, or is complicated by undesirable side actions, stimulation, local irritation, etc.

**Desirable Features.**—The usefulness of a hypnotic depends upon the following qualities: its action must be fairly prompt and lasting, so that the hypnotic effect will persist for some hours. Very volatile or easily decomposable substances are therefore excluded. A good somnifacient must produce the maximum hypnotic action, with the least depression of the medullary centers. It must not possess an odor or taste which would preclude its employment; and it must not irritate the stomach. Preparations which are insoluble in water, but which are nevertheless absorbed, are valuable because they are nearly tasteless, and because their action is apt to be more lasting. A soluble compound which could be used hypodermically would be very useful, but all the present aliphatic narcotics are either too irritant or insoluble.

**Manner of Action.**—Small doses of these drugs depress the sensory and intellectual processes, so that the perception of external stimuli is wored (Kraepelin, 1892). The subject is therefore put into condition favorable to natural sleep. This should be the aim in their therapeutic
use. Larger doses produce an actual stupor; and eventually coma. The stronger hypnotics (chloral) also depress the motor functions. Of other functions, the blood pressure and pulse are somewhat lowered, as in natural sleep. The skin vessels are moderately dilated. The bronchial vessels are also dilated (Berezin, 1916). The chlorinated hypnotics (chloral) in large doses, have a direct depressant effect on the medullary centers, especially the respiration; and on the heart-muscle. All the members are hemolytic when added directly to blood (L. Herrmann).

Respiratory Center.—Cushny and Lieb, 1915, studied the behavior of decerebrated rabbits under urethane. The other lipolytic hypnotics presumably act similarly. They found but little effect on ordinary respiration (in intact animals, the respiration would be diminished by the general narcosis). The respiratory response to reflexes was also normal; the response to oxygen deprivation or CO₂ was, however, lessened or even reversed.

Hypnotic Response of Decerebrated Rabbits.—Chloral and urethane have a much more intensive action than in normal animals. Further, while normal animals are awakened from chloral sleep by oocain or caffeine, decerebrated animals are not awakened. Tetrahydronaphthylamin awakens either (Merita, 1915).

Therapeutic Indications.—Hypnotics (Soporifics, Somnificiens) are used to procure sleep in insomnia, especially when more physiologic measures (removal of the cause, etc.) are not applicable. Their continued use generally leads to tolerance and drug-habits and should be avoided if possible. Full doses often produce acute poisoning. Doses only large enough to induce sleep indirectly by quieting the patient, are rarely dangerous, and can be used temporarily without apprehension.

Limitations.—In the treatment of insomnia it must be remembered that the drug of this class act purely symptomatically; that they soon lose their effect; that none of them are free from objection, be it through the tendency to the formation of drug-habit, through an irritant effect, or through the danger of overdosage. They should therefore be resorted to except in case of necessity. The dose at the beginning should be very small—it must be remembered that in many cases the action of the hypnotic itself need not be very lasting, for sleep once induced tends of itself to continue. And this small dosage presents the opportunity of enlarging the dose when the patient becomes accustomed to it. When the hypnotics need to be continued for a long time, it is well to change frequently to a hypnotic of another type, to return to the first later. This obviates to a great extent the irritant effects and also the difficulty of the patient becoming accustomed to the drug.

Distribution of Hypnotics in Brain.—This has been investigated by Gensler, 1914 and 1915; utilizing the bromin hypnotics, neuronal, bromural and adalin. During the narcotic sleep, the absolute quantity of bromin found in the brain (all in organic form) represents only about 1.4 per cent. of the absorbed hypnotics; but the percentage of bromin is about 1.8 times greater than that in the remainder of the tissues, including the blood. The percentage in excited conditions is about the same; so that the known resistance of excitement to hypnotics, as would be expected, is due to the altered physiologic state, and not to altered distribution. The distribution is also unaffected by injection of magnesium, although the physiologic effects are additive.

Blood Lipoids.—The influence of continued administration of aliphatic hypnotics was investigated by Waser, 1915.

Inflammation.—Chloral, urethane, and presumably the other aliphatic narcotics inhibit the migration of leucocytes from the inflamed frog’s mesentery (Ikeda, 1910).

Comparison of the Aliphatic Hypnotics.—Chloral, the oldest member of the group, is still the standard by which the numerous recent drugs are judged. Its principal disadvantages are the unpleasant taste and gastric irritation, if taken too concentrated, and the frequent formation of a habit. The fear of respiratory and cardiac depression is probably unfounded for ordinary doses. These disadvantages, at most, apply mainly to large doses, which are rarely necessary. For equivalent effects, the disadvan-
s of chloral are probably little if any greater than those of its substi-
tutes. On the other hand, its therapeutic efficiency is probably superior
by its action is certain, prompt, sufficiently lasting, and cas-
sulated by the dosage. The various compounds of chloral have no
un Tiếp: Chloral should be used with some caution in depression
be medullary centers; and in the presence of vascular, cardiac, renal,
monary or gastric disease. Its efficiency is very slight against pain.
Barbituric acid is milder than chloral, but acts very promptly, and does
affect the respiration and heart. It is quite unpleasant to take.
Bromural and urethane act very weakly, and, like bromides, they are
able only for mild nervous insomnias.
Salphenal and trimor are fairly powerful, but act very slowly, and
duce considerable after-depression; they also irritate the kidneys and
dangerous cumulative effects.
Barbital is as effective as chloral, and has less side actions. Full doses
produced severe and fatal poisoning, and therapeutic doses may cause
ulative effects.

critical review of the modern hypnotics is furnished by Gregor, 1912. This also
does the rather insignificant clinical effects on blood pressure (Siegfried, 1913).
mparison with Other Groups.—Morphine is ordinarily less effective than chloral,
ior when insomnia is due to pain. Scopolamin is useful especially in psychic
mia and insanity. Aperosmin is said to be superior in acute alcoholism. These
are the least objectionable, but are effective only in mild nervous cases, worry, etc.
osition and Action.—Certain relations have been found to exist between the
dal structure and action, although the connection is probably not a direct one, as
ined in the discussion of the narcotic theories. The chloral series and the next
homologs seem to be especially valuable in conferring hypnotic action; and these
be most effective in the presence of aldehyde or ketone radicals. Alcohol radicals on
the action, so that glyceral, e.g., is not narcotic. The compounds must resist
ition sufficiently, in order that their action may be lasting.
ise of Chlorin.—The narcotic effect is greatly enhanced by the introduction of
, as shown by the comparison of acetaldehyde and chloral; and by the methane
atives, the efficiency of which increases for each additional chlorin atom from me-
into carbon tetrachloride. This peculiar property of the chlorin compounds has not
explained. Binz, 1877, assumed the liberation of free chlorin; but there is good
ince that this can not occur (Fraenkel).

CH₂CHO \[\text{Acetaldehyde}\] \[\text{CCl₃CHO}\] \[\text{Barbiturate}\]
\[\text{CCl₃CH} \cdots \text{OH}\] \[\text{Chloral}\]

was discovered by Liebig in 1832, and was introduced as a hypnotic by
in 1869. Morphine was the only active hypnotic known to that
. Acetaldehyde is also narcotic; the entrance of chlorin greatly in-
es its efficiency, but also introduces damaging effects on the respi-
ion, heart and metabolism, similar to those of chloroform.
ate.—Chloral is readily absorbed from all mucous membranes. In
body it is mainly reduced to trichlorehyl alcohol, CCl₃-CH₂-OH;
also hypnotic but less powerful. This is excreted by the urine,
e and one-half to eighteen hours, in combination with glycuro
(V. Mering, 1881), as the non-toxic trichlorehyl-glycuronic acid
(urochloralic or chloraluric acid). This reduces Fehling’s solution, and thus gave rise to the erroneous belief that chloral causes glycosuria. It polarizes to the left, but does not ferment. A true hyperglycemia may occur in profound narcosis, analogous to chloroform (Jacobson, 1913).

A small part of the chloral is excreted unchanged, and at most minimal traces as inorganic chlorids and chloroform.

Liebreich’s Theory.—Liebreich, 1860, was led to try chloral by the assumption that it would be converted into chloroform in the organism, as it is by alkalis in the test-tube:

\[
\text{CO}_2\text{H} + \text{KOH} = \text{CHCl}_3 + \text{KOCO}_2\text{H}
\]

Chloral
Chloro-
form

The theory was disproved: The blood and expired air contained no chloroform, or at most insignificant traces (Nicloux, 1906); and the greater part of the chloral is excreted in the conjugated form. Liebreich also stated that a fraction is excreted as chlor; this is contradicted by Kast, 1887.

Hypnotic Action of Ordinary Doses (1 or 2 Gm. for man).—These act very promptly, producing drowsiness in ten or fifteen minutes, and quiet, sound sleep within an hour, mainly by diminishing attention to external stimuli. The sleep lasts at least several hours; but the patient can be easily and completely aroused, and awakens refreshed, generally without depressant after-effects. The sleep is therefore strictly physiological. Very exceptionally, chloral may produce excitement and even delirium.

Other Functions.—The respiration and pulse are somewhat slowed and the blood pressure and temperature slightly lowered, but little more than in ordinary sleep. In respiratory and especially in circulatory diseases, these depressant effects may be somewhat more pronounced, and may perhaps lead to some cyanosis with the larger doses. In fact, however, the fear of respiratory and cardiac depression is based essentially on faulty deductions from animal experiments. There is no good clinical evidence of cardiac depression; while the danger is greater in cardiac diseases, it has often been given without bad effects (Cushny, 1914). The experimental evidence also indicates that the depressant dose is considerably larger than the therapeutic dose (Gunn, 1913, 1914).

Effects of Full Doses.—In man, 2 or 3 Gm. of chloral produce very deep sleep; and as the dosage is increased, this passes into stupor and coma, with complete muscular relaxation. The other depressant effects become much more important.

The depression of the medulla makes itself felt by slowing of the respiration and fall of blood pressure. The vasomotor paralysis is so prominent that chloral is often used in the laboratory to secure paralysis of this center. The pulse is also slowed through direct depression of the cardiac muscle.

As in the case of chloroform, it is impossible to state to what extent the vasomotor and the cardiac paralysis respectively are concerned in the fall of blood pressure. A dilatation of the cutaneous vessels is quite a marked feature and may lead to the appearance of skin eruptions. Larger doses always cause a marked fall of temperature on account of this cutaneous vasodilatation, coupled with the diminished production of heat from muscular relaxation and probably lessened activity of the heat-regulating centers. The temperature regulation in deep chloral-coma resembles that of cold-blooded animals (Sollmann and Hatcher, 1908). In fatal doses death is ordinarily caused by paralysis of the respiratory center,
although it may take place by paralysis of a weakened heart, just as in the case of chloriform.

**Respiratory Effects.**—Cushny, 1913, found the respiratory center depressed, in decerebrated rabbits. With ordinary doses, this depression was masked by the accumulation of CO₂ so that the respiratory movements were almost normal; but with larger doses, the depression predominated, with diminution of rate and depth. Wieland, 1915, also found the CO₂ threshold raised

**Cardiac Effects.**—These are similar to chloriform. Applied to the exposed heart of frogs or turtles, chloral produces progressive slowing; diminished contractility; lessened systole; and diastolic standstill. The arrested heart at first responds easily to stimuli, but can not be started by atropin. Further details are described by W. H. Schultz, 1906. Similar depressant effects are seen in the mammalian heart (Bock, 1925; Gums, 1913). The depressant concentration is at least 1:1,000; the fatal, 1:4,000. The oxygen consumption of the heart is decreased, but not as much as its activity (Rohde and Ogasawara, 1913).

**Sudden stoppage of the heart** may occur from relatively small doses, in cats, under the influence of excitement (Sollmann, 1908). This resembles some of the human cases.

**Vagus Phenomena.**—In rabbits, doses too small to affect blood pressure or heart rate, lessen the irritability of the heart-muscle, so as to delay markedly the resumption of the beat under continued vagus stimulation (O. Loewi, 1912). Similar phenomena occur in frogs. The *accelerator mechanism* is generally depressed by chloral (Fredericq, 1913).

**Exciited Intestines.**—The movements are increased by 0.05 per cent., diminished by stronger concentrations. This may be preceded by stimulation. Later, there may be occasional slow but strong contractions (Sembdner, 1913).

**Action on Metabolism.**—This consists in an increased destruction of protein, the waste products being excreted in a less completely oxidized condition than is the case normally.

The *urine flow* is diminished during the narcosis (Ginsberg, 1912), as also the phenyl-pthalatein output (Whipple and Speed, 1915). The uric acid excretion is somewhat increased (Ahl, 1913).

The output of nitrogen and neutral sulphur is increased; but in *distinction to chloroform* (as it is sometimes displayed for several days after administration (Harnack and Remette, 1883); not is the disturbance as great as with chloroform. Doses so large as to maintain anes-

**The Local Action of Chloral.**—This is so pronounced as to allow of its use as a rubefacient. Its action on the stomach is consequently quite prominent, and it must be largely diluted with water before administra-

**Acute Chloral Poisoning.**—The lighter grades show the narcotic phe-

**The fatal dose averages about 10 Gm., but varies greatly. Death has been reported from 0.5 to 3 Gm., and recovery after 5 Gm. (Hatcher). Doses above 7 Gm. must be used cautiously. (The dosage for cats was studied by Sollmann and Hatcher, 1908.)

**The treatment** consists in gastric lavage; emetics would often be ineffective. The patient should be kept warm. Caffein, strychnin and
atropin are useful. The heart may be stimulated by hypodermic injec-
tions of camphor. Artificial respiration is given as needed.

Efficiency of Cerebral Stimulants.—These are of little avail against toxic doses.
Light chloral sleep, however, is easily broken by caffeine, cocaine or tetrahydroapethy-
amine; not by phenol, epinephrin or pituitary (Airila, 1913).

Chronic Chloral Poisoning.—Chloral habit is not induced as readily
as that of morphine or alcohol; but it is not rare. It presents the symptoms
and degenerations of chronic alcoholism, with more severe gastric and
cutaneous manifestations. The tolerance is only moderately increased
and sudden death is not infrequent.

Addiction to “Bromida,” a chloral nostrum, is not uncommon (Blair, 1919).
Habituation of animals to hypnotics.—This occurs with chloral, amylen hydrox-
paraldehyde, and others of the fatty series, but not with urethane, bromural or mephonal
(Riebefeld, 1918). Chronic chloral poisoning has been studied in dogs by Walker,
1912. Habituation to morphin does not confer tolerance for chloral (H. B. Myer,
1916).

Chloral habit is treated in the same general manner as other drug-
habits.

Therapeutic Uses.—Chloral, as all the aliphatic hypnotics, is used
especially in insomnia of psychic origin. In ordinary nervous insomnia
it should be given in small doses of 0.3 to 1 Gm. (5 to 15 gr.), usefully
combined with 1 Gm. of sodium bromid. Its taste is not easily disguised;
it may be given in sherry or Syr. Aurantii. Larger doses are needed in
mania and in delirium tremens. In the latter condition, the large doses
have often caused collapse. It is not very effective against febrile de-
lirium or pain. The addition of morphin secures a stronger effect than
if either were used alone (Knell, 1907).

Chloral is one of the most useful sedatives against the convulsions of
strycniti, tetanus (Dreyfus, 1914), eclampsia, etc. Fairly large doses are
needed;* but it is safer to use moderate doses (2 to 3 Gm.) repeated at
fairly long intervals (to five or six times per day), and supplemented by
chloroform inhalation. Chloral may be given by rectum; and is this
rather more effective than by mouth. It can not be used hypodermically,
because of its irritant action.

Chloral is also used in asthma and seasickness, but the benefits are
uncertain.

Locally, it is sometimes employed against neuralgia and pruritus, as
an ointment (15 per cent.), or as chloral camphoratum, N.F. (the liquid
resulting by triturating equal parts of chloral and camphor.

PREPARATIONS—CHLORINATED HYPNOTICS

Chloralum Hydratum, U.S.P.; Chloral Hydras, B.P. (Chloral Hydratis;): Hydrat
Choral, CC13COH + H2O.—Colorless transparent crystals, of penetrating aromatic
odor and bitterish caustic taste. Slowly volatilised when exposed to air. Very sol.
water (1:0.25); freely sol. in alc. (1:1.3) or eth. and oils, fixed or volatile. Incompat-
ble with alkales, carbonates, and compounds of Hg. I. or Pb. Dose, 0.5 Gm., 8 gr.
U.S.P.; 0.3 to 1.2 Gm., 5 to 20 gr. B.P.; largely diluted. Maximal dose, 4 Gm., 10 gr.
Syr. Chloral, B.P.—20 per cent. Dose, 2 to 8 c.c., 1/2 to 2 drams. B.P. One dram
contains 11 gr. of chloral.

*In traumatic tetanus, K. Alexander, 1914, advised a single daily dose of 10 Gm.
in 250 c.c. of water by rectum; 5 Gm. were inadequate.
Many of these have been suggested as substitutes for chloral, but none are necessarily superior. Several are compounds which owe their activity merely to the liberation of chloral. Since promptness of action is generally desirable, the slow and uncertain liberation is a disadvantage.

Butyl-chloral Hydras, B.P., N.N.R.; Croton-Chloral Hydrate, $\text{CH}_3\text{CHClCCL}_2\text{H(OH)}_2$—This was also introduced by Liebreich, 1872. Its action is more powerful at shorter time than that of chloral (Mering, 1872). It has been used especially in facial neuralgia. Sol. in water (1 : 50), very sol. in alc. or glycol. Dose, 0.5 to 1.2 Gm., 5 to 20 B.P.

Tri-halogen Tertiary Butyl Alcohols.—These are also hypnotics. Their properties are described by Aldrich, 1916.

Chlorbutanol, N.N.R.; Chloroform-acetone; Methaform; Chloroform, $\text{CCl}_3\text{CH}_2\text{CH}_2\text{OH}$—This is produced by the action of caustic alkalies on a mixture of chloroform and acetone. It acts similarly to chloral, and is probably rather more toxic than chloral. It has caused severe poisoning, but recovery occurred (for further trials, Seifert, Nebenwirk., 1915, p. 44). It is used mainly as a mild local anaesthetic, insipid and preserving for hypodermic solutions. Dose, 0.3 to 1.5 Gm., 2 to 20 B.P., as powder. Locally, as a saturated watery solution (0.6 per cent. at 20°C). It is sol. in oils, and easily sol. in alc. and fat solvents. (Literature, Rowe, 1917).

Chlorbutanol appears in the mother's milk after the continued administration of large doses; but not after therapeutic doses (Blanner, 1910).

Chlorbutanol is used as an anesthetic for laboratory animals, as it allows of long operations without requiring any attention. The dogs are given the usual dose of morphin, soon as vomiting occurs, 0.2 Gm. of chlorbutanol per kilogram of animal, administered by stomach-tube or peritoneally (Rowe, 1916). The chlorbutanol is relatively dissolved in the smallest possible amount of alcohol. The anesthesia is complete in fifteen to twenty minutes, and lasts several hours. The blood pressure falls visibly in rabbits, slowly in dogs. In unanesthetized dogs, it decreases the response of the respiratory-center to carbon dioxide (Vogtlin and Wiggers, 1918).

Chlorbutanol is inadvisable when it is desired to have the animal recover. Chloroformamidum (Chloral Formam.) B.P. (Chloramid), $\text{CCl}_3\text{CH(OH)NH}_2$—This was introduced by v. Mering, 1889, with the idea that the formamid $\text{CHONH}_2$ would counteract the medullary depression of the chloral. This was not valid; it is merely a less active hypnotic, being probably slowly decomposed into chloral. Sol. in water, freely in alc. Dose, 2 to 3 Gm., 15 to 45 gr., B.P.

Chloralose.—This compound of chloral and glucose was introduced by Heffter, 1881, and 1893. It is often contaminated with the non-hypnotic but toxic parachloroalcohol (Mossou, 1893).

Boronal, trichlorisopropyl alcohol, is over twice as active as chloral, and its action is more prompt. Impens, 1905, claimed that it is safer than chloral; but Sollmann and Fritzer, 1908, have shown this claim is to be totally unjustified.

Clinically, it is also uncertain and dangerous (Kleinenschmidt, 1924). The clinical actions are described by Seifert, Nebenwirk., 1915, p. 71.

PARALDEHYD

General Statement.—This was introduced by Cervello, 1882. Its actions are similar to those of alcohol (Kraepelin, 1892); but the hypnotic effect is more powerful, and sets in very promptly, so that the patient may be asleep in ten to fifteen minutes. He should therefore be in bed before the drug is given. The sleep is normal; and with ordinary doses, without after-effects. The drug is less certain and less powerful than chloral; but therapeutic doses do not tend to depress the heart and respiration. It is not analgesic. Its principal disadvantages are the disagreeable urgent taste; fusel-oid odor of the breath, persisting over a day; irritation of the throat and stomach; dizziness and faintness (Seifert, Nebenwirk., 1915, p. 64). Tolerance is generally acquired, and a habit is not infrequent. This presents the phenomena of chronic alcoholism, including dilatation of the kidney (Fornaca and Querell, 1912). Its acute toxicity is low, that 100 Gm. produced only very prolonged sleep.
Indications and Administration.—Paraldehyde is used when chloral is contraindicated, particularly in delirium tremens (Theunissen, 1913); in the insane; in alternation with other hypnotics, etc. The ordinary dose is 3 c.c., 45 minims, raised in severe cases to 5 to 15 c.c. (1 to 45), or better, a teaspoonful every hour, until effective. It is best given in iced water, tea or claret.

Metabolism.—Hypnotic doses (in dogs) lower the blood-sugar, and have no effect on the nitrogen excretion. Anesthetic doses produce considerable hyperglycemia and glycosuria, and a considerable decrease of nitrogen excretion (Powell, 1912).

Other aldehydes of fatty acids are said to produce arterial disease in rabbits (Denny and Frothingham, 1914).

PREPARATIONS—PARALDEHYD

*Paraldehydeum (Paraldehyd), U.S.P., (CH₃CHO)₈.—A polymer of para-
hyd. Colorless transparent liquid, of strong characteristic odor and burning taste. Sol. in water (1:8), freely miscible with alc. Dose, 2 c.c., 30 minims, U.S.P.; 2 to 5 c.c., ½ to 2 drams, B.P. Maximal dose, 5 Gm., 75 gr.

Amylen Hydral (Harnack and Meyer, 1893)—Tertiary amyl alcohol, (CH₃)₃-
C-C,H₅OH. It ranks between chloral and paraldehyde. It is said to lessen the poly-
dipsia and polyuria of diabetes insipidus. Colorless fluid; sol. in 8 parts of water, easily
in alc. Dose, 1 to 2 Gm. (15 to 30 gr.), in glycerin.

SULPHONAL (SULPHONAMETHANUM)

General Statement.—The ethyl-sulphones were introduced by Ba-
mann and Kast, 1888. Sulphonals has the structure:

\[
\begin{align*}
\text{CH}_3 & \quad \text{SO}_2\text{C}_6\text{H}_5 \\
\text{CH}_3 & \quad \text{SO}_2\text{C}_6\text{H}_5
\end{align*}
\]

The hypnotic action is connected with the ethyl radicals, and is further enhanced by replacing the remaining methyl radicals with ethyl (trional, one replaced; tetralon, both replaced).

Sulphonal is a rather powerful hypnotic, but a weak analgesic. Its absorption and therefore its effects are slow, sleep occurring only after one to five hours. Its administration must therefore be properly timed. The sleep lasts six to eight hours, and the effect persists somewhat during the next day, with vertigo, lassitude, drowsiness, and depression. This is due to the delayed excretion, which is even slower than the absorption; thus tending to cumulative effects and very dangerous poisoning, if the administration is continued over longer periods. Sulphonal is therefore unsuitable for prolonged use. In acute cases, or in alternation with other hypnotics, it has several advantages. Its taste is not unpleasant; it does not produce gastric irritation; ordinary doses do not affect respiration and circulation; and the fatal dose is generally much higher than the ther-
peutic. It does not induce tolerance, but may probably cause a habit.

Acute Poisoning.—The symptoms consist in prolonged and profound sleep, with gradual failure of the circulation and respiration. Death occurs usually after several days. It has been reported from 5 to 30 Gm. (Knaggs, 1890); while 100 Gm. have been survived (Neisser, 1891).

Chronic Poisoning.—This has been produced even by ordinary thera-
petic doses, when continued for some weeks. The symptoms develop slowly and consist in nervous depression, gastrointestinal disturbances, and urinary changes. The appearance of hematoporphyrin in the urine
(dark cherry color) is particularly characteristic. Skin eruptions are sometimes seen. If the drug is stopped when the symptoms are light, recovery occurs, but is very slow. After the urine changes have set in, the prognosis is discouraging; death occurring after some weeks by general exhaustion. The autopsy is generally negative (Taylor and Sailer, 1900).

The principal symptoms of chronic poisoning are the following: Nervous; confusion, seizures, epilepsy. Digestive: Almost continuous vomiting, abdominal pain, particularly duet umbilicus, with tympanites and obstinate diarrhea or constipation (W. W. Rogers, 1911). Urine: Hematoporphyrin, methemoglobin and red corpuscles, albumin, casts, high acidity. The literature of the side actions is given by Seifert, Nebezwiski, 1915, p. 72; Trional, p. 94.

The occurrence of hematoporphyrin was described by Stolkvis, 1885. It is rarely seen in acute poisoning, but is very frequent and fairly early in chronic poisoning. It can be produced in rabbits, but not in dogs (Neubauer, 1900). The hematoporphyrin also found in the kite (Pfleiderer, 1914).

Uricaria may be produced by local application to the scarified skin (Sollmann, 1917).

Excretion.—Sulphonal is excreted partly as ethyl-sulphonic acid, partly unchanged, by the urine and intestines.

Administration.—Sulphonal is used in nervous insomnia especially when chloral is contraindicated. The ordinary doses, 0.75 to 1 Gm., 10 to 15 gr., or in severe cases 2 Gm., are taken in hot milk at least four hours before bedtime. A smaller dose may be taken the second night. The administration should not be continued beyond a week, when an interference must be made. It is generally advisable to prescribe cathartics, alkalis and plenty of water.

TRIONAL

Trional is more effective than sulphonal; and being more soluble, its absorption and action are more prompt, producing sleep in one-half to one hour. It has the same dangers as sulphonal, and the latter is more commonly used.

A case of chronic trional poisoning is described by v. Noorden, 1916.

TETRONAL

Tetronal is less soluble, and therefore too slow.

PREPARATIONS—SULPHONALS

Sulphonmethanum (Sulphonmeth.), U.S.P., Sulphonal, B.P. (DiethylylubHONE-methyl-methane): (C\textsubscript{6}H\textsubscript{5})\textsubscript{2}C\textsubscript{2}(SO\textsubscript{3}C\textsubscript{2}H\textsubscript{5})\textsubscript{2}.—Colorless, odorless and nearly tasteless crystalline powder, slightly sol. in water (1:36); sol. in boiling water (1:15) and in alc. (1:5). Dose, 0.75 Gm., 12 gr., U.S.P., 0.6 to 2 Gm., 10 to 30 gr., B.P., as powder. Maximal dose, 2 Gm., 30 gr.

Sulphonmethylethanolum (Sulfonmethethylmethanol, U.S.P., Methysulphonal, B.P. (Tri- nal), Diethylylubhone-methyl-ethyl-methane): (C\textsubscript{6}H\textsubscript{5})\textsubscript{2}C\textsubscript{2}SO\textsubscript{3}C\textsubscript{2}H\textsubscript{5})\textsubscript{2}.—Colorless, odorless, crystalline scales; bitter taste. Slightly sol. in water (1:200); sol. in alc. Dose, 0.75 Gm., 12 gr., U.S.P., 0.6 to 1.2 Gm., 10 to 20 gr., B.P., as powder. Maximal dose, 2 Gm., 30 gr.

HYPNOTIC UREA DERIVATIVES

These furnish a convenient means of exhibiting the alkyl groups, the efficiency being apparently enhanced by the urea combination. The
three most important types of compounds are represented by Bromural, Barbital and Urethane, as may be seen from the following formulas:

\[
\begin{align*}
\text{CO} & \quad \text{CO} \\
\text{NH}_2 & \quad \text{NH}_2 \\
\text{NH}_4 & \quad \text{NH}-\text{CO}-\text{CHBr}-\text{CH}-(\text{CH}_3)_2 \\
& \quad \text{Urea} \quad \text{Bromural (a monobrom-isovaleryl-urea)} \\
\text{CO} & \quad \text{C}_9\text{H}_6 \\
\text{NH} & \quad \text{CH}_4 \\
\text{NH}_4 & \quad \text{Barbital (diethyl-malonyl-urea; diethyl-barbituric acid)} \\
\text{CO} & \quad \text{CO} \\
\text{OH} & \quad \text{CH}_4 \\
& \quad \text{Carbamic acid} \quad \text{Urethane (ethyl-carbamate)} \quad \text{Hedonal (methyl-propanol-carbonol-urethane)}
\end{align*}
\]

BARBITAL (VERONAL; DIETHYL-BARBITURIC ACID)

General Statement.—This was introduced by E. Fischer and Merig, 1903 and 1905. It has a number of advantages over the other hypnotics: It is even more powerful than chloral and somewhat more analgesic; it does not produce local irritation, and the taste is not so disagreeable. The margin between the ordinary therapeutic dose (0.5 Gm.) and the toxic dose (usually 8 to 10 Gm.) is somewhat wider; and the ordinary dose has little effect on the blood pressure and respiration. However, fatal collapse (by peripheral paralysis of the blood vessels) has occurred in several cases from relatively small doses (10 to 15 gr., 0.65 to 1 Gm., J.A.M.A., 53, 1883, 1906). On the other hand, recovery has resulted after 10 Gm. Small doses are somewhat diuretic (A. Hoffman, 1906). The action is rather slower than with chloral, but more rapid than with sulphonal. After-depression is exceptional, but more common than with chloral. The usual dose, 0.5 Gm., 8 gr., induces a deep, dreamless sleep in one-half hour; or even more promptly if the soluble sodium salt is used. The patient generally awakens refreshed, but exceptionally suffer from lassitude, vertigo, headache, nausea, diarrhoea, and skin eruptions.

Barbital is excreted slowly, so that ordinary doses may produce serious cumulative effects similar to those of sulphonal, but rather more slowly. Nervous symptoms are especially prominent (Glaser, 1914). It must therefore be intermitted after a week. Habit has been reported (Kep., 1905), but tolerance is not easily acquired.

Acute Barbital Poisoning.—This has been rather frequent; a number of cases are collected by Hefter and Loeb, 1906. They present the phenomena of coma, fall of blood pressure, feeble heart, vasodilatation, marked fall of temperature even with moderate doses, increased reflexes, sometimes convulsions; slower and especially shallow respiration, asphyxia, but with constricted pupils; renal irritation, diminished urine of anuria; exanthemata (circumscribed dermatitis reported by Zeisel, 1912). Roemer, 1912, describes epithelial necrosis of the kidneys in two fatal cases, without clinical signs of nephritis. The general effects have been investigated by Groebel, 1911; Roemer, 1912, and by Jacob, 1912.

The literature of the clinical side actions is given by Seifert, Nebenwirk., 1915, pp. 75 and 99.
P. Gautier, 1918, described four cases of poisoning from doses of 3.5 to 8 grams. One man who had taken 5 grams, died after 4 days of coma. He believes that addicts are less resistant.

Urticaria.—This is produced by the local application of barbital to the scarified skin of animals, 1917.

Vasodilator Action.—Jacob and Roemer, 1912, refer the toxic peculiarities of barbital to a direct action on the blood vessels, perhaps analogous to an arsenic effect. They therefore advise against its use when the circulation and respiration are depressed. The treatment of acute poisoning would be along the same lines as for chloral: vomit, cathartics and stimulants. Bachem found caffeine the best antidote. Tholl, 19, also recommends acetic ether.

Fate and Excretion.—Barbital is excreted almost exclusively by the urine, only traces appearing in the feces. When given by mouth, about 65 per cent. are eliminated unchanged. This proportion is not altered on continued use, so that the remainder must be destroyed (A. Hoffman, 1906). The proportion excreted may rise to 90 per cent. in small doses hypodermically; and fall to one-half with large doses (Bachem, 1919). In severe cases of poisoning, requiring several days even after 0.5 Gm. This explains the cumulative effects.

Chronic Barbital Poisoning.—This shows confusion, ataxia, debility, gastro-intestinal irritation, anemia and hematoporphyrinism.

Indications.—Barbital is used in nervous insomnia, mania and delirium. It appears to be highly effective in delirium tremens, 0.7 Gm., three times daily (Dreyfus, 1914). It has also been employed against vomiting, nausea, migraine, and for combination anesthetics (Wolfram, 1906). It is taken dry or in hot liquids. If a more rapid action is desired, the double sodium salt may be given (Katzenstein, 1909); but its taste is more disagreeable.

PREPARATIONS—BARBITALS

\textit{Acidum Diathyl-barbituricum} (Acid Diathylbarb.), Barbital, N.N.R.; Barbitum, 8. P. (Veronal); Diethyl-malonamide.—White, crystalline powder, odorless, faintly bitter. Slightly sol. in water (1:20); sol. in boiling water (1:12) and in alc. Dose, 0.3 to 0.6 Gm., 5 to 10 gr. B.P., in hot milk, or hot lemonade. \textit{Maximal dose}, 1 Gm., 15 gr. \textit{Soliii Diathyl-barbituris}, Barbital Sodium, N.N.R. (Veronal-Sodium; Medinal).—The monosodium salt. Freely sol. in water, the solution having a bitter alkaline taste. May be used by rectum and perhaps hypodermically.

\textit{Dipropyl-barbituric Acid, Propanol}, was also introduced by Fischer and Mering, 1904 and 1905. It is more powerful than veronal, but more dangerous and less reliable.

Phenobarbitals: Phenylethyl-barbituric Acid, N.N.R.; Laminal.—Resembles Propanol (Gregor, 1915). It is used especially in epilepsy (M. Klotz, 1915).

It would be especially useful when bromides are not tolerated. The dose in epilepsy is 0.3 gram, one to three times per day. This dose should not be exceeded, and the administration should be omitted on 2 days every week, to guard against accumulation of the drug in the fatty tissues; laminal being almost insoluble.

It is administered in tablets. The sodium salt (Phenobarbitnal-sodium) is soluble and may be used hypodermically (1 c.c. of 20 per cent. = 0.4 grs).

The hypnotic and fatal dose are close together, and the circulatory depression is severe. Taddel, 1913, protests against its use as too dangerous. The literature of the clinical side actions is given by Selfert, Nebenwirk., 1915, p. 72.

\textit{Diallyl-malonamide} has no advantage over other ureid hypnastics (Castaldi, 1915).

BROMURAL, N.N.R.

This is a prompt but very mild hypnotic, effective only in slight nervous insomnia. It is not analgesic, and is rendered ineffective by cough or delirium. Ordinary doses have no side effects (v.d. Eechhout, 1907; Sollmann and Hatcher, 1908; Literature, Selfert, Nebenwirk., 1915, p. 48). In man, 0.3 to 0.6 Gm. are effective in five to twenty-five minutes, producing a natural sleep lasting three to five hours, without excitement (Klapper and V.d. Eechhout). It dissolves in hot water, but not in cold.

\textit{Adalin} (Carbromal, N.N.R.) is a closely related substance, from diethyl acetyl amide. Its efficiency is between bromural and barbital. It is used rather extensively in nervous insomnia. Difficultly soluble in water. Hypnotic dose, 0.6 to 3 Gm. (10 to 20 grs), as powder or tablets.
URETANES

These have been disappointing in man; the hypnotic action is feeble and patients soon become immune. The efficiency increases with the magnitude of the alkyl radicals (Binet). There is also a decided diuretic effect.

ETHYL CARBAMATE

This acts more satisfactorily on animals than on man; producing a rapid and profound narcosis, with little change in the circulation or respiration (Schniedeberg, 1884). It is therefore employed as a laboratory anesthetic. The CO₂ threshold of the respiratory center is, however, somewhat raised (Wieland, 1915). It decreases the oxygen uptake (Winterstein, 1914). Large doses cause in rabbits a vascular degeneration of the hepatic epithelium (Sollmann).

It also lowers the phenol-s-phthalain output (Whipple and Speed, 1913). Large doses produce hyperplasia, independent of the quantity of liver-glycogen and epinephrin, and unaffected by pituitary. Bang, 1914, believes that it acts through pancreatic degeneration. It is excreted as urea. Side actions, Seifert, Nebenwirk., 1915, p. 87.

Urticaria.—Application to the scarified skin produces a wheal (Sollmann, 1917).

PREPARATIONS—URETHANES

Ethyl Carbamates (Ethyl Carbam.), U.S.P. (Urethane); CO₂(C₂H₅)₂NH₂—Colorless, odorless crystals of saline taste. Very sol. in water (1:10.45) and in alc. (1:100).

Dosage: 1 gm. 15 gr. U.S.P.; to 4 Gm.

Hodonal, N.R., is twice as active as urethane (Dreser, 1899). It has the same general effects, its absorption is relatively slow and it is more toxic. Its dose is about double that of chloral. It has been used intravenously for anesthesia (Jeremich: Page, 1912); a 0.75 per cent. solution in normal saline being injected at the rate of 10 c.c. per five minutes, reduced to 20 c.c. when anesthesia is attained. Its use is dangerous.

THE SYSTEMIC ACTIONS OF GASES

General Statement.—The respiration of oxygen is essential to life. A deficient supply of this gas leads to the phenomena of asphyxia. A number of gases (N₂, H₂, CH₄) act merely by excluding oxygen mechanically. This also forms an important element in the action of nitrous oxide, ordinarily used. Carbon monoxide also acts by excluding oxygen, but it does so mechanically. Other gases have specific, direct actions, especially on the central nervous system. Oxygen itself, when at a pressure of several atmospheres, is toxic. Carbonic acid and nitrous oxide produce peculiar actions at lower pressures, but the air must contain considerable proportions. Sulphuric acid and arsenic acid are toxic in very small proportions. The gaseous acids (sulphurous, nitrous, etc.), alkali (ammonia) and halogens (bromin and chlorid) act mainly as local iritants. Compressed air acts mechanically.

Rapidity of Action.—The effects of gases appear very promptly after beginning the inhalation, and disappear as rapidly when the animal is made to respire pure air. This is due to the large surface and large quantity of blood exposed to them in the lungs. As these factors are relatively greater in small mammals, these succumb and recover very much more rapidly than man, and may indeed be used as a test of the safety of suspected airs. Whilst the recovery from the direct effects of gases is rapid, indirect after-effects may be very persistent.

The quantitative effect of gases depends on their partial pressure in the air. At ordinary barometric pressure, this is equal to the volume-percentage of the gas. But it is important to remember that the effect of the normal
Percentage of oxygen at half an atmosphere pressure is the same as that of half the percentage at ordinary pressure; and conversely, that 1 per cent. of a gas at 3 atmospheres produces the same effect as 3 per cent. at 1 atmosphere.

The symptoms produced by most toxic gases resemble those of asphyxia and this whether the effect is produced by the absence of oxygen; or whichever the gas has a specific toxicity. They are closely related to those of anesthetics.

NITROUS OXID

General Statement.—Nitrous oxid, \(N_2O\), nitrogen monoxid or protoxic, “Laughing Gas,” was the first of the inhalation anesthetics and is still the safest. When inhaled undiluted, it produces very rapidly unconsciousness and anesthesia, partly by a direct narcotic action; and partly by exclusion of oxygen. The asphyxia limits its use to very short operations, such as the extraction of teeth. It has the advantages of prompt action and recovery, absence of irritation and of after-effects; and is practically devoid of danger. By the addition of oxygen, the asphyxial factor may be removed. The anesthesia also becomes slower and lighter; but by carefully adjusting the percentage of oxygen (5 to 10 per cent.), a satisfactory degree of surgical anesthesia can be maintained for long periods, without letting the asphyxia obtain dangerous proportions. Nitrous oxid is especially valuable in the “Gas-Ether Sequence,” by avoiding the unpleasant features of the induction of ether anesthesia.

Historical.—Nitrous oxid was first prepared by Priestley about 1776. The discovery of its anesthetic properties by Humphry Davy and by Wells is described under “Ether” and “Chloroform.” Elsworth (Boston Med. and Surg. Jour., 37) in January, 1843, amputated a thigh under successful nitrous oxid anesthesia. Its administration with oxygen was introduced by E. Andrews of Chicago in 1868; and the use of mixed mixtures under pressure by Paul Bert, 1886. The technic of its use in surgical operations has been extensively elaborated in recent years.

Inhalation of Undiluted \(N_2O\).—For short operations, as in dentistry, the gas is administered through a tight-fitting mask, so that all air is excluded. The symptoms run a very rapid course: the preliminary effects consist in a sweetish taste; numbness; exhalation (laughtering); confusion; deeper and quicker respiration; and fuller pulse. Partial anesthesia, with loss of consciousness, ensues in twenty to thirty seconds. The patient is subject to dreams and the anesthesia is imperfect. The reflexes are preserved and excitement may be present, especially if the patient is disturbed. The respiration is still regular, deep and quickened; the pulse full and rapid; the pupils enlarged; the face dusky; livid or pallid; the eyelids twitching and slightly separated. Complete anesthesia occurs in fifty to one hundred and twenty seconds, averaging fifty-six. Its onset is denoted by a change in the respiration, which becomes slightly irregular and noisy. The pulse is quickened by about 30 per cent. and is small. The blood pressure shows a large asphyxial rise (Kemp, 1857). The vasoconstriction diminishes the urine flow. The limbs are relaxed, but individual muscles exhibit clonic or epileptiform contractions. The pupils are almost invariably dilated. The face is cyanosed. Relaxation of the sphincters occurs rarely.

Operative Period.—As soon as this stage is reached, the gas is removed. The pulse at once becomes slower and fuller; the respiration also recovers rapidly; and the asphyxial symptoms disappear. The anesthesia lasts...
some twenty-two to thirty seconds after the gas is removed; and it is
during this period that the operation must be performed. The total time
between the beginning of the administration and complete recovery is
therefore one hundred to one hundred and twenty seconds. The duration
of the after-anesthesia increases with the duration of the administration.
This may be prolonged to several minutes by giving the patient an occa-
sional breath of pure air (every fifth inhalation); or by admitting a little
air into the mask. The admission of air, however, makes the anesthesia
uneven and unsatisfactory.

After-effects are generally absent with short administrations. Some-
times the patients complain of giddiness, headache, lassitude and drowsi-
ness. Nausea is exceptional.

Accidents.—With short administrations, these are very rare, because
of the wide margin between the first danger sign (noisy and irregular
respiration) and death. Only about seventeen deaths have been reported,
making the fatality less than 1 in 5,000,000. In patients with grave car-
diac lesions, the pulse may become feeble and the respiration shallow
before anesthesia is established. If the administration is continued too
long in healthy individuals, the asphyxial phenomena become emphasized,
with violent inspiratory, then forced expiratory movements; then shal-
low and intermittent and finally arrested respiration, in two to four min-
utes (Haggard, 1910). The violence of ordinary asphyxial convulsions is
mitigated by the narcosis. Cyanosis is intense. The heart continues to
beat for some time, so that restorative measures are generally successful.
They should consist in artificial respiration, preferably with oxygen.

Contraindications.—Nitrous oxide should not be used in cardiac lesions,
valvular or myocardial; in elderly patients especially with advanced
arteriosclerosis or high cerebral pressure; and in operations on the brain.
It is often ineffective in hysterical, obese, muscular or alcoholic patients
(S. G. Davis, 1900).

Mechanism of Action.—$N_2O$ is very soluble in blood, which takes up 45 per cent.
by volume (Bert). Davy believed that it acted like oxygen, producing hyperventila-
tion of the blood; but Frankland showed that it is not decomposed. It was then believed
that it acted merely as an anesthetant. The phenomena produced by the undiluted
gas are in fact partly asphyxial. This factor can be removed by the addition of oxygen
when it is seen that narcotics results from the $N_2O$ itself. This may also be demonstrated
on frogs, which preserve their reflexes for hours when placed in pure hydrogen; but lose
them promptly in $N_2O$. Evidently the nitrous oxide has a direct action on the central
nervous system; first stimulating the psychic areas, then depressing these to insensi-
tivity. The motor reflexes are also abolished. The medullary centers are not affected,
and the circulation remains unchanged, in the absence of asphyxia. Nitrous oxide also
has no action on other tissues and is therefore absolutely harmless. Dogs anesthetised
continuously for three days with a mixture of $N_2O$ and oxygen, recovered without any
damage. The mechanism of its central action is probably the same as with the hydro-
carbon narcotics—viz., a physical change in the lipoids. It probably does not combine
with hemoglobin. On account of its feeble chemic affinities, the gas is practically free
from side actions, and herein lies its chief value.

Catalase of Blood.—This is diminished by nitrous oxid, just as in other forms of
anesthesia (Burge et al., 1918).

High Pressures of Nitrous Oxid.—These are fatal above 3 atmospheres, even when
inhaled with adequate oxygen. The symptoms consist in narcosis, convulsions, and
finally depressed respiration. The heart remains strong (Bock, 1917).

Nitrous Oxid with Air or Oxygen.—The respiratory disturbances, convulsive features and cyanosis produced by undiluted $N_2O$ are purely
asphyxial. If the gas is mixed with a sufficient proportion of oxygen
(15 to 20 per cent.), these asphyxial phenomena are entirely absent, and
the anesthesia can therefore be prolonged indefinitely. With smaller percentages of oxygen, the symptoms are intermediate.

The dilution of the gas with oxygen lowers its concentration in the blood to a corresponding degree, so that the narcotic action is not as prompt or deep. It is generally stated that a mixture of 80 per cent. of nitrous oxide and 20 per cent. of oxygen, inhaled at atmospheric pressure, produces only confusion and analgesia, with incomplete loss of consciousness.

However, Hewitt claims to produce deep anesthesia in this way within four minutes; and that the anesthesia becomes incomplete only if the concentration falls below 60 per cent. Paul Bert, 1880, obtained perfect results by a mixture of 85 parts N₂O and 15 parts O₂, condensed by an excess-pressure of 1/4 atmosphere.

D. E. Jackson, 1916, describes an apparatus that involves the continuous rebreathing of the nitrous oxide, with removal of the CO₂ and renewal of the oxygen. This permits of prolonged anesthesia at a minimum cost. Under these conditions, the effects have considerable resemblance to morphine. Man appears sensitive to lower concentrations than are needed for dogs. Careful administration induces an apparently natural sleep.

These methods are not very feasible in practice; but a satisfactory anesthesia may be maintained sufficiently long for ordinary surgical operations by adding only enough oxygen to the gas to prevent the major manifestations of asphyxia.

Hewitt found that 6 per cent. of oxygen are required to prevent the convulsive features and noisy respiration; 11 per cent. to prevent lividity. Above 10 per cent., the reflexes and movements of the patient were more pronounced.

Jackson, 1917, confirms that the addition of more than 10 per cent. of oxygen greatly delays or even prevents the loss of consciousness.

Morphin-scopolamin greatly increases the efficiency of nitrous oxide; so that with these alkaloids, a mixture of 80 per cent. and 20 per cent. oxygen even at atmospheric pressure induces an operative anesthesia (Kochmann, 1914).

Administration of the Mixed Gases.—This requires a special apparatus for adjusting the two gases in any proportion. This is connected with a close-fitting mask. It is advisable to warm the gas mixture before it is inhaled.

To hasten the anesthesia, the administration is begun with a mixture containing 2 per cent. of oxygen. This is gradually increased to 10 per cent., but varying for different patients.

Phenomena.—The primary symptoms are the same as with pure gas. The respiration is at first stimulated, so that the patient feels that he can breathe with less effort (Jackson, 1917).

The anesthetic stage is usually reached in a few minutes. It is characterized by regular, calm, moderately snoring respiration; slightly dusky face; and medium pupils. The pulse is moderately quickened; the blood pressure somewhat high; the blood rather venous. Convulsive phenomena are absent. The reflexes and muscular tone are greatly decreased, but not abolished as with ether; and the anesthesia is not so profound.

After-effects.—When the administration is stopped, the patient awakens fully within two or three minutes. Nausea is exceptional, but more common than after short inhalations.

Advantages.—These consist mainly in the greater comfort of the patient, the smaller danger, and the absence of irritant side effects. The gas would therefore be especially indicated in renal and acute pulmonary diseases; or when the patient dreads the other anesthetics. Crile, 1910, claims that it lessens the danger of shock and infection.

Disadvantages.—The contraindications and limitations were discussed under the undiluted gas. Its application is further limited by the rather
shallow anesthesia; incomplete relaxation; high blood pressure and veno-
ity of the blood; the expense of the gas and apparatus; inconvenience; and
the need for very specialized experience.

Influence of Impurities.—Warner, 1915, finds that ordinary nitrous oxide often pro-
duces severe symptoms, especially cyanosis, which does not occur with proper purifica-
tion. The toxic effects are due partly to nitric oxide, but especially to unidentified
basic impurities, perhaps hydroxylamin and hydrazin. The gas deprived of these (as
is now generally done) can be given with less oxygen, without cyanosis.

Gas-ether Sequence.—This was suggested by Clover, 1875; but has also
come into extensive use only recently. It seems to combine the chief
advantages of the two anesthetics, and is perhaps the nearest approach
to an ideal method.

Nitrous Oxid Analgesia in Obstetrics.—This is being advocated as
much safer than scopolamin-morphin "twilight sleep." It does not
weaken the uterine contractions and has no bad effects on mother or child
(Webster; Lynch; Davis, 1915).

PREPARATIONS—NITROUS OXID

*Nitrogenii Monoxidum (Nitrogen. Monox.), U.S.P. (Nitrous Oxide), N₂O.—Colorless
less gas; possesses a slight characteristic odor; somewhat sweetish taste. It is marketed,
compromised as a liquid, in steel cylinders. It returns to the gaseous state when the
pressure is released.

CARBON DIOXID (CARBONIC ACID)

General Statement.—This acts as a weak acid, producing locally a
rather mild irritation; and after absorption, strong medullary stimula-
tion, and in higher concentrations narcosis. These actions play the
principal role in ordinary asphyxia. Deficiency of CO₂ (Acapnia) leads
to corresponding depressant phenomena. The carbonic acid therefore
acts as a hormone (Bayliss and Starling, 1906), which regulates the ac-
tivities of various functions, especially of the respiration. In this way,
the CO₂ tension of the blood and tissues is normally kept automatically
at a practically constant level.

Local Actions.—CO₂ as gas or solution produces a prickling sensation
and reddening of the skin and mucous membrane, followed by numbness
and local anesthesia. The sensory irritation leads to reflex stimulations
(Quincke, 1877). The cutaneous stimulation is utilized in the form of
carbonated baths (Naunheim baths), especially in cardiac diseases. Fro-
zen CO₂ (carbon dioxide snow) is employed as a superficial cauteriant.
In the stomach, carbonated water ("soda water") hastens absorption,
increases the secretion of acid gastric juice (Chiari, 1915), and acts as a
cautious agent. It is useful against nausea, and valuable for disguising the
taste of medicines.

Effects of Inhaled CO₂.—If oxygen deficiency is excluded by inhaling gas mixture
containing 20 per cent. of oxygen, no effects occur until the concentration of 3 per cent.
volume, of CO₂ is reached (Zanta). With this concentration, there is some hypopnea
and discomfort: 8½ per cent. in man produces in a few minutes distinct dyspnea, rise
of blood pressure and congestion, which become insupportable in fifteen or twenty
minutes, but disappear promptly in fresh air. The symptoms increase to 15 per cent.; but
even 20 per cent. is not dangerous in an hour to animals, and probably not to man.
With 15 to 20 per cent., the stimulating phenomena pass into depression, with diminished
respiration, fall of blood pressure, coma (generally without convulsions), loss of reflex,
anesthesia, and gradual death after some hours; the heart outlasting the respiration.
With higher concentrations, the stimulation is still briefer. With pure CO₂, death
may occur in a few minutes as a mixed effect of carbon dioxide and anoxemia.
Ordinary Asphyxia.—This involves the two factors of deficiency of oxygen or excess of carbon dioxide in the blood. The phenomena in both cases are almost, though not quite, identical. When asphyxia results from breathing in a confined space, both causative factors are intermingled, but the CO₂ factor predominates.

The symptoms of asphyxia vary somewhat according to the rapidity with which it is produced. When it occurs rapidly, three typical stages may be distinguished: During the first stage, the respirations (particularly the inspirations) are increased. In the second stage, the respirations are irregular and convulsive; the inspirations being shallow and weak, the expirations powerful and prolonged. Consciousness is lost. The skin, especially the face, becomes cyanotic. The third stage is characterized by collapse and convulsions. The respiratory centers are depressed. The respiratory movements are shallow and infrequent. The convulsive, vagal, and vasomotor centers are stimulated. The extremities and the muscles of the face and neck twitch convulsively; there are gasping movements; the body of the animal is rigid and arched backward. Urine and feces are expelled. The pulse is very slow and soft, at first strong, then progressively weaker. The pupils are at first constricted, then widely dilated until death. The heart continues to beat weakly for several minutes after the respiration has stopped. Artificial respiration during this interval will generally result in recovery. Death occurs within six or eight minutes, if the trachea is tied.

The autopsy shows a very venous color of the blood. The veins of the upper part of the body, and the right heart, are greatly distended.

If the asphyxia is produced slowly, the first symptoms are cyanosis and dyspnea on exertion. The individual becomes stupified, but so gradually that he may not be aware of his condition. The stupor passes into unconsciousness and this into collapse. The motor symptoms may be entirely absent.

Cyanotic Test.—Asphyxia by excess of carbon dioxide produces a deep-blue cyanosis, with venous congestion. Oxygen deficiency causes a gray tint, without rise of venous pressure (Hallé, 1917). This difference in tint is evidently due to the quantity of venous blood in the skin.

Lundsgaard, 1913, has confirmed that cyanosis proper is due to “oxygen unsaturation” of the capillary blood, appearing when this reaches 6 to 14 per cent.

There is no strict parallel between the two, since the depth of the color of the skin and mucous membranes is determined by the quantity as well as by the color of the blood. The unsaturation may occur through incomplete aeration in the lungs; or through slow peripheral circulation; or through excessive oxygen consumption in the tissues.

Medullary Centers in Asphyxia.—The effects are alike whether they result from CO₂, acidosis, or oxygen deprivation. The stimulation occurs in the order of respiratory, then vasomotor and then vagus centers. It is followed by depression of these centers. The relative preponderance of stimulation and depression depend on the degree and suddenness of the asphyxia, and on the prevailing condition of the centers (Loevenhart, 1915).

According to perfusion experiments on mammalian medulla, carbonic acid appears to be somewhat more stimulating than other acids of equal H-ion concentration (Hooker et al., 1917), presumably because it penetrates the nerve-cells more readily.

Rôle of CO₂ in Asphyxia.—C. Bernard showed that the deprivation of oxygen ordinarily plays a minor part; including the head of an animal in a blubber, he found that the intravascular injection of oxygen does not retard death. Temporary revival from asphyxia may be secured by artificial respiration in an atmosphere of hydrogen or nitrogen; and according to some experiments of the author, even in CO. The investigations of Loevenhart, 1915, however, suggest that the CO₂ itself acts by interfering with oxidation.

Rôle of CO₂ in Impure Air.—The popular idea of this is greatly exaggerated. “Pure” air contains 0.03 per cent. of CO₂; in city streets it rarely rises above 0.04, or at most 0.15 per cent. In badly ventilated rooms it may reach 0.3 per cent., which is far below the 4.5 per cent. concentration. Neither the presence nor the absence of oxygen explains the harmful effect of sojourn in ill-ventilated rooms; nor does the expired air contain any poisonous ingredients. It is supposed that the acute discomfort and the suffocating sensation experienced in these places is largely psychic, being
produced by the heat, humidity, odors, noise, etc. Whether this will also account for the severely detrimental effect on health and resistance, the increased tendency to tuberculosis, etc., which are associated with habitually deficient ventilation, is an open question. Winslow and Palmer, 1917, conclude that the air of unventilated rooms (with controlled temperature and humidity) contains substances which diminish the appetite for food, without producing discomfort or other detectable symptoms. It may be remarked that the continued or repeated exposure to gases—particularly those acting upon the blood, and indeed to any poison which alters the blood, such as acetic acid—does not generally cause tolerance, but increase of susceptibility.

**CO₂ on Circulation.**—Increase of carbon dioxide up to a certain point causes a great rise of blood pressure (Fig. 6, p. 232) mainly by stimulation of the vasomotor center; moderate increase of CO₂ tension perhaps also increases the output of the heart. The peripheral action on blood vessels results in their dilation. High concentrations paralyze the vasomotor center and heart.

**Vasomotor Center.**—The violent stimulation has been shown by Sollmann and Pickert, 1911, and by Mathison, 1913. The latter demonstrated that identical effects are produced by other acids and by lack of oxygen; and that all these act probably by increasing the hydrogen-ion concentration of the blood. The spinal vasomotor center are much less sensitive than the medullary (Mathison, 1910).

**Direct Action on Vessels.**—This results in relaxation (Bayliss, 1902); it also acts in excised arterial or venous rings, with all concentrations (Cow, 1911; Hooker, 1912). A similar dilatation is also produced by other weak acids (Schwarz and Lemberger, 1912). Barcroft, 1914, considers this an important factor for the increase of the local circulation in active organs.

**Pulmonary Circulation.**—The pressure in the pulmonary arteries rises in asphyxia, even if the rise of the systemic blood pressure is prevented by destroying the medulla (Wood, Jr., 1911). The pulmonary circulation time is slowed (Langlois and Debout, 1912), indicating pulmonary vasodilatation.

**Venous Pressure.**—Increase of carbon dioxide causes a large rise of venous pressure, even when the arterial pressure is but little affected. Henderson and Harvey, 1918, interpret this as due to direct dilation of the capillaries and venules.

The increased venous return would increase the diastolic filling and thus the efficiency of the heart. Acapnia would have the opposite result.

**Heart Rate.**—This is ordinarily slowed by stimulation of the vagus center; but if the vago are divided, it is quickened by stimulation of the accelerator center (Duster and Morat, 1884).

**Efficiency of the Heart.**—In intact animals, the cardiac effects are greatly complicated by the other actions. Jerusalem and Starling, 1910, claim that increase of CO₂ in the coronary blood lessens the tone both in systole and diastole. The coronary vessels are also dilated (Markwalder and Starling, 1913). With higher concentrations, the systolic tone is lowered more, so that the excursions are diminished; with moderate concentrations, the diastolic tone is more relaxed and the output increased. A certain concentration would therefore be necessary for the optimum efficiency of the heart; this is insufficient in acapnia. Itami, 1913, claims that the rise of blood pressure with 10% per cent. of CO₂ in the inspired air is chiefly due to increased output of the heart, and that above 8 per cent. the vasconstriction becomes the more important. These results have been contradicted: Ketcham, King and Hooker, 1912, attribute the increased output of the heart to the pulmonary response, for they found that the isolated heart is depressed by all concentrations. In the limulus heart, CO₂ produces depression, acting much more powerfully on the ganglion cells than on the muscle (Newmann, 1908). Perfusion of the coronary vessel of a mammalian heart with CO₂ gas causes prompt fibrillation and arrest, whereas the heart continues to beat for a considerable time if the perfusion is made with oxygen, or even hydrogen (Magnus, 1902).

**Re-breathing in Shock.**—W. T. Porter, 1917, suggested the increased respiration produced by carbon dioxide as a mechanical aid to the circulation in fat embolism, and in shock generally. He apparently obtained some good results; but the clinical results have not been good (Cude) and the injurious direct effects of asphyxia on the heart do not ordinarily justify this method.

**Blood Viscosity.**—This is somewhat increased, but not to an important degree (Burton-Ogilvy, 1913).

**Oxygen on CO₂ of Blood.**—Oxygen (and carbon monoxide) tends to expel CO₂ from the blood; for when exposed to a given CO₂ tension, blood that has been deprived of
oxygen takes up considerably more CO₂ than oxygenated blood (Christiansen, Douglas and Haldane, 1914).

Peristalsis.—In intact animals, this is stimulated by asphyxia. Excised intestine is affected only if at rest. But if it was already rhythmically active (Hooker, 1912).

Oculomotor Center.—The pupils are ordinarily widely dilated by asphyxia, after primary constriction (Guthrie and Ryan, 1912). The mydriasis is not due to sympathetic stimulation, for it occurs after division of the cervical sympathetic (Braunstein, 1804). It must therefore be ascribed to inhibition of the oculomotor center. 'Rhythmically, CO₂ acts as a miotic on frog's pupil' (Avery, 1909).

Respiration.—The CO₂ content of the blood is the chief regulating factor in ordinary respiration (Zuntz, 1887). The respiratory center being stimulated (mainly the rate) even by very slight increase of the CO₂ tension. The normal CO₂ percentage of the alveolar air is 5.6 per cent. A rise of 0.2 per cent. of CO₂ (1.6 mm.) in the alveolar air doubles the respiration, and a slight reduction (0.2 per cent.) of the CO₂ produces pnoe. The sensitizer to oxygen is very much less, the respiration being unaffected by variations of the oxygen in the air between 13 and 90 per cent. (Haldane and Priestley, 1905; Fitzgerald and Haldane, 1905). The effective increase of CO₂ also produces a slight but measurable change in the hydrogen ion concentration of the blood (Campbell and coworkers, 1913). Other acids are similarly stimulant (Winterstein, 1911; Laquer and Verzar, 1911) although not quite as much (Hooker et al., 1917). Loevenhaut, 1913, refers the effects ultimately to interference with oxygenation. The response to CO₂ is used experimentally as a test of the excitability of the respiratory center (A. Loewy, 1890).

Bronchial Muscle (Excised).—This is constricted by moderate, relaxed by high concentrations of CO₂ (Zuntz, 1912).

Strychnin Convolutions.—These may be suppressed by CO₂ inhalation (Winterstein, 1900; Ryan and Guthrie, 1908). On the other hand, moderate asphyxia increases the convulsive effect (Guthrie). Concentrations above 0.2 per cent. also heighten the susceptibility to acid shock convulsions (Joseph, 1915).

Temperature.—CO₂ dyspnea lowers the temperature in health, and especially in fever. It also reduces metabolism (v. Magyar-Kossa, 1910).

Asphyxial Glycosuria.—All forms of asphyxia—whether from CO₂ or deficiency of oxygen—lead to hyperglycemia and glycosuria. All asphyxiant drugs produce this effect, although there may be additional factors. The glycosuria does not occur if the liver is excluded, nor in poorly nourished animals (Auel, 1914). It seems therefore that the glycojenolysis is stimulated in the liver, but not in the muscles. This effect is probably due to the increased H-ion concentration of the blood, acting through the nervous centers, but requiring the cooperation of the adrenals, for it does not occur if these have been excised (MacLeod, 1913).

Drugs Leading to the Appearance of Reducing Substances in the Urine.—The following may be enumerated as among the most important (review, S. Weber, 1904): CO₂, N₂O, H₂S, HCN, amyl nitrite, nitrobenzol, nitroglycerin, chlorates, chloral, urethane, chloroform, acetone, strychnin, morphin, atropin, curare, chloralum, caffeine and other methyl xanthines, H₂O₂, many acids, Pb, As, Hg, U, Cr, cantharidin, P, spinosin, thyroid, salines.

Deficiency of CO₂ (Acapnia).—The carbon dioxide tension regulates the heart rate, vascular tone, peristalsis, mental condition, and a number of other functions. A decrease of this tension in the blood and tissues produces depressant effects.

Phenomena of Acapnia.—These have been emphasized especially by Y. Henderson, 1908 to 1910. Even a slight reduction of the CO₂ causes marked increase of the heart rate and slowing of respiration. Further reduction produces tachycardia, venous stasis, arrest of peristalsis, failure of many reflexes, coma and stoppage of respiration. Extreme reduction causes an almost tetanic condition of the heart, abolishing its output, overworking blood pressure and resulting in death. In the lighter grades, recovery occurs promptly if the CO₂ tension is increased, as by breathing through a long tube.
Acapnia and Respiration.—The respiratory center is readily depressed by deficiency of CO₂ in the blood. This is the main factor in the apnea following hypopnea, and one factor in Cheyne-Stokes respiration (Haldane, 1905 and 1906). Weil, 1906, 12, showed that the apnea is the shorter, the more CO₂ is in the air; and that it can be prolonged by fixing the CO₂ with NaOH. The increased oxygen content, to which it was formerly attributed, seems to be unessential although excessive oxygen concentration is also depressant (Levene and Hart, 1913).

The direct depressant effect of CO₂ deficiency on the respiratory center was also demonstrated by Winterstein’s (1911) perfusion experiments. The respiration was not restored by oxygen, but by carbonic or other acids, and is therefore an hydrogen-ion effect. In intact animals, a persistently low oxygen tension leads to the accumulation of lactic and other acids, and hence to stimulation of the respiration.

Acapnia and Shock.—Y. Henderson, 1908 and 1909, pointed out the analogies between the phenomena of acapnia and surgical shock. He believed that the latter may be explained by loss of CO₂ through hypopnea, exposure of intestines, etc. This may be one of the factors but it is unlikely that it is the only one. Henderson’s contentions are contradicted by Janeway and Ewing, 1913.

Apnea.—This suspension of the respiratory movements is usually due to depression of the respiratory center by excessively low CO₂ content of the blood (acapnia); for instance, as a consequence of hypopnea. Frederick showed that apnea can be produced by the transfusion of the blood of an apneic animal.

However, acapnia is not essential; for excessive distention of the lungs may produce apnea even when the air contains 5 per cent. of CO₂. This phenomenon does not occur if the vags were divided (Githens and Meltzer, 1914). In fowls, CO₂ deficiency also stops the respiratory movements, but in this case the effect consists in tonic spasm of the respiratory muscles, and not in heightened threshold. The function of CO₂ would therefore consist in the maintenance of the respiratory rhythm (Meyer and Metter, 1914).

Normal CO₂ Percentages and Tensions.—These are as follows:

CARBONIC OXID (CARBON MONOXID, CO₂); ILLUMINATING GAS

General Statement.—Carbonic oxid gas has considerable toxicological importance, through its occurrence in illuminating gas, especially water-gas, and as a product of incomplete combustion. Accidental and suicidal poisoning by it are very common. It forms a firm compound with hemoglobin, thereby preventing it from carrying oxygen, and thus produces asphyxia. This agrees with ordinary asphyxia, except that the skin and mucous membranes are not cyanotic but bright red, due to the color of CO-hemoglobin.

Occurrence.—Carbonic oxid constitutes 4 to 10 per cent. of ordinary coal-gas, and 30 to 40 per cent. of water-gas (which is consequently more dangerous, Sedgewick, 1911). It is formed during incomplete combustion and is therefore present in the smoke of damped stoves, the vapor of burning charcoal, after mine explosions, etc. It is the principal toxic ingredient of these gases. Coal-gas, however, is said by Vahin (1903) to possess more than double the toxicity which would correspond to its CO₂ content and which he and Haggard state that dogs exposed to illuminating gas hydric die when 75 per cent. of their hemoglobin is saturated with CO₂, but that they survive considerably higher concentrations when exposed to pure CO. When death does occur, the CO does not account fully for the toxicity of coal gas. The difference is due to coal-tar products (which may be removed by passing the gas through oil). The disagreeable odor of gas is not due to the carbonic oxid (which is practically odorless), but to sulphur compounds. These are not toxic, but serve as a useful warning of the escape of gas. This odor can be detected in air containing 0.01 to 0.02 per cent. of gas, i.e., much below the danger limit. They are
removed by filtration through soil; so that underground breaks in gas mains are especially dangerous.

Manner of Action.—Carbonic oxide acts only by displacing oxygen and has no direct action of any kind; for if an animal is made to breathe oxygen under 2 atmospheres pressure (which renders it independent of the hemoglobin) the addition of carbonic oxide in any amount produces no symptoms. However, Geppert, 1892, believes that there is a direct but insignificant action on the central nervous system; and Glanvoll, 1905, even claims that the blood changes do not play the principal rôle in CO-poisoning.

Action on Plants and Lower Organisms.—Carbon monoxide (or illuminating gas) slightly retards the growth of bacterial cultures, but is not germicidal. Intusoria and ciliated epithelia are also checked, but not killed. The germination of the seeds of higher plants is not affected. The gas kills plants when applied to the leaves, but not to the roots (Heider, 1914).

Action on Blood.—Carbon monoxide combines with hemoglobin to form carboxic oxic hemoglobin. The compound is very firm; it is distinguished spectroscopically from hemoglobin, and it is not reduced by ammonium sulphid (Hoppe-Seyler, 1864 and 1865). (See Fig. 29.) It has a cherry red color (Poirier, 1826), which is quite different from that of oxyhemoglobin, especially when it is diluted. This forms one of the best tests for its presence.

The affinity of hemoglobin for carbonic oxide is about 210 times as great as that of oxygen; even very small proportions therefore prevent the complete oxygcnation of blood and produce asphyxia.

Fate.—The CO is excreted unchanged, and is not oxidized to CO₂. In fatal cases, a part persists for a long time (over a month) in the blood, and to a less extent in the muscles (Wachholz and Lemberger, 1905). It may penetrate postmortem into a cadaver, but so slowly that it can not be demonstrated in the internal organs (Stoll, 1909). Cl. Bernard observed that CO delays the postmortem degeneration of blood corpuscles, the serum separating very clear.

Toxic Concentrations.—The absorption of CO is proportional to its concentration in the air. Gruber, 1881, found that 0.024 per cent. is harmless even after several hours. The toxicity begins with about 0.05 per cent., is severe with 0.07 per cent., and dangerous with 0.10 per cent.; 0.2 to 0.4 per cent. is generally fatal. Dizziness and hyperpnea occur when about 20 per cent. of the hemoglobin is saturated; unconsciousness with 50 per cent.; death with 60 to 80 per cent. of saturation (Dreser, 1891; Balthazard and Nicoux, 1912).

Course.—The phenomena agree with those of ordinary asphyxia, except that cyanosis may be absent; the skin being pink or pale, and the lips bright red (i.e., the color of CO-hemoglobin). This is diagnostic importance. The effects are insidious, the person becoming unconscious often with no premonitory symptoms.

The clinical cases may be classified as acute, chronic, and relapsing (McConnell and Spiller, 1912).

Symptoms of Acute Illuminating Gas Poisoning.—These may be divided into three stages (following McCombs, 1912): (1) till loss of consciousness; (2) from beginning of syncope to the onset of aspnea; (3) coma with arrested respiration.

Onset.—The symptoms generally begin with a feeling of discomfort, throbbing blood vessels; dizziness, headache, weakness, and sometimes nausea and vomiting; sometimes pain in the extremities, and muscular twitching. The temperature is normal; the pulse full and bounding, the blood pressure elevated; feeling of constricted thorax; pupils widely dilated; gradual drowsiness, stupor and unconsciousness.

After this has set in, the respiration becomes accelerated and stertorous; the skin dusky; lips and extremities blue; or pale or pink; loss of reflexes and sphincter control. Tetanusiform convulsions may occur and be followed by marked muscular rigidity, especially in the jaws. The pulse and respiration gradually weaken, ending in apnea, and finally arrest of the heart.

The coma is longer and more severe in illuminating gas poisoning, than with pure CO (Y. Henderson and Haggard, 1918).
Death sometimes occurs acutely through aspiration of vomited matter during unconsciousness. 

Recovery from the acute effects occurs generally in 48 to 72 hours; but convalescence is often tardy, with pulmonary and nervous sequelae. 

Sequelae: aspiration pneumonia, often fatal; palpitation, localized hyperemias, gastrointestinal disturbances, transient asphyxial glycosuria (review, S. Weber, 1924); cutaneous eruptions, localized edemas, gangrene; paralyses of central and peripheral types, choreiform movements, persistent headache; mental changes, loss of memory, confusional insensates, etc. 

Chronic Type.—Headache, nausea, vertigo, weakness, anemia, slowed intellect and failure of memory, and all the phenomena of the acute type more slowly developed. The memory for recent events is impaired much more than for those of older standing (S. Brown, 1906). The nervous phenomena have been referred to serious leptomeninitis (Sieler, 1897). 

Relapsing Type.—The acute symptoms are followed by complete recovery, but after some weeks grave paralytic phenomena appear and are often fatal. These cases show softening of the lenticular nucleus, referred to fatty degeneration of the vessels, proceeding to calcification. 

Induced Tolerance.—Guinea pigs can be accustomed to live for months in an atmosphere by which 25 per cent. of their hemoglobin is saturated with CO. This tolerance is attained by an increase of the corpuscles and hemoglobin, so that the oxygen capacity becomes almost normal. 

Treatment of CO and Illuminating Gas Poisoning.—This is usually successful if begun while the heart is beating. In the presence of a large excess of oxygen, the carbonic acid hemoglobin is again decomposed, and the CO eliminated (not burned). The treatment therefore consists in artificial respiration, or still better, the forced inhalation of oxygen. Bleeding with transfusion of healthy blood is very effective (Worm-Mueller; Crile and Lenhart, 1907). Patients should not be exposed to cold. 

With respiration, natural or artificial, of ordinary air, the CO-hemoglobin is decomposed below the danger limit within an hour, the CO being practically eliminated in two or three hours. It is therefore superfluous to use oxygen or transfusion after an hour. 

If the coma continues longer, this is due to persisting injury of the nerve-centers by the early asphyxia. Once this injury has occurred, it would not be helped by oxygen. The existence of acidosis indicates alkalies; otherwise the late treatment would be expectant (V. Henderson, 1916). 

The prognosis varies with the duration of the exposure and of the coma. It is bad if the coma has lasted more than forty-eight hours, or if edema or cutaneous blebs have developed (G. I. Jones, 1909). Even in favorable cases, recovery is rather more slow than with most gases; but the acute effects have generally disappeared within three hours. 

OXGEN

The Inhalation of Pure Oxygen.—Oxygen constitutes about one-fifth (20.94 per cent.), by volume, of ordinary air. An increase of this proportion, and even the inhalation of undiluted oxygen, produces no noticeable effect under ordinary conditions. The rate of oxidation or the consumption of oxygen is not at all increased (Pilzegger); indeed, the output of CO₂ is rather decreased. Evidently, the proportion of oxygen in air suffices for all ordinary needs (or, rather, it is greater than necessary); and additional oxygen acts merely as an indifferent gas—as so much nitrogen or hydrogen. In other conditions, however, namely when the supply of oxygen is deficient from any cause, its inhalation will remove the asphyxial symptoms with striking promptness and efficiency.
Condition of the Oxygen in the Blood.—The effects of most gases are strictly proportional to their partial pressure in the respired air. Oxygen departs from this rule, for there are practically no effects when its percentage is varied between 10 to 15 or 100 per cent. This is explained by the fact that only a small part of the oxygen is carried in physical solution in the blood plasma. By far the greater part is in loose chemic combination with hemoglobin, 1 molecule of hemoglobin combining with 1 molecule of O₂ (Butcherfield, 1913). This combination is only slightly affected by the above changes of pressure. When respiring ordinary air without obstruction, the hemoglobin of the arterial blood is already four-fifths to ninetenths saturated with oxygen; and the amount taken up can therefore be but little increased by raising the oxygen tension (Buckmater and Gardiner, 1915). The oxygen of the alveolar air, however, increases directly with the oxygen percentage of the alveolar air. While the amount thus carried is numerically small, it becomes important in conditions in which the hemoglobin can not perform its functions properly, as in anemias or CO poisoning. The plasma oxygen may also play a part when the demands for oxygen are greater than can be supplied by the hemoglobin; as in very severe muscular exertion or in cardiac disease.

Ordinary arterial blood contains about 38.5 per cent. of oxygen in chemische combination with hemoglobin; and 0.6 per cent. dissolved in the plasma—a total of 19.1 per cent. Inhalation of undiluted oxygen increases the percentage in oxyhemoglobin only to 38.7 per cent.; the dissolved oxygen is increased in proportion to the partial pressure; i.e., to 3.4 per cent., giving a total of 21.7 per cent., or an increase of 2.6 per cent. This is not really as small as it appears; for it seems that the oxyhemoglobin does not yield all its oxygen to the tissues (for instance, after death by asphyxia the blood still contains considerable oxygen). Haldane, 1917, considers that the increase of 2.6 per cent. really equals about 40 per cent. of the easily available oxygen of the blood.

Dissociation Curve of Oxyhemoglobin.—This follows the law of mass-action, showing that the reaction is chemic and not absorptive. The curve is identical for pure solutions of hemoglobin, whatever their origin; but it is markedly affected by electrolytes, and therefore differs in the blood of different animals or even individuals. The action of electrolytes is explained by aggregation of the hemoglobin molecules. It is especially great with acids (H⁺ ion concentration). Increased acidity diminishes the affinity, and therefore the effective concentration of oxygen. Thus 40 mm. of CO₂ will completely dissociate the hemoglobin into oxygen. The same laws hold for CO-hemoglobin (Burt, 1914).

Oxygen Pressure in Blood.—The partial pressure of oxygen in arterial blood is about 93 mm. Hg.; that of venous blood is variable, but about one-half or less of this figure.

Absorption of Oxygen in the Lungs.—There has been much discussion whether this follows purely physical laws. The question is even now not absolutely decided. According to Douglas and Haldane, 1910, the absorption is simply physical under ordinary conditions but if so much O₂ is inhaled that the supply of oxygen to the tissues becomes inadequate, there is an active (secretory) absorption, so that the partial pressure of oxygen in the arterial blood becomes higher than in the alveolar air. This occurs also when the demand for oxygen is increased by muscular work. It is not known how this correlation is brought about.

Mechanism of Oxidations in Tissues.—The oxidations of metabolism are not accomplished by oxygen directly, for they can not be reproduced in vivo at ordinary temperature. There must be some activation of the oxygen. The most commonly accepted theories are modifications of that of M. Traube, i.e. the production of superoxide, which produce in vivo types of oxidation corresponding closely to those in the body. The oxidases are supposed to consist of organic peroxides and a catalyst (peroxidase). Catalases, which occur in many tissues, act only on hydrogen peroxide; their function is problematic (Bibliography, Kastle, Hyg. Lab., Bul. No. 59). The oxidating ferments so far identified are apparently not connected with the energy-producing oxidations of the body (Batelli and Stern, 1919).
Relation to Medullary Centers.—These are stimulated by moderate deficiency of oxygen; paralyzed by extreme deficiency. The respiratory center is the most sensitive, then the vasomotor, and least the vagus center. The intensity of the reaction is determined by the rapidity and degree of the change and by the state of the center. Excessive oxygen is depressant. Loevenhart, 1913, attributes ordinary asphyxial stimulation to depression of the oxidative processes of the cells, by actual abstraction of oxygen, or by increase of hydrogen-ion concentration (acidosis, CO₂). Very similar phenomena are produced very promptly by cyanids, which are known to interfere with oxidation. The response occurs so promptly that there would scarcely be time for the accumulation of acid, so that deficiency of oxygen probably acts directly (Gasser and Loevenhart, 1914).

Two-phase Oxidation Theory.—Loevenhart, 1915, suggests that asphyxia may be explained by assuming two phases of oxidation: the “rest process,” occurring during rest and recovery, and requiring external oxygen; and the “activity process,” during activity, which consumes internal oxygen. Both processes would be constantly in operation; their relative intensity determining the state of activity of the cell. The addition of external oxygen would reinforce the “rest process” and thus cause depression; while oxygen deficiency would have the opposite effect.

Relation of Oxygen to Activity.—Every increase of activity, in any organ, appears to produce an increased consumption of oxygen. This outlasts by far the time of actual stimulation and visible response. The same is true of the production of heat. The response to the “rest process,” and is evidently concerned in the storage of potential energy.

Minor Effects of Oxygen Inhalation. Metabolism.—Lavoué and Seguin, 1792, claimed that pure oxygen has no effect on metabolism. This has been confirmed by the modern investigators. However, the reputed benefits from the inhalation of oxygen is faulty degeneration and some other obscure diseases (if the reports are reliable) would point to some effect on metabolism, perhaps too small to be detected by the usual methods of observation.

Oxygen Inhalation also produces some other slight effects: Cl. Bernard claimed that when placed in pure oxygen are greatly excited; and that the urine of rabbits becomes acid. Benedict and Higgins, 1911, observed some slowing of the pulse, with no change in respiration. There are rather more marked effects after exercise (Cook and Pembrey, 1913). The efficiency of athletes is increased and forced respiration on the lungs and maintained longer (Hill and Plack, 1909 and 1910). Christensen and co-workers, 1913, attribute this to the smaller solvent power of blood for CO₂ in the presence of oxygen.

Oxygen under excessive pressures (above 1.7 atmospheres) produces pneumonia, pressures above 3 or 4 atmospheres, cause violent convulsions and ultimately death. These effects are not due to pressure as such, for they are not produced by compressed air until the partial pressure of oxygen reaches the above figures. Of the, 1912, and A. Schmidt and David, 1912, claimed that prolonged inhalation, even of 70 per cent. oxygen at ordinary pressure would produce fatal pneumonia. Bruechner, 1912, refutes these results to the dryness of their gas, since the same effects were produced with dry compressed air, and not if moist oxygen was inhaled.

However, Karner, 1915, found that even when these precautions are taken, rabbit exposed forty-eight hours to 80 per cent. oxygen showed congestive or inflammatory changes in the lungs. Exposure for twenty-four hours did not usually produce air damage. With 67 per cent. of oxygen, exposure for 11 days produced very slight pulmonary irritation, but not true inflammation. Exposure to 53 per cent. of oxygen for 34 days showed no change (Karner and Ahn, 1917).

Phagocytosis.—This has been studied in vitro by H. J. Hamburger, 1915. Deprivation of oxygen stimulates phagocytosis for a time; prolonged exposure is depressant. Increase of oxygen is also generally depressant. Hydrogen peroxide stimuliates macrophages. Potassium chloride and ferricyanid produce no effect.

Infammation.—Mustard conjunctivitis is checked by the intravenous injection of substances containing chemically active oxygen, such as lodosobenzoic acid. Conversely, inflammation is intensified by cyanids, which check oxidation (Amberg and 1917).

Oxygen in Asphyxial Conditions.—The results are especially striking in those forms of asphyxia, in which the access of oxygen to the blood is hindered, as by vitiated air (anesthesia, mines, wells, etc.); by mechanical interference with respiration (suffocation, drowning, crowd, etc.); by depressed respiration (anesthesia, collapse); or by a diminished absorbing
urface of the lung (pneumonia). In all these cases the blood is dis-

inctly venous, i.e., the hemoglobin is not saturated with oxygen; and the

halation of the gas promotes the saturation (Haldane, 1917).

According to Haldane, 1918, oxygen inhalation is of considerable benefit in emphy-

ma and gives temporary relief in asthma; but has little effect on the dyspnea of cardiac

sease or of nephritis.

* Pulmonary Edema from Irritant Gases. —The gas exchange in the lung is hindered

the alveolar and bronchial foam. The inhalation of oxygen converts this into an

ygen-foam, and relieves the cyanosis. It does not, however, help to remove the

cumulation of carbon dioxide, so that the air-hunger persists (C. F. Hoover, 1918).

Oxygen against Shallow Respiration. —Haldane and Meakins, 1918, regard shallow

piration as an important element of gas-poisoning, since it diminishes the alveolar

change, even if the minute volume of the respiration were increased. This could be

mepnated by increased oxygen inhalation.

In anemia (whether from hemorrhage or any other cause, such as

orosis or leucemia) asphyxial conditions result, not from deficient

pny of oxygen, but from a deficiency of hemoglobin. The inhalation

xygen, in these cases, does not increase the quantity of oxygen carried

the hemoglobin, but that carried in solution by the plasma, as has been

ained.

The inhalation of oxygen is also useful, in an analogous manner, in

anced cardiac disease, when the circulation is too slow to convey the

quired oxygen to the tissues.

Another factor may possibly come into play, for G. N. Stewart, 1911, found that

ygen inhalation, while it produces no effect on the blood flow of the hand in normal

viduals, produced a marked increase in a cyanotic patient. Artificially perfused

ses (frogs) are constricted by oxygen (Hooker, 1911).

Administration. —Compressed oxygen is marketed in metal tanks. The gas

hould be passed through warm water and delivered through a

nel suspended over the face of the patient. The rate and duration of

administration is regulated by the symptoms.

The funnel method, however, is wasteful, and only enriches the air by 5 to 15 per

nt. of oxygen. If higher concentrations are desired, a mask with valves must be

ed (V. Henderson, 1910).

Subcutaneous Injection of Oxygen. —This was introduced by Derose, 1912. McCrae,

14, believes that it has a limited field as substitute for inhalation.

V. Henderson, 1918, states that life may be maintained by intraperitoneal injection

xygen.

Intravenous Injection of Oxygen. —This is described by Tunnicliffe and Stebbing,

6. It gives rapid relief to the cyanosis and dyspnea. In man, the gas can be in-

cted into a vein at the rate of 600 to 1200 c.c. per hour; usually beginning with the

te of 100. The heart must be watched, the injection being stopped if any irregularity

pears.

PREPARATIONS—OXYGEN

*Oxygenanum (Oxygen). U. S. P.

OXYGEN DEFICIENCY

Asphyxia Through Lack of Oxygen. —This may result from a deficiency of oxygen in

air by breathing rarefied air, or air diluted with indifferent gases (N, H, CH4); the

ence of CO; by anemia; etc. Ordinary air may be diluted until it contains

bout 15 per cent. of oxygen (or may be rarefied to the same degree), without

ucing any immediate effect (Bernstein, 1885). A candle will be extinguished when

xygen has fallen to about 17.5 per cent., and is therefore a test for the safety of

ir, as far as oxygen is concerned. At about 10 per cent. slight symptoms are notice-

le, especially on exertion, but they are not alarming—dizziness, shortness of breath,

per and more frequent respiration, quickened pulse, slight cyanosis. With 7 per
cent., these symptoms become serious, and stupor sets in. With a slightly lesser percentage, unconsciousness occurs. With 2 to 3 per cent., death occurs within forty-five seconds (the effects of low tensions of oxygen are described by Haldane, 1908; the effects on respiration are reported by Schenk, 1908). Anoxemia dilates the blood vessels (including the coronary) on direct perfusion (Richards, 1914).

Cyanosis.—The skin in oxygen deficiency assumes a dusky color, in contrast to the deep blue color of ordinary asphyxia (Haldane, 1918). The latter is due to the congestion of the veins with reduced blood.

Anoxemia without Carbon Dioxide Accumulation.—This may also exist in pneumonia and cardiac decompensation; namely, when obstruction of a part of the lungs is compensated by overventilation of other parts; this washes out the excessive carbon-dioxide, but does not increase the oxygen tension. Thus, irritation of the upper larynx (R. G. Bower, 1917).

Minor Grades of Oxygen Deficiency.—These have been studied by the Air Service Medical Research Board, because of their importance in aviation. It was found that even slight lowering of the oxygen tensions produces reactions of the respiration and circulation to compensate for the diminished oxygen supply of the tissues (V. Henderson and Selbert, 1918).

The chief reactions are increased ventilation of the lungs and more rapid blood flow. In a few men there is also concentration of the blood.

The great difference in tolerance depend upon the completeness of these reactions. Some tolerate 6 per cent. of oxygen for brief periods; others are incapacitated by much smaller changes. The degree of tolerance and of the reactions is an objective test of general "fitness," and is diminished by any indisposition, colds, worry, etc. (Schneider, 1918).

Respiratory Response.—This generally starts about 16 to 14 per cent. of oxygen, and becomes marked with 12.5 to 9 per cent. It usually affects the depth more than the rate; indeed, the rate may stay unchanged especially if the reaction is good (Schneider, 1918).

This increased respiration exaggerates the loss of CO₂ and thereby lowers the alveolar reserve of the blood. This renders the respiration more shallow, and establishes a lower rate of ventilation (V. Henderson and Haggard, 1918).

Haldane, 1910, states that the first response of anoxemia is periodicity of the respiration. With further reduction, the type becomes very rapid and shallow. Patients with "irritable heart" type are especially apt to react in this way to exertion. Oxygen inhalation gives relief.

Heart Rate.—This is also a reliable index of the reaction. A slight quicken occurs at about 15.5 per cent. oxygen; becomes marked at 13 to 9 per cent.; and reaches 15 to 40 beats at 7 per cent. When the capacity of response is exceeded, the heart may either slow, or quicken by 70 to 90 beats (Schneider, 1918).

Blood Pressure.—This shows several types of response. If the reaction is good, it may be unchanged or if the heart quickens, the systolic pressure may rise and the diastolic fall gradually.

If the reaction is poor, the systolic pressure falls suddenly, this is soon followed by fall of diastolic pressure and then slowing of the heart. These phenomena are often accompanied by fainting (Schneider, 1918).

Temporary Heart Failures.—This is not uncommon. It is shown by dilation of 2 to 5 cm., also followed by collapse and fainting, unless the oxygen is increased (Whitn, 1918).

Disturbances of Vision.—These are among the minor manifestations of oxygen deficiency (Wilmer and Berent, 1918).

Chronic Oxygen Deficiency.—As seen in anemias, etc., this causes considerable increased tissue destruction, fatty degeneration, and acidosis (ammonia and uric). Finally there is general paralyzsis of all organ functions.

Exposure to slightly rereiced air, as on mountains, causes "mountain sickness"—nausea, headache, insomnia, etc. This generally disappears after a few days. A curious phenomenon is a prompt and persistent increase in the corpuscle and hemoglobin content of the blood (22 to 40 per cent.). This is at first due to a diminution of the plasma, the total quantity of hemoglobin being unaltered. After a time, however, the absolute hemoglobin is also increased; the formation of corpuscles by the bone-marrow being stimulated (Dallwig, Kolls and Loewenhart, 1915; G. H. Martin, Bunting and Loewenhart, 1916). There is retention of N., S. and P. The respiratory metabolism is increased. These effects are attributed to oxygen deficiency (Douglas, Haldane, Henderson and Schneider, 1913, Loewenhart).

Cheyne-Stokes respiration is also referable to oxygen deficiency (Douglas and Haldane, 1909); the apnea lowers the oxygen and leads to accumulation of lactic acid.
his increases the excitability of the respiratory center, so that a very low CO₂ tension suffices to produce hyperpnea. This lowers the CO₂ and increases the oxygen, so that a lactric acid is oxidised, aspna reappears and the whole process is repeated.

**HYDROCYANIC ACID AND CYANIDS**

**General Statement.**—Hydrocyanic (prussic) acid is probably the most rapidly acting poison. It produces death under asphyxial symptoms, by inhibiting the oxidative processes of the tissues. It also interferes with most other ferments and is therefore a general protoplasmic poison. Compounds containing the CN radical are toxic only if they can liberate CN. Ferro-, ferri-, and sulphocyanids are stable and therefore do not show these effects.

**Occurrence.**—Hydrocyanic acid exists in glucosidal form as amygdalin in many nuts, especially in the seeds and leaves of the cherry, almond, peach, etc. This amygdala, when pure, is almost entirely harmless, except as it is decomposed in the body. But most plants it coexists with the ferment emulsin, by which it is split up in the presence water into hydrocyanic acid, glucose, and benzaldehyde:

\[ \text{C}_6\text{H}_5\text{NO}_3 + \text{H}_2\text{O} \rightarrow \text{C}_6\text{H}_3\text{O}_4 + 
\text{HCN} + \text{C}_6\text{H}_5\text{CHO} \]

One gram of cherry kernels yields 0.7 mg. hydrocyanic acid; 1 gram bitter almondulp yields 2.5 mg. hydrocyanic acid.

The most important cyanogen (CN) compounds are the acid (prussic acid, official the dilute, 2 per cent. solution) and cyanid of potassium. Mercury cyanid has only a mercurial action. The cyanid action is also shared by the organic esters (nitriles); use differ from potassium cyanid only in the rapidity with which the cyanogen is erated (Lang, 1894; Heymans and Mazin, 1897, 1900, 1901; R. H. ant, 1904).

**Effects on Higher Animals.**—When given in doses small enough to permit of watching its action, this is seen to consist in a fleeting stimulation certain parts of the central nervous system, followed by depression and analysis. The action begins in the medulla. The vomiting, respiratory, jugs, pupil-dilator, and vasomotor centers are all stimulated. Then comes unconsciousness, and after this convulsions. In man these are probably mainly, medullary in origin. Then follows paralysis of the whole central nervous system. Involuntary evacuations of feces, urine, and men are frequent.

**The Respiration.**—This is at first greatly increased, especially in depth; then becomes slow, shallow, and irregular (Cheyne-Stokes type). It tops considerably before the heart, paralysis of the respiratory center eing the immediate cause of death.

The efficiency of respiratory stimulants was tested by Loenvaehnert et al., 1918, on dogs whose respiration had been arrested by intracranial pressure. Caffeine and atropine were found useless; lactric acid gave variable results; strychnin produced distinct and lively hastening stimulation.

The most powerful stimulation, however, resulted from sodium cyanid; the degree of duration depending on the rapidity of the intravenous injection. Decided temporary stimulation of respiration occurs with 0.1 c.c. of 1% per cent. \( \frac{N}{100} \) per Kg.; this may be maintained by injecting 0.1 c.c. of ½% per cent. per 1½ to 3½ minutes. This indicates rapid disinocxiation, supposed by conversion into thiocyanate. This usage causes but little change in the circulation. The fatal dose is 1½ to 6½ c.c. of 10 per cent. per Kg., i.e., about 20 times the effective dose, so that there is an ample margin of safety.
The effects on respiration are central, for they are not affected by section of the vagi, or by atropin (Boehm and Kaie, 1874). The smallest effective doses increase both the rate and depth of respiration; HCN being one of the strongest stimulants of the respiratory center. This is more sensitive to cyanids than the vasomotor center, and this again is more sensitive than the vagus center. Larger doses slow the rate, but greatly increase the depth of respiration. Toxic doses depress and paralyze the center. The respiratory effects are antagonized by jodoohenenate, which yields active oxygen (Grove and Leech, 1864).

In frogs, the respiratory center is also stimulated by small and depressed by large doses. Decerebrated animals require larger doses than normal to produce respiratory paralysis (Reep, 1873).

Convolusions.—Rabbits deprived of their hemispheres exhibit the usual type of convulsions; but the course is more rapid (Morita, 1915).

The Effect on the Circulation.—This is entirely analogous to that of asphyxia (see Fig. 1, page 243). As in the latter, the heart may again exceed its customary movements for a moment, and then it has stopped for a time (k in the figure); but these do not suffice to maintain the circulation.

Vasomotor Center.—This shows intense stimulation, with corresponding rise of blood pressure. The effects correspond with asphyxia (Pilcher and Sollmann, 1914).

Peripheral Action on Vessels.—In excised kidney perfused with saline solution, the addition of hydrocyanic acid causes a very marked dilation of the renal vessels. The effect is apparently due to a paralysis of the arterial muscle. It disappears promptly on removing the cyanid (Sollmann, 1908). The coronary vessels are also dilated (Loewenhart and Kyster, 1912). It is quite possible that these dilations are due to the interference with the oxygenation of metabolic waste-products.

Heart.—Applied directly to the frog’s heart, cyanids cause a standstill which is not removed by atropin; however, the heart responds strongly to electric or mechanical stimulation. The paralysis evidently involves the automatic property of the cardiac musculature. There is no evidence of this action on the blood-pressure tracings from mammals.

In stimulans, weak concentrations stimulate the heart muscle and ganglia (Carlin, 1897).

Cyanid Action Explained by Tissue Anoxia.—The phenomena of the action of hydrocyanic acid on the central nervous system—the stimulation of the medullary centers, the convulsions, the vascular paralysis, etc.—bear a close resemblance to those of asphyxia and can be easily shown that oxygenation is enormously diminished. There is, however, one very marked difference from ordinary anoxia, for the blood remains of a bright arterial color, indeed, the oxygen content of the venous blood in typical cyanid poisoning approaches that of ordinary arterial blood (Cl. Bernard). The oxygen is in the ordinary combination with hemoglobin, and can be removed as readily as normally in vivo. It is therefore evident that the oxygen supply to the tissues is not lessened. The cause of the anoxia, of the lessened oxygenation, must lie in the protoplasm of the tissues. This undergoes what might be termed “internal asphyxia,” in sight of abundant oxygen (Geppert, 1886). The interference with oxygenation has also been demonstrated with “salted frogs;” excised kidneys (Vernon, 1906); many lower animals; and with ferments. It may therefore be assumed that the cyanid interferes with the fermentative processes by which the utilization of oxygen is accomplished.

Hyman, 1916, has measured the effects on oxygen consumption in organisms. They consist in a primary increase followed by diminution. The depression increases with the concentration of the cyanid, so that high concentrations produce practically pure depression.

In planaria, G. Allen, 1910, found the oxidation reduced by 30 per cent. through minute doses of cyanid. Larger doses caused a further reduction to 20 per cent.; beyond which there was no further reduction, even with large doses. The action is reversible; i.e., rapid and complete recovery occurs after removal of the cyanid.

Lund, 1915, could not confirm any direct effect of potassium cyanid on the intracellular oxidation of paramcnemum.

Action on Ferments.—Schoenlein, 1867, first showed that hydrocyanic acid inhibits oxidizing ferments, preventing the catalytic action of shed blood on HzO.". The catalyst is not destroyed, but only inhibited. (In acute cyanid poisoning, the inhibitory depression is not reached; Duncker and Jodlbauer, 1911). It has a similar inhibitory effect on many other organic ferments and inorganic catalysts (spongy platinum).

Hart, 1911, claims that the red color of the venous blood is not due to ferrous oxidaation, but to more rapid circulation from vasodilatation and cardiac stimulation.
The effect on metals is probably produced by a minute film of cyanid, and its mechanism is therefore probably not analogous to that on organic ferments. 

Action on Hemoglobin.—It is doubtful whether HCN combines directly with hemoglobin under ordinary conditions. Zeynek, 1901, states that cyanid does not combine at all with hemoglobin; and that with oxymethemoglobin it does so only after several hours; even at body temperature.

When added to methemoglobin, it causes the formation of cyan-hemoglobin (Kobert, 1891; v. Zeynek), which differs from ordinary hemoglobin in its bright red color and is a peculiar hand (Fig. 20). This compound is responsible for the bright red ecchymotic spots seen after hydrocyanic poisoning. Methemoglobin can be used as a test for hydrocyanic acid.

Lower Organisms.—Cyanid is a violent proteolytic poison, presumably through its restraint of the fermentations which play a most important role in life processes. All forms of life, all tissues and organs, are affected. Intusors are killed in a concentration of 0.1 per cent. The growth of yeasts and of higher plants, the germination of seeds, the contractility of animal cells, the conductivity of nerves, etc., are inhibited. If the action is sufficiently continued, all vitality is destroyed; but if the cyanid is promptly removed, complete recovery occurs. Its effects agree with those of deprivation of oxygen. J. Loeb, 1910, found in arachia ova that this lessens the toxic effects of a number of poisons (salts, saccharose, lipoid-narcotics), and Warburg, 1915, claims that the combined inhibitory action of HCN and hydrocarbon narcotics is less than simple summation. In certain fish ova, cyanid also suspend the autolytic processes accompanying death, so that the cells remain in a condition between life and death for several days (Sollman, 1906).

Phagocytosis.—This is stimulated in vitro by traces of HCN; the effect being analogous to oxygen deprivation (H. J. Hamburger, 1915).

Inflammation.—Intravenous injections of cyanid intensifies mustard conjunctivitis (Amberg, Lowenhart and McClure, 1917).

Membrane Permeability.—Even very dilute cyanid solutions increase the permeability of Tradescantia cells. This effect is enhanced by very low concentrations of chloroform or alcohol; diminished by higher concentrations (Krehan, 1914).

Other Effects on Metabolism.—Severe cyanid poisoning increases the total N excretion. It depresses, both in starving and fed animals.

Excised Intestines.—Potassium cyanid interferes with the contractions, especially of the higher portions, in which metabolism is probably more active (Alvarez, 1918).

Local Anesthesia.—Direct application of HCN, even to the intact skin, produces local anesthesia.

Fate.—Hydrocyanic acid is very unstable; it changes very readily, even by mere exposure to light and air; and it undergoes still quicker decomposition in the body. Part of it combines with sulphur-containing molecules to form sulphocyanids. A part is excreted unchanged by the lungs. The fate of the remainder is unknown. Post-mortem, Waller, 1910, found the largest quantity in the heart and brain.

Sulphocyanid is found in the human parotid saliva, while it is absent in that of all other animals. The nervous connection of the gland must be intact, for it is absent in middle-ear disease, for instance, Juergens, 1901. Gschiedlen found it constantly in human urine; and Nencki claims that traces exist normally in the stomach. Its significance is not understood, but it does not result from bacterial decomposition as was formerly supposed. It is suggestive that some proteins with loosely combined sulphur convert KCN into KCNS in vitro at room temperature (Paschoel). Its amount can be increased by taking HCN—even that existing in tobacco smoke causing an increase.

Acute Cyanid Poisoning.—Hydrocyanic acid is not much used in criminal poisoning (0.5 per cent. of the recorded cases), because its quick action would soon lead to the detection of the crime. On the other hand, it or the cyanids are favorite methods with suicides. On account of the technical uses of potassium cyanid (in photography, electroplating, cleaning of metals, etc.), it can generally be obtained with little trouble. Some cases are also reported of accidental poisoning by the gaseous acid.

Pure hydrocyanic acid is extremely volatile and very toxic. The famous chemist Scheele, who discovered hydrocyanic acid, was killed by the vapors set free in the breaking of a flask of this fluid. Many fatalities have been produced by the use of cyanid vapors as insecticide.
The strength of the official (dilute) acid should be 2 per cent.; but many samples are much weaker, on account of decomposition. Potassium cyanide is also very variable. The pharmacopoeia requires a strength of 99 per cent.; but the commercial article sometimes contains only 30 or 40 per cent. This accounts in part for the variability in the appearance and severity of the symptoms. Another variable factor is the rate of absorption, according to whether the stomach is full or empty. In the latter case, there is a much better chance of saving the patient. However, the absorption is always very rapid; it occurs even to some extent from the intact skin. Application to raw surfaces or to cuts has given rise to poisoning. Inhalation of the vapors has proven fatal. The fatal dose of absolute HCN is about 0.05 Gm. (0.01 gr.); that of KCN is 0.2 to 0.3 Gm. (4 to 5 grs.). that of dilute hydrocyanic acid would be about 0.5 Gm.; 50 or 60 bitter almond seeds, would be fatal. Correspondingly larger doses are needed if the drugs are improperly decomposed. The impression prevails quite widely that prussic acid is one of the most powerful poisons. This reputation is justified by its extremely rapid action, rather than by its toxic dose.

In the so-called apoplectic form; i.e., when very large doses are taken, the patient may fall unconscious, often with a loud cry, within ten seconds, and die within two to five minutes, after some convulsions. Ordinarily, the course is rather more prolonged; several minutes may elapse after taking the poison before any effect is noticed; death occurs between fifteen minutes to an hour.

The symptoms consist in vertigo, mental dimness, headache, palpitation; the dyspnea, which may be very great from stimulation of the respiratory center; the patient then becomes totally unconscious and falls into violent convulsions. During this stage the heart may be greatly quickened. The respiration becomes first difficult and then ceases. The heart at this time is very much weakened, but still continues to beat for a short time and then stops.

The mortality is very high: 95 per cent. If the patient survives an hour, recovery is the rule. It is often followed by persistent headache, tremors, etc.

The prompt diagnosis of cyanide poisoning is very important in view of the treatment. The odor is quite characteristic. (The student should familiarize himself with the appearance and odor of potassium cyanide.) The very rapid onset of the symptoms is also characteristic.

At the autopsy, the odor is also noticeable on opening the body. There are no peculiar lesions, except with potassium cyanide, which acts as an alkaline caustic. The blood is generally liquid, and remains so after removal from the body (by interference with the fibrin ferment). Its color is stated to be very dark—but this is not true of all cases: it may be of a very bright arterial color. Bright red oxyhemoglobin spots, due to cyan-hemoglobin, occur during putrefaction. The final proof of cyanide poisoning rests on chemical tests. The poison disappears within two weeks during putrefaction, but remains for a long time if the latter is prevented and if there is no evaporation.

Chronic Poisoning.—The repeated administration of sublethal doses of cyanides leads to chronic cachexia, without altering the susceptibility to the poison (Schlegel, 1897). Peripheral neuritis has been reported (Collins and Martland, 1908).

Treatment of Cyanide Poisoning.—This must be very prompt. It consists in lavage with chemical antidotes, and in symptomatic stimulation. The chemical antidotes are oxidizing agents (H₂O₂: potassium permanganate, ½ to ⅔ per cent.; “arsenic antidote”; or sodium thiosulphate (“Hypo”), 1 per cent. These form harmless molecular compounds. Unfortunately, the absorption of the poison is so rapid that the antidote are often ineffective.

Chemical Antidotes.—H₂O₂ is only effective if the stomach is empty. It forms cyanogen. FeSO₄ (CO, NH₂, Alkaline ferrous sulphate). It was advocated by Smith, 1884, and is indorsed by Sandwick, 1908. It is conveniently prepared by adding FeSO₄ to the official “arsenic antidote.” Cobaltous nitrate (½ per cent.) forms cobaltic cyanide; and thiosulphate forms sulphocyanid. Thiosulphate has given especially good results as a prophylactic, and in nitric poisoning in animals.

1This is the shortest time reported—a fact which may be of some medico-legal importance.
(Meurice, 1900), but is of little value in developed cyanid poisoning (Heymans and Masoin, 1897). It may be injected intravenously (0.5 to 1 per cent., added to 0.6 per cent. NaCl) or hypodermically (3 per cent.), using 100 to 300 c.c. It has also been suggested to bleed the patient profusely, replacing the blood by saline solution.

The symptomatic treatment consists essentially in supporting the respiration. Brisk artificial respiration should be begun at once and maintained as long as the heart beats. This acts mainly by aiding the elimination of the poison through the lungs. Counterirritation, and general stimulants (cafein and atropin) may also be used.

Therapeutic Uses—The local irritant action is used against itching of the skin and pruritus, against cough, and against vomiting.

The usefulness for these purposes is doubtful in view of the brief action and high toxicity. A more definite field is for temporary respiratory stimulation.

Bitter almond water is used mainly as a flavor.

Fumigation, with HCN is used for the destruction of insects and larger vermin. Rather high concentrations are required (McClintock, Hamilton and Lowe, 1911), and fatal accidents are frequent.

Respiratory Stimulation by Intravenous Sodium Cyanide—This was suggested by Lovenhart et al., 1918, in depression of the respiration from intracranial pressure; resuscitation from drowning; anesthetic accidents, etc. A 1:1000 solution in sterile saline (the solution must not be heated) is injected intravenously at the rate of 1 c.c. per 30 to 15 seconds, for man, continued as long as necessary. The injection is slowed or stopped on the appearance of marked pallor, signs of nausea, marked increase of pulse rate, or depression of respiration.

PREPARATIONS—CYANIDS

*Acidum Hydrocyanicum Dil., U.S.P., B.P.—About 2 per cent. of HCN. Colorless liquid, with odor of bitter almonds. Incompatible with metals. *Dose*, 0.1 c.c., 1/2 minims, U.S.P.; 0.125 to 0.3 c.c., 2 to 5 minims, B.P.; *maximum dose*, 0.3 c.c., 5 minims.

On standing, it loses strength rapidly, decomposing into ammonia formate CO₂, cyanic acid, and a brown precipitate of paracynogen (L. A. Brown, 1910). The decomposition is retarded by acid, alcohol, and acetanilid (Cohnen and May, 1908).

*Fol. Cyperi, K.C.N.—Occurs usually as white, opaque masses, with cyanid odor, *Dose*, 5 mg., 1/2 gr. Commercial samples are often very impure.

*Sodi Cyanidum (Sod. Cyanidi.), U.S.P.; NaCN.—White, opaque pieces, or granular powder, deliquescent in the air and exhaling the odor of hydrocyanic acid. Freely soluble in cold water.

Amygdala Amara, B.P.; Bitter Almond.—The ripe seed of Prunus Amygdalus amara. Contains amygdalin, starch and volatile oil, etc.

*Ag. Amygdal., U.S.P.—Bitter Almond Water contains a mere trace of hydrocyanic acid and differs from the preparation of the same name, recommended by the Brussels Conference of 1902, which contains 0.1 per cent. of hydrocyanic acid. *Dose*, 4 c.c., 1 dram, U.S.P.; *maximum dose*, 4 c.c., 2 dram.

*O. Amygdal., U.S.P.—The distilled oil. Yields not less than 85 per cent. of benzaldehyde, and not less than 2 per cent. nor more than 4 per cent. of hydrocyanic acid. *Dose*, 0.05 c.c., 1/2 minims, U.S.P.

*Sp. Amygdal., U.S.P.—1 per cent. of oil. *Dose*, 0.5 c.c., 8 minims, U.S.P.

*Sinodehydron, U.S.P., C.H₃.CO.H.—An aldehyde produced synthetically or obtained from natural oil of bitter almond. A colorless or yellowish, strongly refractive liquid; bitter-almond-like odor; burning aromatic taste. Slightly sol. in water, miscible with alc., eth., and fixed and volatile oils. *Dose*, 0.02 c.c., 1/4 minims, U.S.P.

*Lauroceras Folia, B.P.—The fresh leaves of Prunus Laurocerasus (Cherry-Laurel).

*Ag. Laurocer. B.P.—0.01 per cent. of HCN. *Dose*, 2 to 8 c.c., 1/2 to 2 drams, B.P.

*Tr. Prun. Virgin., B.P.—20 per cent. *Dose*, 2 to 4 c.c., 1/2 to 1 dram, B.P.
PHYSICAL FACTORS OF SALT ACTIONS

General Statement.—The drugs so far studied produce their actions mainly by entering into chemic combination with the protoplasm. Since these chemic changes are distinct for each drug, the effects are also distinctive, differing in kind as well as in degree. Besides the properties which are ordinarily designated as chemical, substances in solution or suspension also possess certain physical properties, depending on their molecular state, and independent of their chemic composition. These properties are possessed both by the drugs and by the cells.

Molecules in solution have qualitatively and quantitatively identical effects on the boiling and freezing-point, osmosis, etc., the so-called "colligative properties." By influencing the osmotic exchanges and the surface tension, these alter mainly the water and salt content and internal pressure of the cells. This produces changes in composition and therefore in function, even when the substance itself does not enter into the cells. These effects are produced by all substances which form true solutions (the "crystalloids"). Since the results are proportional to the molecular concentration (the number of molecules dissolved in the unit volume of the solvent), their importance varies with the quantity of the drug that can be introduced without producing serious chemic changes. These physical actions are therefore physiologically insignificant for those substances which cause pronounced chemic effects. They are practically important mainly for the neutral salts of alkalies, and are therefore commonly called "salt actions." Even these salts, however, or rather their constituent ions, produce in addition specific effects, due partly to their electric charges, partly to their specific chemic properties. These specific effects may be called "ion actions." It must also be remembered that the cells are normally bathed in a saline solution; the salt and ion effects are therefore due to a disturbance in the normal environment of the cell, to the relative diminution of the normal constituents, as well as to the increase of the added constituent.

The "colloids" of the cells likewise play a highly important part in these salt actions. Colloid solutions, such as those of the proteins, differ in important particulars from the true solutions, such as those of the salts, although there is a gradual transition. In true solutions, the molecules of the solute are dispersed through the solvent, and behave very much as do gases. In colloid solutions, the solute occurs in smaller or larger groups or "aggregates" of molecules; and according to their size they approach more or less in their properties to mere suspensions of solids or liquids. They therefore lack (practically) the colligative qualities of the true solutions. On the other hand, the suspensions exhibit the electric and surface phenomena of particles. Because of the relatively high state of subdivision, the "surface phenomena"—surface tension, adsorption, catalytic properties, etc.—are very conspicuous, and play a highly important part in the functionation of protoplasm. The consistency of the protoplasm, fluid or gelatinous, and the quantity of water imbibed, also depend on the colloids. These properties are greatly influenced by the physical, electrical and chemical conditions of the medium in which the colloid is suspended. It is in this interaction of the saline medium with the protein and lipid colloids that the salt actions consist.

*An interesting discussion of "Colloid Reactions in Biology" is given in the Harvey Lecture of Heber, 1912.*
COLOIDAL SOLUTIONS

Relation of Colloids and Crystalloids.—Graham, 1862, divided soluble substances into crystalloids and colloids, according to whether they diffuse through parchment and similar membranes. This criterion is by no means a sharp one, and has been supplemented by others as knowledge has increased; but the division is important and has been retained. The terms "colloid" and "crystallloid" do not refer to any particular substance or class of substances, but to the physical state which may be assumed by any substance in a solution under suitable conditions.

As the size of the aggregates of molecules which constitute the colloid state varies, the transition between the physical properties of the two kinds of solutions is not abrupt but gradual. Solutions containing discrete molecules (i.e., true solutions of crystalloids) approach the colloid state especially when the solution is concentrated and the molecules are large; while colloid solutions approach true solutions when they are dilute and the aggregates are small. It must also be remembered that there is no material difference in the purely chemical properties of the two kinds of solutions. These are essentially the same for a given substance, whether it be in the colloid or crystallloid state.

Size of Particles.—This determines the character of the solution. If the particles are larger than 0.1 μ (i.e., visible with the ordinary microscope), the mixture is a suspension (if the particles are solid), or an emulsion (if liquid). These mixtures are separated more or less rapidly by gravity. When the diameter falls below 0.1 μ, sedimentation does not occur, and the solution assumes colloid character. This holds down to 0.001 μ, i.e., somewhat below the limits of the ultramicroscope (0.001 μ). Below this limit, the characters are those of a true solution. It is believed that molecules are but little smaller than this limit (sugar, 0.0007 μ; NaCl, 0.00007 μ).

Properties of Colloids.—Each aggregate behaves like a single molecule, so that the molecular concentration of colloid solutions is relatively low. Colloids therefore have little influence on the osmotic pressure, or boiling or freezing-point. One of the most distinctive properties of colloid solutions is their turbidity, which may be perceived directly, or only by the Tyndall phenomenon (viz., a beam of light becomes visible when passed through a colloid solution). The colloids do not dissolve through parchment orcellulose membranes. Diffusion through the solvent is also very slow or practically absent.

The electric properties are characteristic: Colloids are usually electrically charged, the quantity and sign of the charge being variable at will. This is very different from ions, whose charge is fixed in character and quantity. The important surface actions will be discussed later. The colloids easily undergo further aggregation to larger particles, i.e., coagulation. Colloid solutions are often permanently changed by temporary physical conditions, such as boiling, freezing or keeping (hysteresis).

Suspension and Emulsion Colloids.—Colloid solutions again fall into two classes: the suspension colloids, in which the particles behave as solids; and the emulsion colloids, in which they behave as fluids. The difference is probably one of affinity for the solvent. The emulsion colloids are hydrophilic, i.e., they seem to attract the solvent into the aggregates which are thereby more or less liquefied; the suspension aggregates are hydrophobic; i.e., they do not take up water, and therefore remain discreet and solid. The emulsoids approach more nearly to true solutions, and may sometimes consist of discreet but very large molecules. They are typified by gelatin and other soluble proteins and are therefore of a special biologic importance. Silicic acid also behaves as an emulsoi. The colloid metals and sulphids, congo red, etc., are suspensoids. The emulsoids form viscous solutions or jellies, lower the surface tension, and are coagulated only by large quantities of electrolytes. The suspensoids are not viscous, have little effect on surface tension, and are easily precipitated by traces of electrolytes.
Permanence of Suspensions.—It is a familiar phenomenon (f.i., in the case of oil or mercury) that small particles suspended in a liquid tend to coalesce by surface attraction, to form larger particles. The molecular particles in colloid solutions possess the same tendency, as is shown by the readiness with which they may be precipitated. They are only kept apart by their molecular motion, and by their electric charges. The more the motion is increased (e.g., by increasing the quantity of solvent, or by raising the temperature within the limits which do not produce chemic changes) the greater will be the tendency of the aggregates to fly apart, and to form smaller aggregates. It is quite conceivable that this motion and separation are really electric phenomena. We know that the colloid particles may be charged with electricity, either positive or negative. Since all the particles in a solution are charged with electricity of the same sign (let us say with negative electricity, since this is the case with most proteoplasm), they repel each other, just as do the gold leaves of an electroscope. Any increase of the charge (negative in our example) increases this repulsion, and consequently diminishes the size of the aggregates and the viscosity of the solution. If, on the other hand, a small amount of electricity of the opposite sign (positive) is introduced, some of the charges carried by the particles are neutralized and they tend to coalesce. If this (positive) electricity is increased beyond the point when all the original (negative) charges are neutralized, the particles will become charged with positive electricity, and again fly apart. These modifications may be produced by the passage of an electric current; and also, by the electric charges of the ions (see next chapter) of electrolytes. The latter (salts, acids, and bases) may therefore influence the state of aggregation of colloids by withdrawing water and by altering the electric charges. There is yet another way in which the state of aggregation may be varied, viz., by chemic action. This introduces at once profound changes in the state of aggregation, and in the electric condition.

All these changes which we have just described for colloid solutions may be observed in living cells: Withdrawal of water, lowering of temperature, decrease of the electric charge, and certain chemic changes, render the proteoplasm more viscous, opaque, and granular, and diminish its motility. A reversal of these conditions leads to the opposite effects.

Precipitation of Suspension Colloids by Electrolytes.—Since suspensions have an affinity for the solvent, they are very readily precipitated when their electric charges are removed. This occurs most rapidly when their electric charges are small, i.e., when they approach the "isoelectric point." Minute traces of electrolytes are sufficient. The precipitation of positively charged colloids depends mainly on the affinity, they have for the negative ions on the cations (Hardy's Law); the other ions play practically no part. The precipitant power of the ions is a function of their valence (Schulze, 1854 and 1854a, since this determines their electric activity. However ions of the same valence are not equally active. Commonly there are the chemic changes, so that the precipitation is generally irreversible.

Precipitation of Hydrophilic Colloids by Electrolytes.—These, like the suspensions, are precipitated only by electrolytes, not by non-electrolyzed crystalloids (the precipitation of proteins by alcohol is due simply to insolubility). The process, however, is probably quite different. With the emulsoids, much higher concentrations of the salts are required; the precipitation is generally reversible; the electrolytes may also have solvent actions, the end result being the algebraic sum of the actions of the cation and anion (Pauli, 1905 and 1908).

Lyotropic Series.—The various ions form a regular series ("lyotropic series"), which is reproduced in many different phenomena. The anion series run SCN, I ≈ ClO₄ < NO₃, Br < Cl < CH₄COO < SO₄, PO₄ < tartrate < citrate. With (negative) proteins, lecithin, etc., the left side of this series is solvent, the right side precipitant. They have a similar influence on heat-coagulation temperature; on the solubility of globulins; on the solubility of gases, alcohols, etc.; on the viscosity and surface tension of water; on the saponification of esters, etc. It has been suggested that all these phenomena can be explained by the progressive affinity of these salts for water, thus competing, e.g., with the emulsion colloids.

The alkali cations are much less important. Their series runs rather irregularly, generally Mg < NH₄ < K < Na < Li (Li being most precipitant). If the electric charge of the colloid is reversed, f.i., by acids, then the anion and cation series are also reversed.
The earthy metals (Ca, etc.) form irreversible precipitates. They also reverse the charge and therefore the effects of the anion series (Mg acts like the alkalai metals). The tendency to irreversible precipitation is very much greater with metallic salts.

**Electric Condition of Proteins.**—The amino-acid character of proteins renders them amphoteric electrolytes, in which the acid character predominates. They are generally positively charged in acid solutions, negatively in alkaline. If they are brought to the isoelectric point (H-ion concentration about 2 X 10⁻⁴) all coagulation reactions reach their maximum, and the viscosity is lowest (Pauli, 1913).

The colloids of the living cytoplasm are predominantly electro-negative; hemoglobin is positive. Serum proteins are always positively charged in alkaline and neutral, as well as in acid solutions (Field and Teague, 1907).

**Protein-ion Compounds.**—It must not be forgotten that proteins are also capable of ordinary chemical reactions and combinations. They may form complex salts not only with acids and alkalies, but also with neutral salts; f.e., with chloride ions (Oyryng and Pauli, 1915).

J. Loeb attributes the differences in the swelling of gelatin in various salt solutions to the formation of ionizable gelatin-union salts.

**Mutual Precipitation of Colloids.**—Colloids of opposite electric charge precipitate each other by neutralization. Emulsoids may also be precipitated by suspensoids, irrespective of the charge, perhaps by an adsorption process. On the other hand, excess of the hydrophilic colloid prevents precipitation, and protects suspensoids against precipitation by other substances. It is conceivable, in these cases, that the emulsoid envelops the suspensoid particles, and thus confines them hydrophilic properties.

An important illustration of this phenomenon is the inhibitory action of serum on the precipitation of urates, calcium salts, etc. Colloids also modify the solubility of electrolytes (Pauli and Samec, 1909).

**Electrolytes on Osmotic Pressure of Colloids.**—Acids and alkalies increase the osmotic pressure, salts generally cause a decrease, while non-electrolytes are indifferent (R. S. Lilie, 1907).

**Gels.**—Solutions of hydrophilic colloids, when very viscous, form jellies or "gels," such as gelatin, agar or protoplasm. The high viscosity means that there is but little solvent between the particles; either because the particles are naturally large, or have swollen by taking up the solvent; or because the amount of solvent is relatively small. Gels may arise in any of these ways.

M. H. Fischer and Cossman, 1918, contend that the hydration and solution of proteins are not merely steps in the same process, but that different factors are involved, especially polymerization.

The gel resembles a solid in preserving its form, when it is not subjected to external agencies. But it also resembles fluids in being readily changed by external causes, and in permitting the penetration of water, and the diffusion of crystalloids. The latter penetrate it almost as rapidly as they would water. Chemical reactions may occur in its interior very much as they would in water. Other colloids, however, can not diffuse through a gel.

In fact, gels retain all the characters of hydrophilic colloids, and are influenced in the same way by salts; as seen, f.e., in imbibition.

**Imbibition.**—Plates of gelatin (glue) or other hydrophilic colloids, when laid in water or watery solutions, imbibe a certain quantity of water and dissolved substance, and thus swell. The water is attracted and retained with considerable force, according to the affinity of the emulsoid for water. This mechanism is important in the regulation of the fluid content of the cells and tissues. The colloid must compete for the water with the dissolved substance. The imbition is therefore influenced by the anion series, in the usual order; iodid to chlorid increasing, acetate to sulphate decreasing the imbibition (Hofmeister, 1891). The cations have relatively little effect. OH and still more H ions greatly increase imbibition (Spiro, 1904; Ostwald, 1905).
Influence of Reaction.—Acids and alkalies increase the imbibition of gelatin, not only in water, but also in solutions of phosphates, citrates and carbonates (Fischer and Hooker, 1918). The reaction that gives the minimal imbibition is different for gelatin and albumin (Fischer and Benzinger, 1918).

Concentration of the Salt.—The effect of electrolytes on imbibition is largely influenced by the concentration of the salt. Ehrenberg, 1912, found the lyotropic series reversed for gelatin when dilute solutions were used (Δ less than 0.5). Ostwald (1916) also noted that the results differ according to whether dry gelatin is used (Ostwald) or moist gelatin (Leek).

Leek (1916) found that for the salts of most monobasic anions (chlorides, etc.) the swelling increases with the concentration; whereas with dibasic and tribasic anions (sulphates, citrates, etc.) the maximal swelling occurs with medium concentrations.

Non-Electrolytes.—The swelling of gelatin is also influenced by non-electrolytes, being decreased by sugars and glycerine, and increased by alcohol and especially urea (Paul and Rona, 1902). In mixtures, the swelling corresponds to the simple algebraic sum of the swelling coefficients. Entirely analogous results are produced on the insolubility of gelatin solutions; this being increased by the substances which lessen swelling, and vice versa (Paul, 1907).

Sugar retard the diffusion of II+ ions through gelatin (Graham and Graham, 1919).

In agar jellies, the phenomena are exactly reversed. According to Ehrenberg, 1913, the lyotropic series is reversed for gelatin when the concentration of the salts is low (Δ less than 0.5).

Distribution of Salts in Imbibition.—The gelatin also takes up the solutes. Hofmeister found that the quantity taken up increases with the concentration of the solution, to a certain limit, which is reached late with the iodid end of the series, and early with the sulphate group. This influences the imbibition, for enough water must then be taken up to render the salt isotonic; and this would be greater for the large quantity of iodid than for the small quantity of sulphate which the gelatin has imbibe.

Subsequent Washing.—When powdered gelatin is soaked in salt solutions and then washed with water, the imbibition series is quite different from that of Hofmeister. J. Leeb (1916) concludes that the phenomena suggest the formation of incipient gelatin salts with the anions.

He also finds (1918) that neutral salts with monovalent cations increase the viscosity of gelatin solutions; those with bivalent cations do not.

Agar Jellies.—The effects of the Hofmeister series are the reverse of those on gelatin.

Surface Phenomena.—Surfaces—the planes of separation of two phases—give rise to very important phenomena, such as surface tension and adsorption. These are especially prominent in colloids and therefore in protoplasm, the particles of which give rise to very extensive surfaces (A. B. Macallum, 1912 and 1913).

Surface Tension.—This is manifested in the tendency of liquids to assume a spherical form, so as to present the smallest possible surface. It may be explained by the mutual attraction of the molecules (estimated at 10,000 to 25,000 atmospheres). The molecules in the interior of the fluid are attracted equally by the molecules on all sides; but at the surface, the attraction of the molecules from within is not balanced by any molecules outward. Consequently, the surface molecules are subjected to a strong pull from the interior, constituting the surface tension (Segner, 1751).

The degree of this force depends on the nature of the fluid, on the temperature, and on electric forces: Heat and electric charges decrease the surface tension, because they increase the distance between the molecules and therefore diminish the molecular attraction (by the fourth power of the distance). Surface tension may also be resisted by the attraction of the second phase (the air, glass, etc.) on the surface molecules of the fluid. Surface tension may be measured by the rise of capillary surfaces, or by the number of drops delivered from a given surface (stalagmometer).
Biologic Importance of Surface Tension.—This is concerned in the shape and size of the cells; in the consumption or liberation of energy (for any change in surface tension implies a corresponding change in energy); and in the distribution of solutes. Only the last need be considered here.

Solutions on Surface Tension.—Dissolved substances generally modify the molecular attraction and therefore the surface tension. In watery solutions, inorganic substances generally increase, organic generally diminish the surface tension; but there is no simple general law, and the effect is not simply proportional to the concentration.

Distribution of Salts in Cells.—Whenever the surface tension is reduced, the solutes will be concentrated at the surface, irrespective of their distribution under ordinary conditions. Accordingly, the distribution and transportation of substances in cells may be controlled by changes in their surface tension. Macallum has shown this to be true for K and Cl, and probably for other ions; and has pointed out the important part which this may play in the mechanism of secretion and absorption; ameboid and muscular movements; nerve impulse, narcosis, etc.

Solution-Affinity; "Haft-druk."—The surface condensation is proportional to the lowering of surface tension. A substance that lowers surface tension therefore passes more readily out of the solution and into the surface. In the phraseology of Traube, such a substance has a low solution-affinity or "Haft-druk." He believes that this favors the penetration of the substance into cells or through membranes, and that it is an essential factor in narcosis and osmosis.

Adsorption.—The concentration of solutes on surfaces is illustrated by the adsorption of dissolved substances by powders; i.e., by the decolorization of potassium permanganate by filtering through sand; the adsorption of colors or alkaloids by charcoal, etc. This adsorption is a very rapid process.

Sugars are not adsorbed because they have relatively little effect on surface tension. These adsorptions are reversible; i.e., the adsorbed substance may be removed by the addition of another solute which lowers surface tension more powerfully. If several substances are present together, each is adsorbed less than if it is adsorbed alone. Salts may have a marked influence, i.e., diphtheria toxin in pure solution is scarcely adsorbed by bone-black, but is perfectly adsorbed from normal saline or Ringer's solution (Jacqaud and Zanz, 1900).

Catalytic Actions.—Adsorption, by bringing the dissolved molecules into closer contact, facilitates chemical reactions. Accordingly, suspension colloids with their large surfaces generally act as catalysts. The application of adsorption to ferment action is discussed by Bayliss, 1915, in his paper on "Phase Boundaries."

Membrane Formation.—If the adsorbed substance increases viscosity, its concentration on the surface may produce resistant membranes, such as occur in the shaking of proteins, saponins, soaps, many dyes, etc. The adsorption of colloids also presents some other peculiarities; i.e., it is generally irreversible; crystalloids do not displace each other; and the adsorption is not proportional to the concentration, as it is with crystalloids.

The Physical Status of Emulsions.—Emulsions consist of fine and permanent suspensions of one liquid in another; immiscible liquid; i.e., oil in water, or vice versa. Surface tension tends to make immiscible liquids separate. This tendency may be overcome by lowering the surface tension of the dispersing medium (as by saponin or soap) or by increasing its viscosity, and by adsorbing the water by hydrophilic colloids (as
by gums or proteins). Emulsification by colloids, is destroyed if an excess of water is added, or if the affinity of the colloid for salts is diminished. (Fischer and Hooker, 1916; Room, 1916.)

The water-soluble alkali soaps secure the suspension of lipoids in water, whilst the oil-soluble calcium soaps change the phases to as to suspend the water in the oil. With the alkali-soaps, droplets of oil are suspended in a continuous matrix of water; with calcium soaps, droplets of water are suspended in a matrix of oil. The addition of sodium or calcium ions therefore changes the phase of an emulsion. It also thereby influences the permeability; the effect of electrolytes on the permeability of soap-film being similar to their effects on the permeability of living cells; the sodium-soap system being freely permeable to water, the calcium system being impermeable. (Clover, 1916 to 1919.)

Most protoplasm contains emulsions. Fischer looks upon fatty degeneration as due largely to the breaking up of these emulsions by diminished water-affinity of the cell colloids.

The analogies of the fat in protoplasm with that in emulsions is discussed by Fischer and Hooker, 1916.

OSMOSIS

Osmotic Phenomena of Crystalloids.—These belong to the more important effects of the bio-chemically inactive salts and other crystalloids, and of water. They occur whenever two solutions of different (molecular) concentration are separated by a ("semi-permeable") membrane that permits the passage of the solvent, but which interposes an obstacle to the free diffusion of the solute. Dissolved molecules always tend to distribute themselves equally throughout a solvent. If their passage is hindered by a membrane, the equality can only be obtained by the passage of the solvent from the more dilute to the more concentrated solution. The more concentrated solution then tends to increase in volume. If this increase is prevented (e.g., if the solution is inclosed by rigid walls), a certain "osmotic pressure" is developed. The phenomenon is illustrated by the familiar "egg" experiment; by the swelling of red blood and other cells in water; and conversely, by the shrinking of plant cells, and creation of red corpuscles in strong salt solution.

Egg Experiment.—The shell is removed from the broad pole of an egg, but without breaking the inner "skin." The narrow pole is then pierced through the skin with a needle, and over this hole a long narrow glass tube is cemented with sealing wax. When the prepared egg is set in a glass of water, the fluid rises slowly in the tube to a considerable height. The contents of the egg contain salts, and therefore have a higher molecular concentration than the water. The "skin" of the egg acts as a strictly semipermeable membrane.

Osmotic Pressure and Molecular Concentration.—If the membrane is "strictly semipermeable"—i.e., freely permeable to the solvent, but absolutely impermeable to the solute—then the amount of the osmotic pressure is strictly proportional to the difference in the molecular concentration of the two liquids, independent of the nature of the molecules. The stronger solution is said to be hypertonic, the weaker hypotonic. If the solutions on the two sides are equipotential, i.e., have the same molecular concentration, there will be no tendency to movement of the solvent and therefore no pressure; or more accurately, no difference in the pressure. The two solutions will be isotonie.

Strictly and Partly Semipermeable Membranes.—Only colloids, organic or inorganic, can form semipermeable membranes (Morse; Meigs, 1915). The envelope or boundary layer of all cells—and indeed the interior cytoplasm (Kite, 1913)—offers more or less obstacle to the passage of solutes, and is therefore more or less semipermeable. Membranes
produced artificially by precipitating ferrocyanid of copper in the pores of an unglazed porcelain cup are almost ideally semipermeable to sugar (Traube, 1867). They are, however, permeable to NaCl and KCl. The envelopes of certain vegetable and animal cells, f.i., the red blood corpuscles, also approach fairly closely to the definition. Most cells, however, and dialyzing membranes in general, are not absolutely impermeable to the solutes, but offer only a partial obstacle ("partly semipermeable membranes"); so that the solutes pass the membranes, but more slowly than does the solvent. In this case, the concentration is equalized partly by the passage of the solute, and to a correspondingly smaller degree by the passage of the solvent; so that the osmotic pressure is correspondingly less than with strictly semipermeable membranes.

Differences in Permeability of Solutes.—Semipermeable membranes are not usually equally impermeable to all solutes, but permit some to pass rapidly, others more slowly. This will establish differences in osmotic pressure, because the dialyzable substance will pass across to the non-dialyzable. Non-dialyzable solutes are therefore hypertonic to those which are easily dialyzable. It is important to note that the passage of the fluid and the osmotic pressure are governed not only by the molecular concentration, but also by the permeability of the membrane to different substances.

Empiric Laws of Osmosis.—For convenience, the data which have been discussed in the preceding paragraphs may be summed up in the form of laws:

1. Solutions separated by a membrane permeable to water tend to have an identical molecular composition, both in number and kind of molecules.
2. If the membrane is perfectly permeable to both solvent and dissolved substance, the exchange of molecules will take place without change in pressure or volume.
3. If the membrane is less permeable to the dissolved substance than to the solvent, an increase of liquid, or increase of pressure will occur in the stronger solution.
4. If a membrane is differently permeable to one dissolved substance than to another, equimolecular solutions of the less diffusible substance will be hyperisotonic to the more diffusible.

Nature of Osmosis.—Several theories are current for the explanation of osmotic pressure. The most important are the kinetic motion theory of Van't Hoff; the solution-affinity theory of Kahlenberg; the hydration theory of Morse; and the surface-tension theory of Traube. None of these theories is conclusively proven to the exclusion of the others. It is conceivable that all these processes are concerned in the passage of the solution; but that the actual pressure is caused by the motion of the molecules, as formulated by Van't Hoff.

Van't Hoff's Theory of Osmotic Pressure.—This is the theory which has found the widest acceptance among physicists. From the observations of osmotic pressure by means of Pfeffer's ferrocyanid of copper cell, Van't Hoff (1885 and 1887) arrived at the conclusion that the phenomena of osmotic pressure are governed by the same laws as the pressure of gases, quantitatively as well as qualitatively. This would imply, that the pressure in both cases is produced by the same cause, namely, the kinetic motion of the molecules bombarding the walls of the container. Dis-
solved molecules would behave precisely like gaseous molecules. The membrane would play a purely passive part; being important only by making the kinetic motion manifest to the senses.

According to the Van't Hoff theory, the molecules of both solvent and solute are in constant motion, moving with the same energy as if they were in the form of a gas. Every molecule, by striking against the walls of the container, or against other mole-
cules, exerts a certain pressure, which is precisely the same whether the substance is in the form of a gas or of a solution. If the same number of molecules per cubic space exist in two solutions separated by a semipermeable membrane, the pressure will be equal on each side of the membrane. The nature of the molecules is immaterial in this, as long as they all penetrate through the membrane with equal readiness. If all the molecules can pass through the membrane, an exchange will take place; but since as many pass to one side as to the other, there will be no difference in the pressure in the two compartments. If, on the other hand, the molecules on the one side can pass through readily, while some of the molecules on the other side are not capable of diffusing through the membrane, then the pressure in the two compartments will become unequal.

In an osmotic cell, the non-diffusible molecules will all rebound from the membrane, and so remain confined to their own side. The diffusible molecules will, like gases, tend to pass through, irrespective of the other molecules, until they exist in equal concentration on each side, i.e., until the partial pressure of each kind of molecule is the same on both sides.

If a solution consisting of $x$ molecules of salt and $(y - x)$ molecules of water per cubic centimeter were inclosed in a closed vessel and separated from water containing $y$ molecules per cubic centimeter by a semipermeable membrane, then water would pass into the solution until it also contained $y$ molecules of water per cubic centimeter. But it would then also contain $x$ molecules of salt. Its total molecular concentration per cubic centimeter would therefore be $y + x$, higher by $x$ than that of the liquid outside of the vessel. The pressure in the vessel would therefore be increased by $x$ molecules.

The process might be represented as follows:

$$\text{Partial Molecular concentration: } \frac{nH_2O}{x} \text{ salt } \frac{yH_2O}{y - xH_2O}$$

$$\text{Total Molecular concentration: } \frac{y}{y} \text{ tends to become } \frac{y}{y + x}$$

This excess of total molecular concentration constitutes the osmotic pressure.

An experiment analogous to osmosis can be performed on gases directly. Palladium is permeable for H but not for N. Ramsay, 1894, found that when a palladium vessel is filled with N, closed, and immersed in an atmosphere of H, the pressure rises within the vessel until it exceeds the outside pressure by the partial pressure of the H. However, this experiment could also be explained by the other theories.

Application of Gas Laws to Osmotic Pressure.—Van't Hoff claimed as chief support of his theory, that the osmotic pressure obeys quantitatively the laws of gas pressure. As applied to osmotic pressure, these would read: Boyle-Mariotte's Law: With constant temperature, the osmotic pressure of a solution is proportional to its concentration. Under standard conditions, a gram-molecule distributed over a liter of space, exists 22.44 atmospheres of pressure.

Gay-Lussac's Law: With equal concentration, the osmotic pressure grows by $\frac{1}{273}$ for each degree C.

Avogadro's Law: With equal osmotic pressure and equal temperature, equal volumes of solutions contain the same number of dissolved molecules, and the same number as would be contained in an equal volume of gas of the same temperature and pressure.

Experimental Evidence.—The experimental confirmation of these laws is unfortunately very incomplete (Kahlenberg), because of the difficulty of constructing strictly semipermeable membranes which will resist the high pressures. The experiments which form the original basis of the Van't Hoff theory were very inaccurate. Since then, only a few rigorous determinations of absolute osmotic pressure have been attempted (especially by Morse, Holland and co-workers, 1911 and 1912). These
showed a good agreement with the theory; but they were confined to a single type of membrane (ferrocyanide of copper) and to a single substance (cane sugar), within a limited range of concentration and temperature. Outside of these limits, there were considerable discrepancies. The numerous determinations of relative osmotic pressure, which can be easily made, are inconclusive; for while they agree with this theory, they also harmonize with the competing theories. On the other hand, Kahlenberg, using different, but typically semipermeable membranes, finds that the gas laws do not hold at all; and that the phenomena can be explained quite simply on an entirely different basis. The evidence for the Van't Hoff theory is therefore incomplete.

Advantages of the Van't Hoff Theory.—This is very attractive in that it reduces all the physical phenomena of gases and solutions to a common basis, and thereby permits convenient and far-reaching theoretical and practical deductions. For instance, by postulating that osmotic pressure is directly proportional to the molecular concentration, it justifies the substitution of an easy calculation for the very difficult experimental determination of the pressure. Since it assumes that the membrane is purely passive, it allows the estimation of osmotic pressure in situations which are inaccessible to direct experimentation. In a word, if it is correct, it makes the difficult method of direct experimentation more or less superfluous, substituting for it an easily applied formula. This would be highly convenient and desirable—but before relying on such deductions, the correctness of the formula must be more securely established.

Kahlenberg’s Theory.—This has the advantage that it furnishes the simplest explanation of the nature of osmotic pressure; and that it is in the best accord with these phenomena as exhibited in living structures. The theory refers osmosis to solution-affinity, and may be best understood from an experiment made by L’Hermitte in 1854.

L’Hermitte’s Experiment.—A layer of chloroform is poured into a vessel, then a layer of water, and finally a layer of ether. Even if any mechanical mixing of the strata is carefully avoided, it will be found that the ether layer gradually diminishes, until finally there are only two layers, the upper containing mainly the water, the lower the chloroform and the ether. In other words, this process passed through the strata, the chloroform, just as water passes through a semipermeable membrane into a salt solution. The analogy can be carried even further: If a cork saturated with water is firmly wedged between the ether and chloroform layers and the chloroform compartment is connected with a manometer, a very considerable pressure will be developed. Analogous experiments have been devised by Nernst, 1890 (passage of ether into benzol, through pig’s bladder), and by Gies, 1912 (passage of ether into oil, through rubber condom).

It is difficult to see in what essential respect these arrangements differ from an osmic cell. In both cases two dissimilar fluids are separated by a septum. In both cases, one of the fluids passes into the other; and if this is prevented, a pressure is produced. In L’Hermitte’s experiment we can easily see the explanation: Ether is soluble in water, and therefore diffuses into the latter; it is, however, much more soluble in chloroform, and therefore the ether which is dissolved in the aqueous layer tends to pass into the chloroform. The watery layer therefore would lose some of its ether to the chloroform, and would then take up more from the etheral layer; and this process would continue until practically all the ether had passed into the chloroform. In other words, the passage of the ether, and the pressure which may thus be developed, is not due to any gas pressure, but simply to the fact that ether has a solution-affinity for water, and hence passes into the latter; and that it has a still greater solution-affinity for chloroform and hence passes into this from the water. If we substitute the hypothetical “semipermeable” membrane for the water, we may say that “osmotic pressure” measures not the gas pressure, but the solution-affinity of the solvent for the solute, less the affinity for the membrane.

There is one further complication; for, since the chloroform is also somewhat soluble in water, there is also some stream in the contrary direction. This is equivalent to saying that the arrangement is not strictly semipermeable. For our present purpose this may be neglected, except in so far as it emphasizes the fact that osmotic changes (generally and not always) do occur in both directions. This is of considerable importance in biology.

It is another important advantage of the theory that it emphasizes that the membrane plays an active part as well as the solute. Its greatest advantage, however, is the simple explanation which it gives of the nature of the osmotic process, namely as a phenomenon of chemical or solution affinity. Osmotic pressure will result if the solute
is relatively insoluble in the membrane, *i.e.*, if it has a greater affinity for the solvent than for the membrane. In the case of two solutions the transfer of fluid will occur in the direction of the solution which has the greater affinity; and osmotic pressure is simply the hydrostatic pressure which is required to prevent this attraction of fluid. Further, the theory supposed that the solution-affinity increases with the molecular concentration; and since it is a fact that equimolar solutions of all substances are isotonic—at least with strictly semipermeable membranes and aqueous solutions—it follows that the solution-affinity must depend solely upon the molecular concentration; *i.e.*, it must be independent of the nature of the dissolved substances. This agrees entirely with the known effect of molecular concentration on the freezing- and boiling-points. The affinity is also raised by temperature.

**Relation of Van't Hoff and Kahlenberg Theories.**—In brief, then, the main facts of osmosis are explainable by either theory. The principal difference in their practical application lies in the fact that Van't Hoff's theory gives a definite formula for calculating the osmotic pressure from the molecular concentration; while Kahlenberg's theory does not attempt an exact quantitative formula. Presumably, however, even this difference is not of very fundamental practical importance; for the absolute osmotic pressure may well be that of the gas formula, whether it is produced by kinetic motion or by solution-affinity; indeed, as has been intimated, the pressure proper may be due to kinetic motion in either case.

It will be recalled that Van't Hoff's theory postulates a very definite quantitative value for the osmotic pressure, namely 22.4 atmospheres for a molecular solution. According to Kahlenberg's theory, this value is much less definite. If a membrane were strictly semipermeable, the solution-affinity should undoubtedly give rise, eventually, to a constant and definite osmotic pressure. This would quite likely be something like that of Van't Hoff. In practice, however, and especially in biology, this value is never attained. Living membranes are not strictly semipermeable, so that there is more or less passage of solute out of the solution, thereby reducing the concentration. Further, the passage of fluid becomes slower and slower as the concentrations on the two sides of the membrane approach equality; the full pressure would therefore never be realized in any time which would come into practical consideration.

**Morse's Hydration Theory.**—Morse attributes the passage of the water to unequal hydration of the colloids on the two sides of the membrane. The solutes dehydrate the side of the membrane in contact with them; and this is equalized by the attraction of water from the opposite side. The theory is somewhat related to that of Kahlenberg's; but it helps to explain why the rate of osmosis is not parallel to the semipermeability, or to the final osmotic pressure. Salts generally develop an osmotic pressure more rapidly than sugar, even when the final osmotic pressure of the salt solution is lower.

**Differences Between Rate of Osmosis and Osmotic Pressure.**—These are often not parallel. For instance, the copper ferrocyanide is impermeable to sucrose, and fairly permeable to salt. A sugar solution will therefore be eventually hypertonic to a salt solution. In the start, however, *i.e.*, before the salt molecules have had time to diffuse through the membrane, water passes from the sugar into the salt; it is only as diffusion proceeds that the process is reversed as would be expected. Other membranes show similar phenomena (Meigs, 1918). Indeed, acids actually diminish in volume when diffused through a pig's bladder against water (Graham).

Morse explains these observations by the fact that neutral electrolytes dehydrate colloids more readily than non-electrolytes. The "negative osmosis" of acids is due to their hydrating action (see "Imbibition"). Alkalis are intermediate.

**Surface-tension Theory of Osmosis.**—J. Traube (1904 and later) refers osmotic phenomena to surface tension. He observed that substances which lower surface tension, and which therefore accumulate at the surface according to the Gibbs-Thomson principle, penetrate through membranes more rapidly. Conversely, salts, etc., which increase surface tension, and which therefore accumulate in the interior, would attract the solvent to equalize the pressure. In other words, the fluid of lower surface tension...
would be drawn into that of higher surface tension. An attraction pressure would thus be created.

Surface tension may well play a part in osmosis. P. J. Macalum, 1933, finds that a very low surface tension in a film may retain salts so firmly as to act as a semipermeable membrane. However, it is improbable that surface tension is an adequate explanation of the ordinary osmotic phenomena. Thus, it does not explain why substances which affect surface tension very unequally, e.g., sugar and salt, are nevertheless isotonic. It also takes no account of the differences introduced by the nature of the membrane.

Traube has later modified his theory to meet some of these objections; but this only introduces further complications and still fails to explain all the facts.

**Direct Determination of Osmotic Pressure.**—The absolute osmotic pressure would be measured by the rise of a manometer attached to an osmotic cell, i.e., a rigid vessel filled with a solution, surrounded by a semipermeable membrane, and immersed in water. Perfect osmometers are difficult to construct, and perhaps theoretically impossible. However, even imperfect instruments give practically useful data as to the velocity and magnitude of osmotic pressure and these show at least an approximation to the gas laws.

**Magnitude of Osmotic Pressure.**—According to the gas laws, the pressure exerted by a gram-molecule (the molecular weight expressed in grams) or “mol” of any substance, when confined to a liter of space, equals 22.34 atmospheres. In a “molecular” solution therefore (one containing a mol dissolved in a liter of solvent) the osmotic pressure would raise a column of water to a height of about 725 feet! The osmotic pressure of the salts in the blood would raise it about 250 feet. This may suffice to indicate the enormous molecular force latent in solutions, even if it may not be absolutely correct.

An actual osmotic pressure will only be developed if the solution is confined; if it is free to expand, the incoming molecules will merely increase the volume of the fluid.

In this way a single molecule of a non-diffusible salt would theoretically be capable of attracting an infinite amount of water across a semipermeable membrane—for it is evident that the number of H₂O molecules per cubic space would always be less, by the molecules of salt, than they are in pure water.

The rapidity with which water will pass into the salt solution across the same impermeable membrane will, of course, depend upon the concentration of salt; i.e., the partial vacuum of H₂O molecules in the solution. The rate of osmosis will therefore be slowed as the process progresses.

**Determination of Relative Osmotic Pressure.**—This can be easily made by using artificial membranes, or more conveniently animal or vegetable cells; diluting the solution under investigation until its osmotic effects on the cells are identical with those of a known solution.

The earliest quantitative studies of osmosis (Historical Review, Hamburger, 1911) were made in this way by de Vries, 1882, by the use of certain plant cells (Tradescania) which exhibit Plasmolysis (retraction of the protoplasm from the cellulose envelope) in hypertonic solutions. He was thus able to determine the isotonic concentrations of a long series of substances. H. J. Hamburger, 1889, introduced the hemolytic method, i.e., the determination of the concentration which produces laking of red blood corpuscles. This is also isotonic, provided that the corpuscles are semipermeable, i.e., that the substances do not penetrate. This may be ascertained by direct chemic analysis and holds practically for most salts and sugars, but not for urea, alcohols, etc. The changes in the weight of tissues after immersion in the solution may also be used as an index; but with these, partial semipermeability is much more common, and inhibition may come into play; thus, according to Overton, 1906, serum is isotonic with 0.9 per cent. NaCl, but when concentrated four times, it requires 5 per cent. NaCl; and when six times, 10 per cent.
Value of the Comparative Methods.—All these methods involve comparison with a known solution; and if the absolute osmotic pressure of the latter were known, and if the membrane were truly semipermeable, then the absolute osmotic pressure of the unknown solution could be easily calculated. This, however, is mainly of theoretical importance, for as has been repeatedly said, strictly semipermeable membranes probably do not exist in nature. The true value of these comparative estimations lies rather in the picture which they furnish of the direction and relative value of the osmotic pressure for the particular solution and membrane (or cell) with which they are made—often a matter of great biological importance.

Calculation of Molecular Concentration and Osmotic Pressure.—Since the osmotic pressure has a definite relation to the molecular concentration, the determination of the one quantity permits the calculation of the other.

If a cell-membrane were truly semipermeable, then two solutions which had the same effect on the cell volume (or laking) would need to have an identical molecular concentration. The concentration of any unknown solution could therefore be determined by diluting or concentrating it until it became isotonic with a standard solution of known concentration. The semipermeability of certain cells is sufficiently complete to make this method available for practical purposes; but it is less exact and generally less convenient than the calculation from the freezing- or boiling-point.

Estimation of the Molecular Concentration by the Freezing-point.—The depression of the freezing-point (denoted by $\Delta$) is easily determined by the Beckmann apparatus. It is strictly proportional to the molecular concentration; every mol of substance per liter of solution depressing the freezing-point of water by 1.85°C, and this no matter what the nature of the substance (Raoult's Law), except as it is modified by electrolytic dissociation. The molecular concentration is therefore calculated by dividing $\Delta$ by 1.85; and the osmotic pressure by multiplying the molecular concentration by 22.4 atmospheres.

Molecular Solutions.—Some confusion exists in the use of this term (abbreviated "M"). The correct practice is to add the calculated quantity of solute to a liter of solvent (Raoult). It is inadmissible to dissolve the mol in water enough to make a liter (Arrhenius's method), as is commonly done in making chemical solutions.

Molecular solutions are sometimes called "normal." This is objectionable; for the normal solution of chemists differs from the molecular solution, in that the molecular weight is divided by the valence. The normal solutions of physiologists are again quite different from the above; they are saline solutions of a strength of 0.6 to 0.9 per cent.

Departure of Electrolytes from Raoult's Law.—According to this law the molecular concentration, and therefore the freezing-point, osmotic tension, etc., should be calculable by dividing the per cent. of the solution by one-tenth the molecular weight of the dissolved substance. This is found to hold true for concentrated solutions of all substances, and for dilute solutions of nonelectrolytes—substances which do not conduct the electric current, such as the sugars, urea, glycerin, alcohol, etc. Dilute solutions of electrolytes—salts, acids, or bases—however, show a greater concentration than would be deduced from Raoult's law.

A solution of NaCl containing 0.584 gram of NaCl per liter (equals $\frac{5}{2}$ M) should depress the freezing-point by 0.0185°C. It is found, however, that its depression is nearer to 0.025; almost twice as great as would be expected. Very dilute solutions of NaCl have three times the calculated concentrations; those of HPO$_4$ four times.

The dissociation of salts, as revealed by the freezing-point, bears a striking relation to the conductivity of salt solutions for electricity. It has been found that salt solutions conduct electricity proportionately better the more they are diluted. If, e.g., a solution which contains 0.1 mol has a coefficient of conductivity which we will call $K$, a solution which contains only 0.05 mol will have a coefficient higher than $\frac{K}{5}$. This increase is exactly proportional to the increased molecular concentration revealed by the freezing point. The two phenomena must therefore have the same cause.
ELECTROLYTIC DISSOCIATION

General Statement.—To account for the fact that electrolytes depress the freezing-point more than would agree with Raoult’s law, Arrhenius, 1887, advanced the hypothesis that a certain proportion of the electrolytic molecules, by acquiring an electric charge, separate into their constituent ions: NaCl into Na⁺ and Cl⁻; (NH₄)₂SO₄ into NH₄⁺, NH₄⁺ and SO₄²⁻; H₃PO₄ into H⁺, H⁺, H⁺ and PO₄⁻; Ca(OH)₂ into Ca²⁺, OH⁻ and OH⁻. The + and — signs denote the nature and quantity of the electric charge. The metals of salts, and hydrogen of acids, carry a positive charge, and therefore Cl⁻ and S0₄²⁻ in the cathode area, and Ca²⁺, OH⁻ and OH⁻, in the “acid radicals” of salts, and the hydroxyl of bases, carry the negative charge, go to the positive pole, and are therefore the anions. The conduction of electricity through solutions occurs by the conveyance of these ions.

It is scarcely necessary to insist that the ions are not identical with atoms (from which they differ in that they carry charges), nor with the free elements (which exist as molecules). In a dilute solution of NaCl there does not exist metallic (Na) nor gaseous chlorine (Cl), but Na ions (Na⁺) and Cl ions (Cl⁻), whose properties are altogether different. It must also be remembered that this ionization exists in only a limited class of compounds, viz., in all acids, bases, and salts (electrolytes), and not in compounds which do not conduct electricity (non-electrolytes).

The electric charges are further important, since they may leave the ions to combine with the tissue elements, so that the electrolytes cause electric stimulation of the protoplasm.

Degree of Ionization.—This increases with the dilution of the solution until complete dissociation is attained.

In concentrated solutions, the two charges approach sufficiently close to neutralize each other, and the two ions combine into an ordinary molecule, e.g., NaCl. In dilute solutions they are separated so far as to exert little attraction, and act as independent molecules.

With similar ions, the degree of dissociation is fairly constant for the same degree of dilution. In 1 per cent. solution of NaCl (and in blood) about 82.6 per cent. of the molecules undergo this process, and about the same percentage in equimolecular solutions of KCl or NH₄Cl. Dissimilar elements, such as Mg, Ca, SO₄, PO₄, etc., have different constants. If several salts are present in a solution—particularly if they have a common ion—the degree of dissociation of each salt will be less than if it were present alone in the same concentration, but greater than if it were present alone in the concentration corresponding to the sum of the several salts.

Effect on Freezing-point, Osmotic Pressure, Etc.—Each of these fractions (ions) has the physical properties of molecules, and thus causes a corresponding depression of freezing-point or increase of osmotic pressure. These quantities would therefore be twice as great if the molecules had dissociated completely into two ions (NaCl); three times as great when dissociated completely into three ions (Na₂SO₄); four times with H₃PO₄, etc. With partial dissociation, intermediate values would be obtained.

The total molecular concentration of a dilute solution of a single salt corresponds to the number of undissociated molecules, plus the number of dissociated molecules multiplied by the number of parts into which they divide. For instance, if 80 per cent. of the NaCl molecules in a solution are dissociated, the concentration will be 1 — 0.8 + (0.8 X 2) = 0.8 times the theoretical; if 80 per cent. of Na₂SO₄ is dissociated, it will be 1 — 0.8 + (0.8 X 3) = 2.6. (Tables of the dissociation of the various salts are given by A. A. Noyes and Falk; J. A. Ch. S., 1912.)

Limitation of Terms.—To avoid confusion it may be well to confine the term “mol,” or better, “mole,” to the molecular concentration actually deduced from the freezing-
point (i.e., 1.8 is the preceding example of NaCl); and "gram-molecular" to the concentration deduced from the molecular weight (i.e., in the example) without taking account of the dissociation. The abbreviation "M" is always applied to the latter. Several solutions may be related to each other in the following ways: Equimolecular (same number of gram-molecules); Equimivic (same number of moles); and Isotonic (same effect on a given cell). The term isometric coefficient is applied to the factor by which the molecular concentration must be multiplied to obtain the molarionic concentration.

**Ion Actions.**—In addition to the osmotic actions which have just been described, electrolytes show effects which are due to their constituent ions. These actions are generally proportional to the degree of ionization:

The comparatively firm mercuric albuminate is much less active than the ionized mercuric chloride; ferrocyanides, in which the iron does not exist as an ion, act quite differently from ferrous salts, and these again differ from ferric salts. Gaseous chlorine does not behave at all like the chlorid ion of NaCl, etc. The chemical behavior varies in the same way with the degree and state of ionization. The ions may act by entering into chemical combinations with the protoplasm, producing various compounds, synthetic, and decompositions, and thereby lead to functional changes. They may also alter the permeability of the cell wall. Besides these chemical actions, it appears more than probable that the electric charges carried by the ions exert actions which are independent of the chemie nature of the ions. These latter actions may well be termed "static actions," whilst the sum of the chemie and electric actions produced by the ions may be grouped together as "specific ion actions." It is quite conceivable that the chemie actions are also in the last instance resolvable into electric manifestations. But since the proof for this has not yet been furnished, and since the two classes of actions exhibit striking differences, it is well to keep them apart, in so far as this is practicable.

**Electron Actions.**—By this term we understand those actions which are produced by the electric charges carried by ions. These modify the electric condition of the protoplasmic colloids, and hence their aggregation. This leads to important modifications of functions.

The existence of these actions is shown by the fact that all electrolytes produce certain effects in common, which are not produced by non-electrolytes. For instance an egg-albumin solution cannot be coagulated by heating when the electrolytes has been removed by dialysis. The coagulability is restored by the addition of electrolyte, but not by non-electrolytes (sugar, etc.). These effects are largely independent of the chemical properties of the ions, but vary with their electric properties, such as the sign of their electric charge and the ease with which they part with this. The effects agree with those of positive and negative electric stimulation; anions and cathode, cations and anode. The opposite effects, the action of an electrolyte being determined by the predominating ion; analogous phenomena are exhibited when electrolytes are added to solutions of colloids.

**The Relation of the Toxicity of Ions to Their Electric Properties.**—The quantitative effects of ions on protoplasm can be estimated most exactly and most conveniently by observing the molecular concentration in which the solution will just cause death. This has been studied by a number of investigators. It was noticed that the toxicity increases generally with the atomic weight of the ion—Hg, for instance, being much more toxic than Na; but, on the other hand, H was found to be more toxic than the heavier Na. The toxicity also increases generally with the valency; but here also there are very striking exceptions, the monovalent Ag being more toxic than the trivalent Al. The general rule is so striking, both as to the atomic weight and valency, that some connection could not be doubted; but it is evidently not a simple one. The subject has been very greatly dilated by the extensive experiments of A. P. Mathews (1904) on fundus eggs, which are peculiarly adapted to these investigations. They showed a remarkable agreement between the toxicity and the solution-tension of ions. The solution-tension signifies the tendency of a metal to go into solution, and thus to acquire an electric charge. This may be estimated by physical methods. The greater the solution-tension, the greater is the affinity of the ion for its charge; the less apt will this ion be to part with its charge, and therefore the less its effect on colloids. This is precisely what Mathews found: the toxicity of an ion varies inversely as its solution-tension; the toxicity of a salt varies inversely as its "decomposition-tension," i.e., as

---

1 Many authors use the term "ion actions" to designate what is here called electron actions.
sum of the solution-tension of both its ions. (For instance, if the solution-tension of the anion is 1 and of the cation 2, the decomposition-tension of the salt is 3.) The same law applies to the inhibitory action of electrolytes on ferments. Mathews also found that the toxicity increases with the quotient: equivalent weight of the anion divided by the equivalent weight of the cation.

When we understand the electric condition of ions and colloids better, we shall probably find that there is a common basis to these connected phenomena; and some apparent exceptions, which still exist, will probably be explained.

Other forms of life do not show precisely the same correspondence. This disagreement could be expected from the complicated conditions which prevail in most cells, and does not at all speak against Mathews' law. The latter deals only with the affinity of the ion for its charge; but the colloid is also an active factor in the reaction, some protoplasm showing a greater affinity for positive charges, and others for negative charges. The factor of penetration introduces important complications. Electron actions must occur even when the ions do not penetrate into the cell, the charges being transferred through the intermediation of the colloidal cell wall. This is indeed the most favorable condition for the study of electron actions, since it excludes the possibility of chemical changes. It probably explains the comparatively simple results obtained with fundulus ova, for the experiments of O. H. Brown (1905) have demonstrated their comparatively great impermeability to salts and water. With most cells, however, the possibility of strictly chemical modifications of the protoplasm by the ions is more or less important. The action of the added ions will be greatly modified by the ions which are already present in the tissues.

Again, a solution containing a single electrolyte will tend to withdraw all other electrolytes from the cell; and the toxicity may in some cases be due to deficiency of the latter ions, rather than to excess of the former (Osborne, 1905). Even non-electrolytes may affect the proportion of electrolytes, since these diffuse with unequal facility (e.g., Na and K more readily than Ca or Mg; W. Denis, 1906).

Limitations of the Electron Theory.—The theory of electron actions has furnished new and fruitful conceptions, a deeper insight into the reactions of protoplasm, and new indications of research. It should be remembered, however, that it does not as yet attempt to explain the actions of non-electrolytes; and that it cannot be said to explain fully all the actions of electrolytes. It does not, for instance, explain the qualitative differences in the actions of the iodides, bromides, and chlorides; of calcium, magnesium, or strontium; the specific toxicity of potassium for muscle and nerve; nor the need for the presence of several ions. We must not forget that protoplasm has chemical, as well as physical, properties; and that many, if not all, ions are capable of entering into ordinary chemical reaction with the protoplasm. The specific ion actions, as we can observe them, are therefore the result of a cooperation of physical and chemical changes. In the present state of knowledge, it would be unremunerative to attempt to distinguish between these. A more practical conception of the action of the individual ions can still be obtained by describing the phenomena as they are observed, without trying, as a rule, to penetrate into their meaning.

OSMOTIC EFFECTS ON CELLS

It may now be attempted to apply these physical processes of salt action to the explanation of the phenomena of life. It will be remembered that the latter may be influenced by the osmotic, electric and chemical properties of the salts. The osmotic effects are independent of the nature of the molecules. The electric effects depend solely on the sign and transmissibility of the charge. The chemic effects are distinctive. All these effects are influenced by the special permeability of the cell membrane; by the solutes already present in the cell and in its surroundings; and by the special properties of the cell colloids.

Osmotic Actions on Cells.—These are due primarily to the changes in the total water or salt content of the cell. It is therefore necessary to distinguish between hyper-, hypo-, and isotonic solutions. In effect, however, the final functional results of different concentrations are often very similar.
Changes in the Composition of the Cells.—In a physical sense, a cell may be conceived as a solution, the protoplasm, chiefly of hydrophilic colloids and largely dissociated electrolytes; inclosed in a membrane (the cell wall) of characteristic permeability; and generally containing suspended lipoids or solid granules.

The cell walls (which may be merely a modification of the cytoplasm) are usually easily permeable to water, impermeable to colloids and more or less difficulty permeable to electrolytes and other crystalloids. In this way they permit a certain amount of exchange between the cell and its surroundings (the lymph, etc.) which is necessary for metabolism. At the same time, since the permeability is limited, and varies for different substances, it enables the cell to preserve its own composition, which is quite different from that of the lymph. However, this protection is not perfect, especially if artificial changes are made.

The cell walls (and indeed also the interior cytoplasm, Kite, 1918) behave essentially like what we have defined as a "partly semipermeable" membrane (as suggested by Traube, 1867). If therefore the molecular constitution of the medium surrounding the cells be in any way changed, this will effect, in the first place, a change in the total water or salt content of the cell. A hyperosmotic solution will cause the withdrawal of water, and a hypoosmotic solution the withdrawal of salts. If the ratio of the different salts in the surrounding medium is not the same as that in the cells, their ratio in the latter will also be altered. Again, when salts are drawn out of the cell, certain of its salts will leave more quickly than others. The changes will be the greater, on the whole, the more the composition of the surrounding liquid departs from that of the cell.

Molecular Concentration of the Blood and Tissues.—The total molecular concentration of the living cells is not accurately known. It is probably somewhat higher than that of the body-fluids. The plasma, lymph, and all other body-fluids (except urine and gastric juice) of all mammals, depress the freezing-point by about 0.56°, corresponding to 0.33 mol per liter. Relatively slight departures from this are promptly injurious. Its maintenance is therefore very important. Accordingly, the organism resists very powerfully any attempts to alter its osmotic concentration. The fluids of lower animals have a somewhat different concentration, adapted to their environment.

Protoplasma.—The osmotic pressure of cells can not be measured during life. Direct cryoscopy of the organs gives unreliable results. Buchner juices generally depress the freezing-point somewhat more than does blood, but this might be due to chemical change. The protoplastic pressure is not solely osmotic, but also due to imbibition, surface tension, and the elasticity of the cell wall (Pfeffer, 1897).

Human Blood.—The extreme variations of the freezing-point in health are between 0.40 and 0.50. The molecular concentration of the blood is not altered by the quantity of fluid or salt in the food; nor by hypodermic produced by hemorrhage; nor by thickening the blood by profuse diaphoresis. The intravenous injection of anisotropic solutions alters it but temporarily. About the only method of raising it permanently consists in interfering with the regulating mechanism, by seriously injuring the kidneys; and then it proves fatal when the a approaches 0.8°C. The importance of comparatively slight changes in the concentration is also shown strikingly by the red blood corpuscles. These swell in hypoosmotic, and shrink (cremate) in hypertonic solutions. If the serum is diluted to about 30.25, the hemoglobin begins to leave the corpuscles, their structure being destroyed. There is reason to believe that the same holds for most other cells, and that the limits between which cells of mammals can function at all, are comprised between 30.35 and 0.6 or somewhat higher.

Osmotic Equilibrium of Lower Animals.—The narrow limits of mammals are considerably extended in the lower forms of life. With marine animals, up to the Su-
molecular concentration of the body-fluids approaches that of sea water, and dependent only in the Teleosteians. Dog-fish are intermediate (Scott, 1913). Rise animals, a concentration equal to that of the serum of mammals would be hemoglobin. In other words, the resistance of cells is somewhat adapted to salt environments. This resistance is curiously developed in the small fish which thrives equally well in sea water and in distilled water. It is due, in to a high degree of impermeability to both water and salts, so that osmotic gradient be not be developed.

Water animals have a considerable molecular concentration approaching that of the sea, the salts being probably retained by chemical or physical affinity for the tissue. The molecular concentration of plant juices is also considerably higher than that of sea water. Fungi often have a very high resistance against osmotic changes, whereas their envelopes are relatively impermeable. Torula, e.g., can in a saturated solution of sodium or lithium chlorid, the latter having an osmotic f 2700 atmospheres (Raciborski, 1906; see also L. A. Hawkins, 1916).

**Sural Changes Resulting from Osmosis.**—With most cells, however, any departure from the normal concentration of the liquid in which they are bathed, produces the changes which we would expect; these can be best seen in a unicellular organism, white blood cells, or even: these show shrinkage or swelling, condensation and precipitation. These often lead to even more important decomposition; which may cause the cells to swell even more in a hyperosmotic solution than they do in water (Sollmann, 1904).

**Osmotic Changes in Red Blood Cells.**—Hypertonic solutions produce lysis; if the solutions are hypertonic beyond a certain degree, hemolysis. The cells swell and lose their hemoglobin and salts. In life, changes could be produced only by intravenous injection of anisotropic solutions.

**Resistance to Hemolysis.**—This varies in different species; and somewhat individuals. The following figures are normal averages (Mussere and Krumbh, and others):

<table>

Specific differences refer only to hemolysis; the osmotic swelling, measured natocrite, being about equal in the different species. The specific difference in swelling is generally inverse to that for saponin-laking (Krywosch, 1907).

**Ice of Dna and Etc.**—Changes in the resistance to hemolysis have been found in conditions (tumors, etc.). It is diminished in purpura (Mussere and Krumbh, 1915), practically unchanged in pernicious and in secondary anemias. The latter is said to be increased by therapeutic doses of arsenic (L. W. Hill, 1915).

**Powder of Various Salts.**—Hemolysis depends not only on the concentration, but also on the nature of ions, following the usual lytropic series. Hoeker, 1908, hemolysis least with the SO4 and Na end, and most with the I and K end of the series.

The sequence is reversed by combination with lipidic agents, saponin or ovis. The differences are referable to the different permeability of the salts or effects on the cell membrane.

**The use of Hypertonic Solutions.**—This has been investigated by C. C. Guthrie (1914).

**Proliferation of Red Blood Cells.**—These are practically impermeable to most substances. However, both anions and cations pass to a slight degree, even to hyperosmotic conditions (Hamburger and Bubanovic, 1907); and certain sub-nominal ions, urea pass very readily. In general, the permeability is high to the lipid soluble agents. Aqueous solutions are an exception for they are impenetrable; they lake even when added to isotonic NaCI solution. The permeability is increased by combination with saponin and other hemolytic agents, a saponin-laking, an increased permeability of the cell membrane can be tested directly, before the salts pass out of the cell (G. N. Stewart; Woelfel,
The permeability of the corpuscles for Na and K ions has been denied (Garber, 1803), but has been established by H. J. Hamburger, 1916. He also finds that the addition, within physiologic limits, of CO₂ to the serum drives K ions into, and Na ions out of the corpuscles. NaCl drives Na in and K out; and KC1 does the reverse. Rohon and Lortat, 1916, report that dilute lead nitrate inulin in the serum fixes the corpuscles to the serum, with an increase of serum alkalinity. Similar changes occur in hemolysis.

Preservation of Living Erythrocytes.—Blood cells, when suspended in saline solution die rather rapidly, partly by mechanical and partly by chemical injury. Roux and Turner, 1915, found that the addition of gelatin protects them against the mechanical injury, but not against the chemical. The addition of glucose or saccharose, on the other hand, preserves them for a long time, so that they show no morphologic changes, and take up and surrender oxygen in the normal manner.

Selective Permeability of Cell Membranes.—This varies for each class of cells, some being impermeable to one substance, some to another. This is doubtless important for maintaining the normal differences of composition. It is subject to changes with the functional states of the cell. The permeability is often different in one direction from that in the other.

Permeability to Different Substances.—With most living cells, lipid-soluble substances penetrate more readily than those which are only water-soluble. The penetration is also influenced by the presence of lipolytic agents (anesthetics). The lipoids of the cell membrane are therefore important elements in determining its permeability. They are not, however, the only factor. The membrane is not absolutely impermeable to salts; and some substances penetrate independently of their lipoid solubility. It is generally assumed that the membrane is a mixture of lipid and protein colloids, and that both play a part in the penetration.

When discussing the red blood corpuscles, it was stated that they were almost impermeable to most salts and sugars, but permeable to ammonium, urea and lipolytic agents. This applies also to plant cells, in which the phenomena have been most extensively studied. Kies and de Vries, 1900, found that glycerin and urea do not produce pleomolysis. Overton, 1895 and 1899, has added many data.

A general discussion of cell-permeability and its applications is given by R. S. Lille, 1918, in connection with sea-urchin ova.

Surface water is also nearly semipermeable (similarly to a celluloid membrane is which CaH₂PO₄ has been deposited); while smooth muscle is highly permeable to sugars and salts (Meigs, 1912 and 1913). The changes of weight in stripped muscle in various conditions were investigated by J. Loeb.

With intact muscle, the changes in anisotonic sodium chloride solutions are purely osmotic. The osmotic property is destroyed by grinding with sand (H. Winterstein, 1915).

Lipoid Solubility as Condition for Entrance.—The numerous observations of Overton and others show no direct relation between chemical constitution and permeability. Trouche, 1872, believed that the differences depend on the size of the molecule; but this is untenable. L'Hermite, 1885, attributed the penetration to solubility in the cell membrane. This is undoubtedly a prerequisite to absorption. Overton found that all lipoid-soluble substances penetrate readily into all cells; and those which are not lipoid-soluble penetrate with difficulty.

This rule, although not absolute, holds so widely, that it must be a simple physical phenomenon. It is not absolute, however, or metabolism would be impossible. Nathanroth, 1904, therefore assumed that the cell membranes consist of a mosaic of cholesterol and protoplasm. However, this is not a necessary deduction; for Nathanroth, 1904, and Ruhland, 1909, showed that artificial lipoid membranes, when soaked in water, become quite permeable to substances that dissolve in water, even if these are insoluble in lipoids; while water-free lipoid membranes are impermeable to the water as well as to the solutes.

Calcium and magnesium phosphates perhaps also play a part in semipermeability, but the degree of impermeability is so different that they are probably unimportant factors (Meigs, 1915).

Permeability for Alkaloids.—This is easily observed in plants by the precipitability of the tannin within the cells. Only the free (basic) alkaloids penetrate; the alkaloid
salts enter very much more slowly, namely in proportion as they are hydrolyzed. Their toxicity is favored by the addition of alkali, as the alkali salts have greater affinity for sodium and calcium ions than for potassium ions. Harvey, 1919, found that plant membranes are readily permeable to weakly dissociated alkali, but remarkably resistant to those which are strongly dissociated.

Absorption of Dyes.—Ehrlich, 1887 and 1893, found that vital staining occurs especially with basic dyes. Overton, 1900, referred this to their lipid solubility, and advanced the theory that all absorption occurs through the lipoids of the cell envelope. However, exceptions have been discovered. Certain lipid-soluble dyes are not absorbed; while others, which are insoluble in fats, are nevertheless absorbable. Indeed, Asher and Gunsus, 1911; Harvey, 1912; Kite, 1901; and others, have found little relation. Acid dyes stain the protoplasm diffusely, while basic dyes stain mainly the cell granules.

Permeability of Internal Cytoplasm.—Kite, 1915, has shown that all portions of the protoplasmic gel are more or less semipermeable. Incised and punctured cells, for instance, offer the same obstacles to the penetration of dyes as do intact cells. The rate of diffusion is generally inversely proportional to the concentration of the protoplasmic gel.

Structurally, with adult cells the entire substance is gelatous; in young cells, the interior is fluid, the exterior gelatous (Chambers, 1922). Seifriz, 1912, finds that living protoplasm is always immiscible with water. Its consistency varies from very liquid to quite viscous. The plasma membrane is a definite morphologic structure, elastic, pliable, glutinous and capable of self-repair. The capacity of membrane formation is only lost with death. It is probably physical, but inherent in the properties of living protoplasm.

Relation of Penetration to Functional States.—Asher observed that the vital staining of gland cells is greatly influenced by their functional activity, being increased by pilocarpia and diminished by atropin. Temperature influences the plasmolysis of plant cells (W. R. Nyuenberg, 1901); CO₂ increases the permeability of erythrocytes (Hoebel, 1904). The permeability is also influenced by salts and narcotics, and stimulation (Osterhout, 1912; R. S. Lille, 1912; J. Loeb, 1903). Fertilization or electric stimulation increases the permeability of frog eggs, so that their ions diffuse out at a faster rate (McClendon, 1915). It is probable that similar changes in permeability are essential to the metabolism of the cells (Hoebel).

The Permeability of Artificial Membranes also can be varied at will, especially by the strictly physical conditions of hydration. The permeability of celloidin membranes, for instance, depends on the degree to which they are dried before water is applied; the less the drying, the greater their permeability (Mclean, 1901). Influence of Electrolytes on Permeability.—J. Loeb and Cattell, 1915, observed that electrolytes increase the diffusion of K and H ions (Loeb, 1915) out of funnelus ova but retard their passages into these cells. The degree of the effect is parallel to the lyotropic series of anions. They attribute the diffusion to combination of the K or H with the colloid anions of the cell membrane; this combination being diminished by the mass-action of excessive anions in the surrounding solution.

Clowes, 1916, finds that the influence of electrolytes on cell permeability is similar to their effect on the permeability of soap films. Semipermeability Persists only During Life.—It is lost when the cells die, so that dead cells merely imbibe solutions, like gelatin or fibrin. Acids also destroy the semi-permeability (J. Loeb, 1911). Living tissues resist the entrance of all acids (except salicylic), while dead tissues are freely permeable to them (Harvey, 1914).

Functional Responses to Osmotic Changes.—The alterations in the composition of the cells entail corresponding changes in their functions, consisting in a mild or strong stimulation, often irritative; passing into depression and finally disorganization of the cell if the changes have been large. The irritant phase tends to predominate with hyperisotonic solutions, whilst hypoisotonic solutions tend more to depression.

With unspecialized cells the main changes fall upon their metabolism. These nutritive changes are most pronounced in the cells of lowest vitality. As a rule, pathologic formations possess less resistance than normal tissue, so that one of the most conspicuous phenomena of the general salt action is the breaking down of pathologic formations, no matter what their origin, and whether they are chemic or anatomic. Other specialized tissues also respond by their proper functions: Abstraction of water from a
nerve or muscle causes contraction; the unfertilized eggs of certain marine animals undergo parthenogenetic development, etc. (J. Loeb, 1890, 1901).

If a very strong salt solution is injected directly into the circulation, the main symptoms arise from the central nervous system. They consist in stimulation, with subsequent paralysis, being similar to the effects of asphyxia.

**Brain Volume.**—Intravenous injection of hypotonic solutions increases the bulk of the brain, and therefore the intracranial pressure, and the tension of the cerebrospinal fluid. Hypertonic injections, after a initial rise, produce a marked shrinkage of the brain and fall of cerebrospinal pressure. The alternations may be so great as to produce histologic changes (Weed and McKibben, 1910). Hadén, 1916, tried this means with promising results for the relief of the cerebral compression of meningitis. He injects intravenously, in the course of an hour, 250 c.c. of sterile 25 per cent. glucose solution, 2 or 3 times per day.

**Epinephrin Output.**—Stewart and Rogoff, 1916, found his markedly increased by the intravenous injection of small amounts of concentrated sodium carbonate solution. They attribute this to osmotic stimulation of the bulbospinal centers.

**Salt Action on Phagocytosis.**—The sensitiveness of cells to small changes in osmotic concentration is shown by the phagocytic power of leucocytes. According to H. Hamburger and his pupils, 1908 and 1910, the phagocytic power is decreased by very small changes of the osmotic concentration of the serum, such as may occur under physiologic conditions. All anisotonic solutions are injurious, but especially increased concentrations. The leucocytes recover when the normal concentration is restored. NaCl causes but little injury apart from the osmotic effect. NaCl is more toxic than NaBr. Of other ions, a slight excess of calcium stimulated, while decreased activity resulted from a larger excess, and from reduction of calcium by fluorids or citrates. Ba and Sr do not have the stimulant action, so that it is not due to valence. Diminution of the normal alkalinity was deleterious, and to a less degree also an excessive alkalinity.

**Osmotic Response of Muscle.**—Stripped muscle is semipermeable, smooth muscle is permeable. This different permeability is reflected in their response. Immersion in water, [], causes striped muscle to become rigid and to shorten, smooth muscle in lengthen. The effects are counteracted by 2 per cent. NaCl (Meigs, 1912). Dab, 1913, also found the tone of smooth muscle increased by hypo- and diminished by hypertonic Ringer’s solutions (confirmed by Goto, 1916, for isolated intestine and uterus). Slightly hypertonic solutions increased the response to inhibitory drugs and decreased the effects of stimulant drugs. Slightly hypotonic solutions had the opposite effect. The muscle of the Venus agrees with non-striated muscle, in being permeable (Meigs, 1914).

**Fatigue increases the molecular concentration** (depression of freezing point) of excised skeletal muscle by 36 per cent, by the breaking down of molecules. This does not occur when the circulation is intact, for the differences are then equalized by exchange with the blood (A. R. Moore, 1910).

**Osmotic Effects on Heart.**—Goto, 1916, investigated these on the perfused heart. All deviations from the normal are injurious. Hypotonic solutions increase the tone, and the height of the contractions, shorten the A-V interval, but slow the rate. Hypertonic solutions produce the opposite effects.

**Ion Effects on Muscle.**—The immersion of muscle in various solution produces marked effects even when osmotic changes are excluded by having the solutions isotonic. These must therefore be referred to ion actions. The muscles lengthen or shorten; the excitability may be diminished or increased; spontaneous rhythmic contractions may appear; or the muscle may develop “contact irritability” so that it will react to stimuli which are ordinarily ineffective. Invertebrate and mammalian muscle exhibit similar phenomena if proper conditions are maintained.

**Actions of Electrolytes.**

**Importance of Electrolytes.**—Muscles soon lose their excitability completely in solutions of non-electrolytes; but this returns when they are replaced in saline solutions. A medium containing electrolytes is there-
fore essential to muscular contraction; indeed, any change in the ions produces alterations in the muscular functions. The different ions are not equally effective. It appears that the nature of the cations is far more important than the anions. The ions arrange themselves in the usual lyotropic series, the Na and I end being the most favorable, and the K and citrate end being the most unfavorable.

**Toxic Action of Single Salts.**—Immersion in any solution of a single salt also renders muscle inexcitable, but with very different rapidity. These differences follow the lyotropic series in the same sense.

**Rhythmic Contractions of Skeletal Muscle.**—These generally develop before the irritability is lost, when muscle is immersed in solutions of a single electrolyte (Loeb, 1897). If the composition of a calcium and Na salt is added, the rhythmicity reappears again. The rhythmic contraction of the cardiac muscle or of muscle also disappears when calcium is added. Rhythmic contractility is not therefore a property characteristic of skeletal muscle, but it is inherent in all muscular tissues. The reason why the contraction of the heart is ordinarily rhythmic, and that of skeletal muscle not, lies in the fact that the ions in the heart are balanced so as to favor rhythmic contractions, and in the skeletal muscle they are not so balanced.

**Ciliary and Muscular Movement.**—R. S. Lillie (1902) has studied the effects of ions on the larve of a sea- worm (Areniula), which executes both ciliary and muscular movements. He found that the presence of magnesium in the mixture favors the contraction of the cilia, calcium of the muscles; potassium hinders both. Parker (1902) found that potassium reverses the stroke of certain cilia.

**Ion Actions on Heart.**—These are highly important to the cardiac contractions. The excised hearts of cold-blooded animals soon stop their beat when immersed in solutions of non-electrolytes (Carlson); but they continue to contract rhythmically for a long time in certain salt solutions. Analogous phenomena are observed in the perfusion of mammalian hearts. The solutions must contain Na, K, and Ca ions; and these must be in a fairly definite "balanced" ratio, as in Ringer's or Locke's solutions or their modifications. Deficiency or excess of these ions cause derangement of function and are equally fatal. The ratio is much more important than the absolute quantity of the ions. The anions are relatively indifferent.

**Rôle of the Individual Cations.**—NaCl is indispensable to the rhythmic contractions of the heart; but when present alone it produces relaxation and is finally fatal to the heart as to other tissues. The addition of K ions produces a diastolic tendency and standsill. Ca and NaCl produce increased systolic contractions but the diastoles become imperfect and deficient. Starting with a balanced Ringer's solution, sudden increase of K results in slowing and weakening (often halving of the rate), and decreased excitability to vagus stimulation, and with higher concentrations in arrest. This may be removed by the injection of Ca, or by accelerator stimulation. Increase of Ca acts like accelerator stimulation, resulting in increased excursions, prolongation and fusion of diastoles, and systolic standstill. Ca is also necessary for the inhibitory response to vagus stimulation; but excessive Ca concentration paralyzes the vagus (Schiiff; Cazaula, 1913; Bochem, 1914). (However, Brine, 1917 claims that even the normal heart with fluids deficient in calcium does not interfere with vagus inhibition. The K or Ca actions predominate when the percentage of one predominates about three and one-half times over the other. The effects of K-free Ringer's solution resemble Ca-predominance. Ca-free Ringer's solution increases the rate—i.e., the result is the opposite of K in the presence of Ca. Deficiency of Ca, K or OH ions shortens the survival of the heart (Bochem, 1914).

**Theories of Cardiac Ion Relations.**—In the light of these data attempts have been made to assign definite functions to the individual ions. They are not very satisfactory, except in a certain peculiarity of Ca and Na ions. It is well known that Ringer (1882), Ca promoting contraction and K relaxation. Loeb, 1899, attributed the contractions to the Na ions, but requiring the presence of Ca. Howell, 1900, and Loeb, suggested that Ca is concerned in the contraction and K and Na in the relaxation; that these ions enter alternately into relation with the contractile substance.
that accelerator stimulation liberates Ca and vagus stimulation K ions. Martin, 1915, assumed with Howell that Ca promotes the conversion of stable into unstable energy-yielding material; that Na brings about the actual dissociation and thus initiates the beat (Lindau) and that K antagonizes both the Na and Ca. The chemical conditions of cardiac activity are reviewed by Togerstedt, Erg. Physiol., xxii:299.

Abnormal Ions.—These have been studied, e.g., by Lussano, 1913, by modifying the constituents of Ringer’s solution. Sr and Ba can not replace Ca, but their effects do not follow those of excessive Ca. Li is not toxic, but causes some osmotic slowing—HN, more, but increases the irritability and strength.

Radioactive Metals.—Zwemmeraer et al. claim that in heart perfusion the potassium in Ringer’s fluid may be replaced by any radioactive element, in equi-radioactive proportions. The conclusion requires confirmation.

Sinus and Ventricles.—In the frog, these react alike as to tonus and amplitude toward Ca, K, and Na; but their rate changes in opposite directions (Brouwer, 1916).

Arterial Muscle.—Prochow, 1911, tried the replacement of NaCl by other anions. The tone was raised by F; 2->3 Br. Hatcher, 1915, tested the excitability of the kidney vessels to epinephrin and found this preserved twice as long in Locke’s fluid minus glucose, as is 0.9 per cent. NaCl. With glucose, the excitability remained eight times as long. The ability to reduce hemoglobin behaved similarly.

Ion Actions on Nerve.—Nerves also lose their irritability in solutions of non-electrolytes, and recover in salts. The cation series is similar to muscle, but the anion series is reversed.

The reaction of motor-nerves to electrolytes has also been shown to be an additive function of the two ions; the anions (alkalis or increase of valency) stimulating the sciatric nerve of the frog, while cations (acids) lower its irritability (A. P. Mathews, 1902). This agrees with the old observation of Galvani (confirmed by Grandis, 1902), that the nerve is stimulated when it is charged by induction with negative electricity, and depressed by a positive charge. Mathews assumes that the stimulation is caused by the precipitation of the (positive) colloids of the nerve by the anions, and vice versa. This demands further proof, especially before it is extended to other forms of protoplasm.

Cathions may, however, also be stimulating; for instance, N(CH3)4Cl is very stimulating, whereas NH4Cl is indifferent (J. Loeb and Ewald, 1916).

Nervous Center.—Hooker, 1915, performed these studies of the nerves of the mammalian central nervous system. The perfusion of spinal cord of frogs gave similar results (Hooker and Reese, 1914). As to the perfusion of the medullary cardiac centers, predominance of K stimulated the vagus and inhibited the accelerator, while predominance of Ca stimulated the accelerators (Hooker, 1915). The perfused nervous system of mammad, preserves its activity best with a solution of 0.9 per cent. NaCl and 0.05 per cent. CaCl2. These can not be replaced by related ions. Even traces of potassium are harmful (P. Gerlach, 1914).

Ion Effects on the Kidneys.—The polyuria and glycosuria which follow the intravenous injection of large quantities of most sodium salts (especially in slightly hyperchloremic solutions) is probably the result of the action of an ion; and this ion is probably Na (Brown, 1903). It seems that the addition of a small proportion of CaCl2 stops the diuresis, which may then be started again by injecting sodium acetate. Sr or Ba salts prevent the glycosuria without affecting the polyuria.

Sollmann (1905) found that calcium also hinders the filtration of urine and impairs the circulation in excised kidneys, while magnesia favors them. These effects may be referred to ion actions on the renal protoplasm. The effects of most other ions which were investigated in this manner are referable to osmotic changes, due to differences of penetrability.

Guthrie, 1910, claims that direct perfusion of the kidney vessels with saline solutions, even for a short period, is followed by hemorrhagic and degenerative changes in the kidneys, leading to uremia and death after a few weeks or months. Simple anoxia of equal duration is much less detrimental. Carrel claims that he has not observed these results.

Balanced Salt Ratios.—A solution containing a single electrolyte, no matter what the chemical nature of the latter, is fatal to all forms of life. The toxicity can be greatly lessened by the addition of a second salt. This is called the “antitoxic action” of ions. For perfect functioning, several salts are necessary, in a definite “balanced” ratio (J. Loeb, 1916). Departures from this ratio modify the functions of the cell, and large
changes are fatal. The mineral constituents of cells are therefore indispensable to life. The phenomena are probably produced by modifications in the permeability of the cell membrane.

Ions Essential to Life.—The following salt ions are absolutely necessary to plants: K, Mg, PO₄, CO₃ (Na and Cl are not necessary); Ca to all but the lower fungi and algae. Mn forms an essential constituent of vegetable oxidizing enzymes. NO₃ and SO₄ act as nutrients.

In addition to Na, Cl, CO₃, Ca, K, Mg, Fe, PO₄, SO₄. It is very doubtful whether other elements existing only in traces (such as F) are necessary, or merely accidental. The microchemical investigations of A. B. Macalum (1905) indicate that the electrolytes are localized in certain portions of the cell by surface tension.

Mineral Salts in Nutrition.—McCullum and Davis, 1913, found a definite salt mixture essential to the growth of rats. Osborn and Macleod, 1912, also found that rats fed on a diet free from inorganic salts declined continuously in weight, and that a definite mixture of salts must be supplied. Subsequent work (Mendel and Osborn, 1917) showed that rats require considerable calcium and phosphorus, but may grow on very little of either Mg, Na, K or Cl. However, simultaneous lowering of K and Na checks growth. The salt content of the milk undoubtedly plays an important part in the nutrition of infants. Cows' milk is considerably richer in all the important salts than is human milk, but the difference is probably compensated by the better utilization of the salts of human milk.

Antitoxic Action1 of Ions.—As far as known, no cell can remain alive unless it contains some electrolytes. If these are reduced below a certain minimum, the cell dies rapidly. But in many cases it dies even more promptly if it is placed in a solution containing a single electrolyte. This is the toxicity which was described in the preceding paragraphs. It would seem therefore that several electrolytes, in a certain ratio, are required in order that the cell may perform its functions. This was confirmed by J. Loeb (1901), who showed that the toxicity of an electrolyte can be very greatly lessened by the addition of another electrolyte, sometimes in very small proportion. (For instance, the addition of 4.400 m. CaCl₂ neutralizes the toxic action of 9.5 m. NaCl on Fundulus ova.) The antagonism is mutual, at least to some extent. Instructive examples of antagonism are furnished by J. Loeb, 1911.

From his observations, Loeb at first concluded that the cations are responsible both for the toxic and antitoxic actions; and that cations of different valency neutralize each other. The extensive experiments of A. P. Mathews (1905) modify these theories; it would appear that cations and anions are both concerned in the toxic and antitoxic actions (although the cations are probably the more important); and that the valency has no direct connection with either the toxic or antitoxic action (Loeb, 1914). The decomposition-tension seems to be of subsidiary importance in the antitoxic action, and it appears to be necessary to invoke several mechanisms for its explanation. The antagonism is evidently a complex phenomenon, involving also the specific ion actions. It may be noticed, for instance, that certain ions (NH₄, and Li) are particularly difficult to neutralize; Ca is especially antitoxic, Mg much less so; Ni scarcely at all. The optimum ratio and the degree of antagonism vary for different cells. Closely related ions sometimes have very different effects, and can not replace each other. Even when the antagonism of two salts is at its best, it is never perfect; it requires the addition of one or more further salts to enable the cell to perform its functions properly. Indeed, a steady normal condition is not reached until the cell is placed in a solution, the cations of which are within narrow limits the same qualitatively and quantitatively as those of its normal surroundings.

Nature of Ion Action.—There are reasons for believing that the ion actions are exerted only on the surface of the cell, especially by altering the permeability of the envelope (plasma membrane); and that the antitoxic actions are also exerted mainly on the permeability.

The high resistance of cells to the penetration of ions makes any internal effects very improbable. With potassium, f.i., which is highly toxic to muscle cells, it has been shown that it passes neither into nor out of the cells (Uranio; Fahr). The same is true of calcium (W. Straub, 1912). The promptness with which the effect can be

---

1 The term "antitoxic action," applied to ions, means something very different from the same term when it is used in connection with bacterial poisons.
removed by the addition of a second salt also speaks against absorption. It is very probable that the single-salt solutions disturb the semipermeability of the membrane (J. Loeb, 1905, 1914), thus interfering with the maintenance of the electric potential which determines its semipermeability. This influence on semipermeability caused by second salt effects is greatly increased by dilution; and Warburg, 1910, found accordingly that the toxicity is diminished by the addition of NaCl. On the other hand, the toxicity of NaCl for the neuro-muscular mechanism of muscle is quite different; in these it diminishes oxidation, and cyanide is therefore not antitoxic. Electrolytes on Diffusion through Living Cells.—J. Loeb, 1916, found that the presence of electrolytes has a markedly favorable effect on diffusion from or into Fundulus or. Presumably this holds also for other cells. Cell permeability would, therefore, require a certain salt-content of the plasma-membrane. Excess of electrolytes, however, again hinders diffusion. In this way, the penetration, and therefore the effects, of a salt may be either aided or hindered by the presence of a second salt.

Plasma Membrane and Electric Stimulation.—Nernst, 1899, suggested that electric stimulation changes the ion-concentration on the surface of the semipermeable membrane. Lillie, 1912, proposes a similar theory for nerve-conduction. The change in permeability would itself set up electric changes, which would stimulate the adjacent portions of the nerve.

Mechanism of Antitoxic "Action."—G. N. Stewart, 1904, suggested that the antitoxin of salts may be explained in some cases by alteration of permeability, preventing osmotic changes or the penetration of harmful ions. This has been confirmed by J. Loeb, 1905, 1911, and 1912. It is probable that K "loosens" the plasma membrane and thus abolishes excitation; and that Ca counteracts this effect. The reason for the necessity of Na and Mg have not been explained. Loeb (1914) now believes that the conservation of the plasma membrane requires a specific mixture of Na, K, and Ca chlorides; and that any departure from this balanced ratio disturbs the membrane. A partial preservation may be secured by substituting other ions with similar properties. The whole phenomenon is rather analogous to the behavior of soaps (Clowes, 1916). Osterhout, 1917 to 1918, arrives at similar conclusions. He finds that all substances (non-electrolytes as well as electrolytes) that affect permeability belong to one of two classes, which antagonize each other:

1. NaCl type, increasing permeability from the start to death;
2. CaCl₂ type (including also Sr, Mg and H₂O as chlorides), decreasing the permeability to a certain concentration; beyond this acting like NaCl.

Growth of cells occurs only in solutions that preserve the normal permeability. All deleterious conditions alter the normal permeability; and cells of abnormal permeability have a lowered vitality.

Other factors may conceivably cooperate, such as the electric and chemic charges, decrease of dissociation (as in the effect of citrates on Ca; Sabbatani, 1903). Finally, the antagonism may be functional, for it has been noticed that calcium also antagonizes some poisons which are not electrolytes (veratrine, Ringer, 1884; physostigmin, S. A. MacCallum and O. H. Brown, 1904; curare, MacCallum, 1904), and to which it is opposed in its functional effects. Similarly, magnesium is mutually antagonistic with physostigmin (Meltzer).

Magnesium and Calcium Antagonism.—This presents several special features. Increase of either Ca or Mg ions depresses muscle and nervous structures. Nevertheless, the effects of the Mg may be removed by addition of Ca. Ca also antagonizes the inhibitory effects of K, as well as the stimulant effects of Na (Meltzer and Auer, 1916). Strontium does not take the place of Ca in these reactions.

Even more complex relations have been discovered (Joseph and Meltzer, 1916) in frogs. Injection of Mg into the lymph produces a curare action, paralyzing the muscle-nerve endings, but not the muscle. The excitability is restored by Ca. Fusion of Mg paralyzes the muscle as well as the endings. Ca has no restorative effect on the muscle-tissue; Na + Ca restores also the endings.

Gaubert, 1919, asserts that the velocity of the diffusion of Ca ions through cell (for instance milk) is increased by the presence of Mg salts; whereas the diffusion of Mg ions is retarded by Ca salts. On the other hand, the diffusion of glucose through vegetable cells is favored by Ca and retarded by Mg.

"Physiologic" or "Normal" Saline Solutions (Artificial Serums).—The deleterious effects of single-salt solutions have led to the introduction of solutions better adjusted to the physiologic requirements. These
balanced solutions are necessary when experimenting on excised tissues. They are less important for injections into living animals, in which even single-salt solutions are rapidly adjusted by exchange with the tissues.

These solutions have been devised partly empirically, partly by imitating the salts of the blood serum or sea water. Different tissues often require slight modifications to secure the optimal effects. The following are the most important:

**Isotonic NaCl Solutions.**—Nasse, 1869, determined experimentally that 0.6% is the best concentration for preserving the irritability of frogs' tissues. Later, it was shown that this solution was not indifferent. Kronencker and Stirling observed stoppage of the heart; Ringer, twitching of muscles; Locke, contractions and increased irritability. Carlaw and Locke, curare action, etc. These effects can only be overcome by balancing the solution with other salts. However, the solution is practically isotonic with frog's blood, and therefore obviates osmotic changes. On the other hand, it is hypotonic to mammalian blood, which requires about 0.9% NaCl. Solutions of 0.8 to 0.9% are therefore generally preferred for mammals. The concentration of the T.S.P. is 0.85% Abel, however, found in vivissection that a lower concentration, about 0.6% per cent, prevented edema more effectively.

It will be recalled that the exact composition is of relatively small importance for injections into living animals.

**Note 1.**—In making solutions containing NaHCO₃, this must be completely dissolved before the CaCl₂ is added.

**Note 2.**—Other solutions are described in "Digests of Comments on Pharmacopoeia," 1911, p. 21.

The lower K content gives a more rapid heart rate.

**Locke's Solution.**—This is intended to be used with a stream of oxygen. It was originally devised for the mammalian heart; but it also maintains the vitality of arteries (Hatcher, 1906), and of nervous and other tissues (Hedon and Fleig, 1905).

Hering, 1910, found the addition of urea and glycerin to Locke's solution essential for the excitability of the nervous system of frogs. Presumably they influence the permeability of the lipoids. Bomhall, 1913, finds that the favorable effect of urea on the salamander heart is not shared by related substances, and therefore considers it chemic.

It dilutes the perfused vessels of the frog [Hooker, 1911].

**Sea Water.**—This contains the important ions in about the same ratio as the artificial solution; e.g., for 100 molecules NaCl there are the following molecules of other salts:

The freezing-point of sea water is: —2.79°C at Naples (Bottazzi, 1878); —1.9°C at Pacific Grove, California; and —1.8°C at Wood’s Hole, Massachusetts (Garrey, 1905).

OSMOTIC EXCHANGES IN THE BODY

General Statement.—Osmosis tends to operate within as without the body, so as to bring all the fluids into osmotic equilibrium, and if possible, to establish an identical composition. It is, however, modified by other forces. If a foreign solution is introduced—i.e., into the intestines, or peritoneal cavity, or blood—the osmotic forces will very rapidly bring its total molecular concentration to that which is normal for the tissue. This exchange could be effected either by the passage of water; or by the passage of the foreign salts out of the solution into the tissue; or by the passage of the normal salts from the tissues into the solution. In fact, all three processes generally participate, their share varying according to the special permeability of the tissues. In general, the exchange occurs mainly in the direction which will favor the normal physiologic functions; i.e., in the direction of absorption.

When the molecular concentration of the blood has been reached, there remains less scope for osmotic exchanges, and the further absorption must occur by other forces (filtration, imbibition, etc.), generally much more slowly. The rôle of osmosis in absorption is therefore important, but limited. Its active share in the secretion of the body-fluids, i.e., the urine or lymph is normally small; it is important mainly by setting limits to the real secretory forces.

The Rôle of Osmosis in the Absorption of Solutions from Serous C左右yves and Lymph Spaces.—This absorption is almost entirely physical, for it occurs quite well in dead animals, although it is naturally more rapid when the circulation is intact, because the absorbed products are then more rapidly removed. Osmosis plays a very important part in the absorption, especially if the solutions are anisotonic. If a hypotonic solution is introduced, osmosis causes the rapid absorption of water; with hyperosmotic solution, the volume of the fluid will at first increase, until it has become equimolecular with the plasma. At this time, however, the fluid is really hypotonic to the non-diffusible constituents of the cells and blood, so that it would be eventually absorbed, by the operation of osmosis alone. The osmotic absorption, for instance from the peritoneum, is quickened if the body fluids are rendered hyperosmotic, as by nephrectomy, or ligation of the renal vessels, or indeed by operations generally, or by epinephrin. Etherization alone does not affect the osmotic absorption. Caffein lessens it in normal animals, but increases it after nephrectomy (Fleisher and L. Loeb, 1910).

Ordinarily, however, the osmotic absorption is very slow after the solution has become isomolecular; and other factors intervene to hasten the process. Of these filtration and imbibition are the most important. The filtration pressure is furnished especially by muscular, respiratory, and peristaltic movement. The intraperitoneal pressure amounts to 2 to 25 mm. of water (H. Emerson, 1907). It may be increased by massage.
Imbibition in Absorption.—The term "imbibition" is applied to the familiar phenomenon of the swelling of pieces of glue, gelatin, agar, tissues, and other colloidal gels, when these are placed into solutions (F. Hofmeister, 1890 and 1891). This process is quite distinct from osmosis, although both may take place side by side. Imbibition is probably analogous to adsorption.

Hamburger has shown that when a solution is placed in a gelatin cylinder, and this is immersed in a circulating current of the same solution, the stagnant fluid in the cylinder passes gradually through the gelatin into the circulating fluid. The phenomenon is obviously analogous to the absorption of isotonic solutions from serous cavities, and helps to explain the latter. Hamburger considers this process an imbibition effect.

Many physiologists consider that "old forces also cooperate in the absorption; the possibility of this can not be denied; but there is scarcely any positive proof in its support; if it plays any rôle, this must be quite subsidiary.

Absorption of effusions or serum from serous cavities: In this, the cooperation of osmosis is almost excluded, for these contain non-diffusible protein constituents, as well as the tissue fluid. However, the proteins of these fluids tend to break down constantly into more diffusible molecules (as shown by the fact that exudates generally depress the freezing-point somewhat more than does the blood). Osmosis therefore plays a part, but this must be relatively small. The existence of proteins also limits the operation of imbibition, for proteins are not imbibed by colloids. This leaves filtration as the main factor in the absorption of protein-containing fluids. The absorption of these liquids is consequently a much slower process than that of salt solutions.

Absorption from the Alimentary Canal.—This is probably even more dependent upon forces other than the osmosis than absorption from serous cavities.

Filtration aided by the intraintestinal pressure is an important aid (Hamburger). There are also other processes, ill-understood: Thus if an excised and surviving intestine is immersed in a solution, a passage of fluid takes place from the lumen to the surrounding fluid, even when the two fluids are identical (Cohnheim, 1893). Hamburger, 1906, attributes this to imbibition, and finds that even the dead intestine is differently permeable in the two directions. Sodium sulphate, for instance, passes much more readily from the lumen to the exterior than in the reverse direction. He has also demonstrated a "polarity" of absorption in artificial membranes, in which the two surfaces have a different composition. The diffusion through excised intestine is markedly influenced by saliclylates and some other substances (Hanusli, 1912). The absorption of ions from the excised intestine has been investigated by Benedictini, 1906 and by Hoeber, 1905. The latter found the anion series, Cl > Br > I > NO₃ > SO₄. Lipidolytic substances (short of the narcotic concentration) are absorbed more readily than non-lipoid solutes. From analogy with dyes, Hoeber assumes that the lipidolytic are absorbed through the cells, and that the absorption of non-lipoids is confined to the intercellular substance.

Brodie and Vogt, 1910, showed that the oxygen-consumption of the intestines is increased during the absorption of normal saline, water and peptone solutions; indicating that the cells also play an active part in the process.

Absorption Curve.—Hanusli and Sollmann (1909 to 1912) have found that the absorption of phenol, alcohol, iodid and presumably other substances from intestinal loops follows a uniform curve, the rate being very rapid for the first ten to thirty minutes, and then very much slowed. Various factors seem to be concerned in this phenomenon. The rate of absorption, under these conditions, is not greatly influenced by the concentration of the solution or by the extent of the intestinal surface.

Importance of Osmotic Exchanges in the Intestine.—Osmosis has at least a modifying influence on intestinal absorption. The time during which the food remains in the alimentary canal is ample to effect osmotic exchanges between the intestinal contents and the blood. An isotonic condition becomes established quite promptly (but is not completed in the stomach; E. Otto, 1905).

Thus equilibration, with the absorbable salts, is mainly in the direction to facilitate absorption: hyperisotonic solutions being rendered isotonic rather by the absorption of salt than by the pouring out of fluid; while hypoisotonic solutions are rendered isotonic by the absorption of their
water. (In other situations than the alimentary canal, the equalization takes place more uniformly in both directions.)

These changes result in corresponding alterations in the composition of the cells of the gastric and intestinal mucosa, which are therefore also subjected to osmotic salt action. This causes irritation. When the irritation is mild, it increases secretion, absorption, and peristalsis. More severe grades of irritation, however, produce emesis and inflammation.

Salts which are not absorbable by the intestine (cathartic salts) are reduced to isotonic conditions by the absorption of fluid. This fluid is retained in the intestine with the salts, increasing the bulk and fluidity of the intestinal contents, and serving as a mechanical stimulus to peristalsis. This explains largely the cathartic effects of these salts.

Absorption from Colon. — Goldschmidt et al., 1919, found that diffusion occurs in both directions. With fluids below a certain threshold (about 0.6 per cent. NaCl with Δo.1544) chloride pass from the blood into the colon. With hypertonic solutions (above Δo.766 = NaCl 1.2 per cent.) fluid at first goes into the colon. Finally, the Cl and the freezing point comes into equilibrium with the blood.

Molecular Concentration of Gastric Juice. — Carlson, 1914, found the freezing-point of normal human "appetite juice" as −0.25 to 0.62; that of hunger juice as −0.47 to 0.52. Similar results were obtained with dogs.

Osmotic Effects on the Blood and Lymph—Fate of Salt Solutions Within the Body. — In whatever concentration and by whatever channel salts are introduced into the body, they will tend to increase the quantity of blood, or rather of plasma and to render it more watery and less viscid; in other words, to produce hydremic plethora. If isotonic or hypoosmotic solutions are introduced, they will dilute the blood by their own fluid; if hypertonic solutions are injected, the blood will draw fluid from the tissue until it has resumed its original concentration. The result will be hydremia in either case. If antitonic solutions are introduced, they will temporarily alter the molecular concentration of the plasma.

However, the blood possesses a remarkable power of resuming its normal condition, its total molecular concentration, ratio of individual constituents, ratio of corpuscles to plasma, and total quantity (in about this order). The process of restitution takes place very rapidly; it is far advanced before a quick intravenous injection can be completed; the molecular concentration returns to very near normal within ten minutes; the quantity of blood and individual constituents are restored somewhat more slowly; but they are almost normal in half an hour; after two hours, the blood presents only very slight abnormalities, even when very large injections have been made (Magnus, 1901; Sollmann, 1904).

The total molecular concentration is the first factor to be restored; this is accomplished mainly by the passage of the dissolved molecules: If a hypertonic solution is injected, the injected molecules leave the blood very rapidly. Other molecules leave more slowly and water is taken up into the blood. As soon as the normal molecular concentration is restored, the phenomena become identical with those following the injection of isotonic solutions.

If a hypertonic solution is injected, the principal phenomenon at first is the passage of molecules into the blood, the injected molecules leaving the plasma very slowly. The water also leaves only gradually, i.e., mostly after the normal concentration has been reached; and then by the same process as with isotonic solutions.

An isotonic solution of a single salt (sodium chlorid or sulphate) is injected, both and the injected molecules leave the circulation; the molecules somewhat more at the same time, other molecules enter the circulation. This process may take about two hours, until the original quantity of blood and its original osmotic concentration have been practically restored.
OSMOTIC EXCHANGES

Mechanism of Restoration.—The restitution of the blood consists in a process of exchange with the remainder of the body. There can be no doubt that the tissues (especially the striated muscle cells, Engela, 1904; Jappelli, 1906; and the liver, Sherrington and Copeman, 189; Uschinsky, 1905) play the most important rôle in the rapid exchange which we have so far described.

With intravenous injections of hypertonic solutions, the muscles supply most of the water, and take up a large part of the salt; although their salt percentage does not increase as much as that of some other tissues (Wahlgren, 1909). The quantity of material of which tissues can dispose, without visible change, is astonishingly great. In rabbits, for instance, the tissues take up Ringer’s solution about four times the quantity of the blood (Bogert, Underhill and Mendel, 1916). However, very large injections give rise to ascites, effusions, etc.

In addition to the tissues, the lymph and urine flow and all the secretions of the body are also increased; and to them falls the task of finally removing the injected substances from the tissues out of the body. The tissues act the part of elastic reservoirs, as it were, quickly relieving the blood of the disturbing element, again to give up the abnormal substances as rapidly as they can be removed by the more slowly acting excretory mechanisms.

Physical processes, notably osmosis and filtration, play a very important part in the exchange with the tissues, and in the increased lymph flow. Indeed, it is scarcely necessary to invoke any vital mechanism for their explanation.

Conditions Delaying the Restoration of the Blood-volume.—Bogert, Underhill and Mendel, 1916, confirm that in normal dogs and rabbits, the blood-volume returns to normal within half an hour after the intravenous injection of warm Ringer’s fluid, equivalent to the total blood-volume. This is delayed by morphin, and by sephritis (urine, chromate or tartrate), but not by ligation of the kidney vessels. The restoration is not affected by the addition of 0.4 per cent. sodium carbonate, either in normal or in nephritic animals. Gelatin solutions (2 per cent.) may leave the blood as rapidly as plain saline, although more commonly from 11 to 27 per cent. are still present in the blood after half an hour. The gelatin leaves the blood in the same ratio as the fluid (Boycott, 1914) and is partly excreted in the urine.

Salt-actions on the Urine.—The hydremic plethora results in an increased elimination of urine. The excretion of water and the injected substance is especially increased. The other urinary constituents are generally decreased, as concerns their percentage; although their absolute quantity may be increased. (The saline diuresis would therefore result in a “flushing of the body.”)

The diuretic action of saline solutions is largely physical, and can be reproduced point for point in dead kidneys (Sollmann, 1903 to 1905; except the effect on the composition of the urine). It is explained by the hydremic plethora; the increased glomerular pressure, and the lessened viscosity of the blood. This is aided, in the case of hypertonic solutions, by the dehydration and shrinkage of the renal cells. All these processes favor glomerular filtration.

The urine flow and kidney volume of excised and re-implanted kidneys react the same as normal kidneys to urea, hypertonic salt solutions, and to the methyl-xanthins (Quinby, 1917).

The physical element in the diuresis is especially conspicuous in the early periods of the diuresis, when the changes in the blood are relatively large.

It has been observed, however, that the urinary changes may persist, in a slight degree, after the blood has apparently returned to normal. This suggests the cooperation of a vital stimulation, produced by the (very slightly) altered composition of the blood. The concentration of the urine varies with the concentration of the solution which has been introduced; it may fall as low as $0.12$, or rise as high as $3.5^\circ C$. On the whole,
the composition of the urine approaches the more closely to that of the blood, the faster the diuresis.

The degree of diuresis (the total quantity excreted) depends largely on the quantity of solution (both of the dissolved substance and of the water) which has been introduced; but the rate of diuresis (the quantity excreted within a short time after injection) depends largely on the concentration of the solution, if this is given intravenously (water, which is so strongly diuretic when taken by mouth, may diminish the urine when injected by a vein).

Fischer and Sykes, 1935, claim that the diuretic effect of intravenous saline injections is proportional to their dehydrating action on colloids (fibris). This would lessen the affinity of the tissues for water, and would therefore place a larger quantity of fluid at the disposal of the kidneys. It may be an additional factor in saline diuresis, but requires further confirmation.

In the ordinary secretion of urine, osmosis appears to be an obstacle, rather than an aid; for the molecular concentration of urine differs quite widely from that of the blood (Δ urine, ordinarily, 0.0 to 2.5; extreme, 0.1 to 3.0; Δ blood, 0.3 to 0.4); and the kidney has to perform a very considerable labor to overcome the difference in osmotic pressure. However, this work seems to be in no way injurious to normal kidneys.

*Work Performed in Urine-formation.* This cannot be calculated directly from the total molecular concentration, since the departure of every constituent from its concentration in the blood requires work. Barcroft and his coworkers have investigated the problem qualitatively by the increase of oxygen consumption which accompanies work. They found that the diuresis following the injection of isotonic solutions does not involve work; but that the oxygen consumption increases when hypertonic urines are secreted in response to sulphate injection. Caffeine diuresis also involved work.

*Cushny's Theory of Urine Formation.*—Explanations of the mechanism of urine formation are still largely hypothetical. That advocated by Cushny is especially satisfactory for saline diuresis. It is essentially the filtration and reabsorption theory of Ludwig, but supplements the understood physical forces by unexplained forms of energy.

*Glomerular Filtration.*—The theory assumes that all the urinary constituents are separated from the plasma by filtration through the glomerular capillaries. This could be accomplished by the blood-pressure, if the composition of the glomerular filtrate is that of the protein-free plasma, i.e., essentially a "Locke's Fluid." (This, however, has not been proven directly.)

The rate of filtration would be modified by the renal circulation, by the viscosity of the blood, and presumably by the permeability of the glomerular cells. However, the kidney would not expend any energy or work in the process.

*Tubular Absorption.*—The theory assumes that the glomerular fluid on passing through the tubules is changed into urine by the absorption of certain substances by the epithelium. This alters the total and the partial molecular concentration, requiring the expenditure of energy by the epithelial cells, and is therefore an active process.

*Concentration of Constituents.*—The substances excreted in the urine may be arranged into two classes:

**Class I.**—Urea, ammonium, phosphate and sulphate ions, and most foreign substances have ordinarily a much higher concentration in the urine than in the plasma.

**Class II.**—Na and Cl occur in the urine in concentrations that ordinarily are not much greater than in the plasma. Dextrose and colloids fail to pass into the urine.

Substances of Class II are excreted only when their concentration in the plasma surpasses a certain level. They are "threshold substances."

*Selective Absorption.*—Cushny's theory assumes that the solutes of Class I are not reabsorbed by the tubular epithelium and those of Class II are reabsorbable. Those of Class I are therefore concentrated in proportion to the amount of fluid that is reabsorbed from the glomerular filtrate (estimated to vary between 50 to 90 per cent). Class II (the threshold substances) are not reabsorbed indiscriminately, but in about the proportion in which they exist in the normal plasma. The absorbed fluid is therefore assumed to be slightly alkaline, and to contain sugar, amino-acids and other similar food substances, chloride and Na.

When the percentage of any of these in the plasma is abnormally high (for instance, as in diabetes), the glomerular filtrate would contain a correspondingly high percentage...
Since the reabsorption, however, occurs in the normal percentage, a part of the solute will remain unabsorbed and appear in the urine.

Variations of Concentration in Diuresis.—During diuresis there is less time for tubular reabsorption. The composition of the urine therefor tends to approach that of the plasma. The elimination of all the constituents is increased in absolute amount per unit of time. The percentage of non-threshold substances (Class I) is invariably diminished; that of the threshold substances is also often diminished, but may actually rise—according to whether they were previously above or below the concentration of the blood.

Lymph Formation.—The lymph comes from the tissue spaces; and whatever alters tissue fluid must alter the lymph.

Lymph formation would be increased by osmotic pressure, whether as the result of tissue activity, or of hypertonic injections.

Filtration probably plays a part in the increased lymph flow of hydremic plethora, although filtration does not seem to be an adequate explanation of normal lymph formation (Carlson and pupsil, 1908; Boehm and Asher, 1909).

Viscosity of Lymph.—Normally, this is not greatly diminished, even by large intravenous saline injections. After hemorhage, however, saline injections diminish the lymph viscosity very considerably; the lymph evidently returning to the plasma the fluid that has been filtered into the tissues (Burton-Opitz and Nemeser, 1917).

Asher, 1913, points out that filtration can not be an important factor in the secretion of saliva, mucus and bile, since the secretion pressure exceeds the blood pressure.

The physical-chemical condition of salivary secretion have been investigated by Japelli, 1908; those of tears and collyria by Cerrano, 1909.

Edema.—Salt action, osmosis, and colloid inhibition are important factors in edema, i.e., the excessive accumulation and retention of fluid within and between the cells.

The edema fluid is analogous to lymph, and may therefore be increased by the same agencies which increase lymph flow: hydremic plethora; lymphangiae of the "second class" (peptones, etc.); increased blood pressure; venous obstruction; injury to the vascular endothelium, etc. However, for the retention of fluid it is further necessary that the drainage of the lymph be obstructed; or that there be an increased affinity of the tissues for fluid. In fact, the cooperation of several of these factors is generally necessary for the production of noticeable edemas. Experimental edemmas, resembling the clinical, require the simultaneous presence of nephritis, hydremic plethora, and vascular injury (Pearce, 1909).

Extensive intravenous injections of salt solutions produce edema and edema of the internal organs, but not of the normal skin or subcutaneous tissue. To effect these, the skin must be irritated (Cohnheim and Lichtheim, 1877); or the vessels injured, as by arsenic (Magnus) or uranium.

Normal Variations of the Water Content of Tissues.—These depend mainly on age and nutrition. The average water of human tissues decreases from 94 per cent. in the three-month fetus, to 69 to 66 per cent. at birth, and 58 per cent. in adults. It is higher in emaciation, varying inversely to the fat (Albu and Neuberg, 1903)

Edema.—Effusions of a molecular concentration inferior to that of the blood would be promptly absorbed; or rather, they could not be formed. Since they, like other body fluids, owe their concentration mainly to their content of sodium chloride, it is evident that a deficiency of this salt in the body will tend to lessen the production of effusions, and hasten their absorption. This is the rational basis of the treatment of nephritic edema by withholding salt from the food (advocated by Widal and Javal, 1903).

The treatment is not always entirely successful (Booker, 1909), for the salt may not be the cause of the edemas, but only a factor in their production. It is believed, however, that an actual salt retention occurs in some types of nephritis (especially chronic interstitial) and other conditions (Magnus Levy, 1920), owing to diminished permeability of the kidney to salts. These would be most favorably affected by salt withdrawal. In other cases, the effusions are removed more effectively by administering salts, through their diuretic action. Actual trial alone can decide which form of treatment is needed in a given patient. The salt-poor diets are discussed under "Sodium Chloride."

Colloids and Edema.—Martin Fischer (1908 to 1915) believes that the circulation has little if any direct connection with edema; but that this is the condition of the body to changes in the amount of the tissue colloids for water and salts, strictly analogous to the swelling of gelatin or fibrin.
This is modified to a varying degree by electrolytes; not by non-electrolytes. It is especially increased by acids; and the production or accumulation of acid, including CO₂ in inflammation, venous stasis, etc., would therefore be the principal cause of edema (and the concomitant salt retention), and incidentally of nephritis. Fischer is also inclined to deny that osmotic has any part in these or other vital phenomena; and to refer to imbibition all the phenomena which are generally classed as osmotic.

The influence of acids and electrolytes on imbibition can not be doubted. It is therefore very probable that imbibition plays an important rôle along with other factors; but serious objections have been raised to some of Fischer’s experiments and deductions. It would require much stronger evidence to place such sweeping statements on a firm foundation.

Fischer’s theory fails to explain the close resemblance of some of the vital and ordinary osmotic phenomena, i.e., the equivalent effects of isotonic solutions; the semipermeability of blood cells and striped muscle, etc.; the fact that these phenomena are not modified seriously by the addition of gelatin or serum (Beutner, 1913), etc. The absorption of water by the skin of the frog is shown by Maxwell, 1913, to be mainly osmotic. Beutner, 1913, and Moore, 1918, point out the differences between osmotic and collod swelling of muscle. J. Loeb, 1915, believes that the osmotic processes predominate so greatly during life that imbibition does not become important until the semipermeability of the cell has been destroyed by death.

The increase of free acid, on which Fischer bases his theory of edema and nephritis, is only hypothetical. Henderson and pupils, 1914, emphasize that tendency toward acidity in the organism is not usually accompanied by edema; while the acidity of the urine has no relation to albuminuria or nephritis. There is no direct evidence that the free acidity is ever increased to an effective degree during life (Goodridge and Gis. 1911). Koppel, 1913, and L. J. Henderson, Palmer and Newburgh, 1914, point out that the range of variation of H-Ion-concentration, even in the urine, does not affect collod inhibition. Even if it were granted that this may occur in some cases, there is no evidence that it is a universal or important phenomena; nor would the results of such acidity be uniform; for Pincussohn, 1912, found that acids, while they increase the inhibition of gelatin and muscle, lessen that of kidneys, liver, spleen and lung. Hirschfelder, 1915, finds that the conjunctiva in mustard edema is not acid; nor does the excised eyelid or conjunctiva swell in acid Ringer’s fluid. Incidentally, there are agencies other than acids which influence inhibition, i.e., proteoses (Tracy and Gis. 1912). The effects of inflammation may also be explainable on an entirely different basis. Oswald, 1911, found that inflamed cells become permeable to collod (proteoses), especially in acute inflammation. He explains this by increased “quellung” of the cell membrane.

The practical application of Fischer’s theories to glaucoma and nephritis, has given results so discordant that they are not supports of the theory.

CATHARTIC SALTS

General Statement.—A number of salts are not absorbed readily from the alimentary canal. These therefore do not produce any marked direct systemic actions, unless they are injected into the circulation. When they are given by the mouth, their direct action is confined to the intestine; they cause catharsis with soft or fluid, painless stools. Through the catharsis they may produce, indirectly, a drying of the tissues and a slight increase of gaseous metabolism. The cathartic action is mainly the result of the retention of fluid in the intestine by the osmotic action of the unabsorbed salt, for this must retain sufficient fluid to preserve itself isotonic with the blood (Wallace and Cushny, 1808). It is possible that this action is supported by a direct stimulant effect of the salt ions.

Difficultly Absorbable Ions.—The most important cathartic ions are of the cations, Mg; of the inorganic anions, SO₄, and PO₄; of the organic tartrates, citrates, lactates and malates. Certain sugars, particularly milk-sugar, and mannite, also act as cathartics in the same way.
Many other solutes are difficult to absorb and would therefore belong to this class; but those named are the principal ones employed in practice. The others generally have some interfering factors: The heavy metals and algae produce a precipitation of proteins, and in this way an irritant or astringent effect. The earthy metals, Ca, Sr, Ba, are converted into insoluble carbonates. Oxalates and Fluorides are specifically toxic to proteoplasm.

Easily Absorbable Ions.—Of the Cathions, ammonium is the most readily absorbed; then come the alkali metals. The earthy metals are not easily absorbable. Of the Anions, the chlorides, bromides, iodides, nitrates and acetates are rapidly absorbed.

Cause of Different Absorbability.—Why certain ions should be capable of absorption, others not, is not satisfactorily explained. Although recent investigations have shown some striking analogies between the absorption of ions by the intestine and by muscle, and the solubility of their soaps and calcium salts, it is not yet clear whether this is a mere coincidence or has a deeper meaning.

Osmotic Factor in Cathartic Action.—Pousselie, 1838, invoked osmotic to explain the cathartic effect, not only of the salts, but also of the vegetable purgatives. This was mainly hypothetical; and Aubert, 1837, showed that there is no direct ratio between the osmotic and purgative strength of the different salts (since the absorbability was not taken into account). Buchheim, 1834, claimed that the increased water intake in saline catharsis came from the alimentary canal, and not from the blood. Colin, 1834, showed that concentrated solutions of cathartic salts increase in volume when placed in an intestinal loop. It was clear therefore that the salts could either attract or hold water in the intestines. Wallace and Cusinny, 1838, demonstrated conclusively that saline solutions placed in the intestines become and remain isotonic with the blood; and that therefore the amount of fluid held in the intestines depends strictly on the amount of salt which remains unabsorbed.

Interchange of Ions in Colon.—The colon behaves toward sulphate ions as a fairly typical semipermeable membrane; i.e., it is practically impermeable to sulphate (and also to magnesium) ions, but permits free passage to water till isotony is reached. It is freely permeable to chloride ions. Calcium lactate at first accelerates, then retards the absorption of chloride ions (S. Goldschmidt et al, 1919).

Conditions of Absorption.—None of the cathartic salts are altogether unabsorbable; their absorption is favored and their cathartic action correspondingly lessened, if they remain for a long time in the alimentary canal. This is apt to occur if the tissues are very dry. The rate of absorption depends also on the concentration of the salt: Concentrated solutions are generally absorbed more readily than dilute. This is one cause of the somewhat different activity of dilute and strong solutions.

The effect of concentration on absorption has been studied by Merck, 1906; Weise, 1911; and Cobet, 1913. Weise showed that the sulphates become isotonic within half an hour. The sulphate ion is absorbed in the same proportion from Na₂SO₄ and MgSO₄. The percentage of Mg absorbed increases with the dose. The upper and lower intestines do not show essential differences.

Matthew Hay, 1938, found that the cathartic action of salts less extensive if the intake of fluid is restricted; and that the activity is not increased by the injection of water into the blood.

Source of the Fluid in the Stools.—The ordinary ingestion of water and the quantity of fluid normally secreted into the intestines (perhaps 4 liters daily) would suffice to maintain the salts isotonic; and these are probably the chief source of the water of the stools. Should these be insufficient, especially if the salts are given in strong solutions, fluid could be withdrawn by osmosis directly from the mucous membrane, and hence from the blood. Ordinarily, however, this plays only a small part.

Passage Through Intestines.—This is hastened by the greater fluidity of the stools; but the cathartic salts do not increase peristalsis directly (Legros, 1905; Hay, 1883).
Studies with the X-ray method (Padberg, 1909) show that MgSO₄ delays the emptying of the stomach, but hastens the passage through the intestines, so that the solution arrives in the colon in one and one-half to two hours. The colon antiperistalsis is not inhibited; but it does not lead to the concentration of the contents, because of the osmotic retention. The fecal matters in the colon are therefore rendered more fluid, and this hastens their expulsion. The saline catharsis is not checked by morphine, unless this is timed so as to secure gastric retention of the salts.

Other Theories.—In place of osmosis, a number of other factors have been suggested, such as inflammatory irritation, stimulation of intestinal secretion, and muscular stimulation by osmosis, ion action, or by the withdrawal of calcium. None of these rest on adequate evidence, and they probably play at most a minor part.

Secretion Theory.—This was fostered especially by M. Hay, 1885, who did excellent experimental work on the cathartics. He believed that the salts excite a secretion of fluid into the intestines, which is partly balanced by absorption. However, his experimental results are explainable more simply on the basis of osmosis. Headland, 1869, believed that the salts are first absorbed but reabsorbed into the intestines, and that they stimulate secretion during their elimination; but Thiry, 1886, had found no secretion in his fistula. The theory of Carl Schmidt, 1890, that the fluid is a transudate, is without foundation.

Rodic, Cullis and Halliburton, 1910, showed that the oxygen consumption of the intestines is not increased by hypertonic magnesium sulphate, so that its distillation must be a purely physical process.

Intravenous and Hypodermic Injection.—It has been claimed by several observers that the cathartic salts stimulate peristalsis even when they are administered parenterally. This has been taken as evidence of direct stimulation of the intestinal muscles. However, these observations seem to have been based on experimental errors; and even if true, they could not explain the ordinary cathartic effect, since this does not involve any marked increase of peristalsis.

Experimental Data on Parenteral Administration.—Catharsis was reported from intravenous, hypodermic or intramuscular injection of sodium or magnesium sulphate by Aubert; Bernard, 1857; Agulhon; and more recently by J. B. MacCallum, 1903 and 1906; and by Bancroft, 1907. Most observers, however, have failed to obtain any increase of peristalsis and cathartics when proper precautions were taken to exclude exposure and asphyxia (Buchheim and Wagner; Donders; Vulpian; Jolleset and Cahours; Rabuteau; Bert; Moreau; Hay; more recently Auer, 1906 and 1908; Meltzer and Auer, 1906; Frankel, 1907; Mendel and Benedict, 1909). Joseph and Meltzer, 1910, found, indeed, with a careful technic, that intravenous or muscular injection of magnesium inhibits peristalsis.

Hypodermic Injection is also without result, except when made under the abdominal skin. The success in this case is entirely reflex, for injections of NaCI or ZnSO₄ in this region are also cathartic (Hay).

Excited Intestines.—Tyrode, 1906, found that the application of the purgative salts to the peritoneal surface depresses peristalsis. He also claimed that they stimulate peristalsis when applied to the mucous surface. Later observers could not confirm this stimulation (de Heer, 1915; Solomon, 1921).

Evidences of Irritant Action.—While the main effect of the saline cathartics is osmotic, it is quite possible that a muscular stimulation may occur under special conditions. F. J., Hess, Cook and Schlesinger, 1908, state that when doses of epson salt may cause watery evacuations within an hour. Their fluid is greater than could be explained by osmosis. Moreover, the stools of the following morning, which contain distinctly more of the salt, had a normal solid consistency. This muscular action may possibly be due to the formation of the irritant sulphides; or to neutralisation of calcium.

Relation to Calcium.—Chiarini, 1910, suggests that the precipitant effect of much of the cathartic ions for calcium could increase the excitability of the intestine. This may play a part; but at present is only hypothetical.

Experimental Inhibition.—Fisher noted that the cathartic actions belonging to the right hand side of the lyotropic series, diminish the imbibition of fibrin in dilute acetic acid.
This has been confirmed by Hirschfelder, 1916; but he finds that most of these salts diminish the H-ion concentration, thus explaining the effect. Sulphates, however, are not covered by this explanation.

**Fate of the Cathartic Salts.**—The portion which is not absorbed is of course eliminated promptly by the *feces*. The other salts of the feces are also markedly increased; the organic matter only slightly (Hay). The sulphates are in part reduced in the colon to sulphides, which give their characteristic odor to the feces.

*After absorption*, the cathartic ions are eliminated largely by the urine, producing a diuretic action. The urinary excretion is inverse to the purgative effect. With sodium sulphate, one-third to one-half of the excreted salt is in the urine. A considerable portion of the sulphate of magnesium may be retained in the tissues, the excretion extending over several weeks (Hay; Mendel and Benedict, 1909).

**Diuretic Action.**—All the cathartic anions are readily excreted by the urine, and therefore act as saline diuretics; rather more effectively than equivalent amounts of sodium chloride. However, because of the abstraction of water by the feces, the urine flow is generally decreased in the first twelve hours; it is then increased for about a day (Hay). The diuretic effect is proportional to the quantity of the salt absorbed, and therefore inverse to the catharsis.

Sodium sulphate diuresis increases the gas consumption of the kidney (Bainbridge and Evans, 1914).

**Reaction of Urine.**—MgSO₄ markedly increases the ammonium and acidity of the urine; Na₂SO₃ and MgO decrease the acidity, with subsequent return to the normal reaction (Hay, 1911).

**Concentration of the Blood.**—Hay found that this is increased shortly after the administration of concentrated but not of dilute solutions of cathartic salts. The blood count rises from 5,000,000 to 7,000,000 by the abstraction or retention of fluid in the intestines. It returns to normal within four hours, even if no fluid has been taken, since the saline solution is gradually absorbed from the intestines. When diuresis sets in, the blood count again rises to 6,000,000; and this even if the salt has been taken diluted.

**Metabolism.**—This is not measurably increased by the increased peristalsis of saline cathartics (Benedict, 1914).

**Temperature.**—Saline cathartics have been used in fevers, for their supposed "cooling" effect. Hay found no reduction of the internal temperature, but believes that the skin may be cooled through splanchnic dilatation. This is somewhat doubtful.

**Therapeutic Uses.**—The cathartic salts are used to empty the intestines in constipation, etc.; and to remove fluid from the body in edemas. Their introduction is of comparatively recent date (Glauber, about 1658). They are useful and effective as simple cathartics, especially in digestive disturbances, and against occasional constipation; but they do not meet the motor deficiency of chronic constipation as efficiently as the cascara group; they are rather unpleasant to the patient; they seem to lose in efficiency on continued use; and they are not very effective in obstinate constipation or mechanical obstruction. As hydragogue cathartic for the removal of edemas, the absence of irritation renders them generally superior to the drastic vegetable cathartics; their diuretic effect is a further aid.

**Administration as Laxatives.**—For this purpose, the salts should be given in dilute solutions (teaspoon to tumbler; or as the natural mineral waters—Carlsbad, Hunyadi, etc.), since these are less distasteful and act more promptly (one to four hours). The laxative dose of the usual salts is 5 to 10 Gm. (1 to 2 drams). (Larger doses are supposed to accustom the intestines to an abnormal type of peristalsis; Bastedo, 1914.) They
are best administered before breakfast, to hasten their passage through the stomach. If this is delayed, they are less efficient and somewhat irritating. For this reason they should be avoided with bedridden patients; for with these the passage of food from the stomach to the intestine is rather slow one. Some exercise is useful after taking salts, and this is one of the reasons why patients receive benefits in watering places which they fail to secure at home.

**Administration in Dropsy.**—Large doses (15 to 30 Gm., ½ to 1 ounce) should be given in concentrated solution (½ tumbler), also before breakfast. The concentrated solutions act more slowly than the dilute but they remove more fluid since they also increase diuresis. These concentrated solutions are also employed to reduce the secretion of milk.

**Catharsis on Excretion.**—The possibility of sparing the kidneys by catharsis is illustrated by data of Myers and Fine, 1910, on the percentile ratio of the fecal excretions to the total i.e., (urine plus feces) excretion of the following constituents:

<table>

The Choice between the Salt Cathartics.—This is very largely determined by their taste. The sodium sulphate has, perhaps, the most disagreeable taste; the magnesium sulphate somewhat less so. Sodium phosphate and Rochelle salt are perhaps the least disagreeable. MgO and MgCO₃ act as alkalies as well as cathartics.

The best corrective for the taste of the salts is ample dilution with water, when this is permissible. Some of the salts are official in effervescent form; i.e., mixed with sodium bicarbonate and citric or tartaric acid.

**SODIUM SULPHATE**

This is the most typical of the cathartic salts, being but very little absorbed, and almost free from ion action. It has no action on metabolism. On account of its disagreeable taste, it is not much used, except in veterinary practice; but it forms an important ingredient of many mineral waters, e.g., Carlsbad.

The kidneys are even more permeable to sodium sulphate than to NaCl, so that its intravenous injection produces a copious diuresis. The secretion of gastric juice is not increased.

The stimulant action of hypodermic or intravenous injections of sodium sulphate appear to surpass those of sodium chlorid. An isotonic solution (2 per cent. of the dried or 4 per cent. of the crystalline salt) is used in quantities of 500 to 1,000 c.c.

**PREPARATIONS—SULPHATES**

*Sodii Sulphas* (Sod. Sulph.), U.S.P., B.P. (Glauber’s Salt), Na₂SO₄ + 10H₂O—Large or granular colorless crystals, of bitter saline taste. Freely sol. in water (15) practically insol. in alc. All sulphates are incompatible with calcium and lead. Den-15 Gm., 4 drams, U.S.P.; 2 to 8 Gm., ½ to 2 drams, repeated; single, 10 to 16 Gm., ¼ to 4 drams, B.P.; diluted.

*Sodi Sulphas Efermoseli* (Sod. Sulph. Eff.), B.P.—A mixture of dried sodium sulphate, sodium bicarbonate, and tartaric and citric acids; representing 50 per cent. of
the ordinary sulphate. *Dosage: 4 to 8 Gm., 1 to 2 drams, repeated; single, 10 to 16 Gm.,
2 1/2 to 4 drams, B.P.*

Potassium (K) B.P., K₂SO₄.—Sol. in water (1:10); insol. in alc.  *Dosage: 1 to 3 Gm.,
15 to 45 gr., B.P.*

**SODIUM PHOSPHATE**

The phosphates also exhibit merely a local cathartic salt action. The presence of phosphorus in nerve tissue suggested the use of phosphates and phosphoric acid as nerve stimulants. There is no scientific foundation for this. The phosphoric acid of the urine comes almost entirely from the phosphorus of the nuclei of the cells, not from food. The official Na₂H₂PO₄, has a slightly alkaline reaction; but its administration does not influence the true reaction of the urine.

When injected subcutaneously, the phosphates are rapidly excreted by the intestine and kidneys. The feces contain phosphates even in starvation. The urinary phosphates are generally increased by water diuretics (Baezner, 1913). Milk contains a large proportion of phosphates, and it is possible that the administration of these salts might be useful in lactation, but this has not been demonstrated. The administration of phosphates has no effect on nitrogen metabolism. Intravenously, the phosphates stimulate the vagus endings similarly to thyroid, and they have been claimed to be of benefit in the same conditions. This is doubtful.

The intravenous injection of ordinary quantities of sodium phosphate acts similarly to sodium sulphate. Large doses (0.7 Gm. per Kg.) of sodium phosphate (absolute) injected into dogs produces tetany. The Ca content of the blood also drops by 40 per cent. (by dilution?). The calcium reduction is not the essential cause of the tetany, for phosphoric acid injection produces a similar fall of Ca without tetany (C. Ringer, 1917; Greenwald, 1918; the older work of Starkenstein, 1914, appears open to criticism).

**PYROPHOSPHATES**

Crawford, 1914, found these markedly toxic, producing gastro-intestinal irritation, hemorrhages and ulcerations; changes in the liver; with continued administration, nephritis and edema. Metaphosphates acted similarly but weaker; while the ordinary orthophosphate was non-toxic. Crawford believed that the pyrophosphates are responsible for the toxicity of certain cotton-seed meals, but Withers and Ray, 1914, contradict this conclusion.

**PREPARATIONS—PHOSPHATES**

*Sodi Phosphus (Sod. Phosphi), U.S.P., B.P., Na₂H₂PO₄ + 12 H₂O.—Large colorless crystals or granular powder, of cooling saline taste. Freely sol. in water (1:2.7); practically insol. in alc.  *Dosage: 4 Gm., 1 dram. U.S.P.; 2 to 8 Gm., 1 1/2 to 2 drams, repeated; single, 10 to 16 Gm., 2 1/2 to 4 drams, B.P.*

*Sodi Phosphus Efferens (Sod. Phosphi Eff.), U.S.P., B.P.—A mixture of exsiccatum sodium phosphate, sodium bicarbonate, and tartaric and citric acids, representing about 50 per cent. of the ordinary or 70 per cent. of the dried phosphate.  *Dosage: 10 Gm., 2 1/2 drams. U.S.P.; 4 to 8 Gm., 1 to 2 drams, repeated; single, 10 to 16 Gm., 2 1/2 to 4 drams, B.P.*

*Sodi Phosphus Eccessitatus (Sod. Phosphi Ecessit.), U.S.P.; Na₂H₂PO₄.—Sodium phosphate, from which the water of crystallization has been expelled by heating at 100°C. It is about two and one-half times as strong as the ordinary phosphate.  *Dosage: 2 Gm., 30 gr., U.S.P.*

*Sodi Phosph. Cæ, N.F.—Sodium phosphate liquefied in its water of crystallization by sodium nitrate and citric acid. 100 c.c. represents 100 Gm. of sodium phosphate (about two-thirds of the acid phosphate, W. F. Horn, 1910).  *Dosage: 10 Cæ., 2 1/2 drams.*

*Sodi Phosph. Acidus (Sod. Phosphi Acid.), N.N.R., B.P., Sodium Acid Phosphate (mono-sodium phosphate)—Contains at least 82 per cent. of NaH₂PO₄, N.N.R.; 70 per cent. B.P. Large colorless crystals or granular powder, of saline and somewhat acid taste. Very sol. in water; insol. in alc. This salt is used to increase the acidity of the urine (Hanafik and Collins, 1913). It is also cathartic, but more irritant than the ordinary phosphate.  *Dosage: 1 to 1 1/2 Gm., 17 to 20 gr., in water; repeated every one to four hours until the urine becomes acid; 2 to 4 Gm., 30 to 50 gr., B.P. It should not be mixed with hexamethylenamin.
A solution may be prepared extemporaneously by adding Dilute Phosphoric Acid to a solution of the official Di-sodium phosphate until it no longer precipitates a solution of CaCl₂; or as follows: Sod. Phosph., 10 Gm.; Ac. Phosph. Dil., 25 Gm.; Water, q.s. ad 150 c.c.; a tablespoon of this mixture contains about 1 Gm. of the acid phosphate.

TARTRATES

General Statement.—These are difficultly absorbable, and therefore typical saline cathartics, possessing the advantage of a relatively unobjectionable taste. The potassium-sodium tartrate or Rochelle salt is commonly used. Acid potassium tartrate (cream of tartar) acts as a mild acid; and being relatively insoluble, the acid-action extends into the intestines and here stimulates peristalsis. It is therefore more actively cathartic.

Cream of tartar and tartaric acid effervesce with sodium bicarbonate, and are used in baking powders, effervescent drinks, etc.

The tartrates are not readily burned in the body, and therefore do not act as alkalies and diuretics as powerfully as do most other organic anions. When introduced into the circulation, they have a rather high toxicity by immobilizing calcium, and injuring the renal epithelium; but this need not be feared from therapeutic doses (Post, 1914).

Toxic Actions of Tartrates.—The effects on calcium are similar to those described under Citrates. Small doses produce only the renal injury; larger doses also muscular and nervous symptoms. The cardiac excursions are decreased, especially in cases with moderate slowing. The blood pressure is unchanged, the kidney volume slightly increased. The effects may be acute or subacute, according to dose (Salant and Smith, 1914). The four stereoisomerous isomers behave somewhat differently toward calcium and therefore have a different toxicity (Chio, 1912). Salant and Smith, 1913, found that the d- and l- had the same toxicity for frogs and rabbits; but the resistance of different animals varies greatly.

Excised Intestine, and Isolated Frog Heart.—The effects of the various tartrates, citrates and malates, on the small and large intestines are complex. The isolated heart is depressed (Salant et al., 1917).

Renal Action.—Underhill, Wells and Goldschmidt, 1913, and Pearce and Ringer, 1913, found that Rochelle salts produce marked renal changes when given hypodermically in doses of 0.25 Gm. per kilogram to phlorhizin rabbits; somewhat larger doses caused the same changes without phlorhizin. Oral administration also produced nephritis, with doses of 3 Gm. per kilogram. Five Gm. per kilogram was fatal in fasting animals. The toxicity is not as great in well-fed animals; when diarrhea occurs, or when alkalies are administered. Acetate, citrate and carbonates do not produce these renal changes. Analogous effects are produced on dogs.

The epithelial changes are confined mainly to the convoluted tubules, with some extension to Henle's loops. The glomeruli and interstitial tissue are intact. The lesions result in retention of the tartrate so that only traces are excreted by the urine even on increased injection.

In the acute nephritis of rabbits, the phthalaein excretion is materially diminished. In chronic cases, the excretion again improves somewhat with time. The nitrogen excretion is scarcely altered (Underhill and Blatherwick, 1914). Hippuric acid synthesis is not impaired (Kingsbury and Bell, 1915).

The excretion of injected urea, and the excretion of N and dextrose in phlorhizin animals is hindered, but the NaCl excretion is normal (Baer and Biem; Underhill, 1910). The restoration of the blood-volume after injection of saline solution is delayed (Roger, Underhill and Mendel, 1916).

The vascular reactions of the kidneys in dogs are practically unaffected by the tartrate nephritis. The diuretic response to caffeine is somewhat diminished (Karsner, 1917).

Diet on Nephritis.—With rabbits, but not with cats, the diet has a marked influence on the resistance to tartrates. The toxicity is highest when rabbits are fed with salt, hay or cabbage; considerable protection is conferred by food rich in sugar, especially by young carrots. The factors that might be involved have not been differentiated (Salant and Swanson, 1918).
Habituation.—Continuous administration of tartrates to rabbits somewhat increases the tolerance, whilst citrates and oxalates lead to cumulative (Salant and Swanson, 1918).

PREPARATIONS—TARTRATES

Adulam Tartaricum (Acid. Tart.), U.S.P., B.P., C₄H₆(OH)₂(COOH)₂.—A dibasic organic acid obtained from wine lees or argl. Colorless crystals or white powder of acid taste. Very sol. in water (1:100); freely sol. in alc. (1:3-5). Dose, 0.5 Gm., 8 grs., U.S.P.; 0.3 to 1.2 Gm., 5 to 20 grs., B.P.

*Potash Biotartr (Pot. Bitart.), U.S.P.; Pot. Tartar. Acid., B.P. (Cream of Tartar), K₂C₂H₄O₆.—White, somewhat gritty powder, of pleasant acid taste. Slightly sol. in water (1:1553); nearly insol. in alc. Dose, 2 Gm., 30 grs., U.S.P.; 1 to 4 Gm., 15 to 60 grs., B. P.; suspended in water.

Pot. Tart., B.P.; K₂C₂H₄O₆ + 3 ½ H₂O.—Freely sol. in water (1:17). Dose, 2 to 16 Gm., ½ to 4 drams, B.P.

*Pot. of Soda, Tart., U.S.P.; Soda of Pot. Tart., B.P. (Rochelle Salt; Soda Tartrates), KNaC₂H₄O₆ + 4H₂O.—White powder or colorless crystals of cooling saline taste. Very sol. in water (1:0.9); practically insol. in alc. Dose, 10 Gm., 25 drams, U.S.P.; 8 to 16 Gm., 2 to 4 drams, B.P.

MAGNESIUM COMPOUNDS

General Statement.—The salts of magnesium are relatively little absorbed, and therefore act as osmotic cathartics. With magnesium sulphate, both ions have this effect, so that the salt is particularly effective. Magnesium oxide and carbonate act also as alkalies. Being very sparingly soluble, their antacid action extends into the intestines, but with little interference with the stomach. They are converted in the alimentary tract into the soluble and therefore cathartic magnesium bicarbonate. MgO (magnesia) is preferred to the usual alkaline carbonates when the stomach must not be burdened with CO₂ gas. It is therefore the best antidote against poisoning by acids.

A saturated solution of magnesium sulphate is used, apparently with good results, as a local dressing in erysipelas and similar inflammations. Its actual benefits, however, are doubtful.

Administration as Cathartic.—Magnesium sulphate is employed as laxative in doses of 2 to 10 Gm., 1 to 2 ½, in dilute solution; and as hydrogogue cathartic in doses of 10 to 15 Gm., 2 to 4 ½, in concentrated solution. The dilute solution may be mixed with NaHCO₃, but not with Na₂CO₃. It may also be given as an effervescent salt. Solution of Magnesium Citrate is a pleasantly flavored and effervescence draught, dispensed in bottles containing 12 ounces. The dose is from ½ to 1 bottle. Magnesium carbonate and the oxide are administered as powder, ¼ to 2 Gm.,
5 to 30 gr. “Milk of Magnesia” (Magna Magnesia) is a suspension of magnesium hydroxid, used as a laxative in doses of 1 to 4 teaspoons; and as an alkaline dentifrice.

Cathartic Action.—Magnesium salts are converted into the acid carbonate in the small intestine, according to the formula:

\[ \text{MgSO}_4 + 2 \text{NaHCO}_3 = \text{Mg(HCO}_3\text{)}_2 + \text{Na}_2\text{SO}_4 \]

In this respect it is quite immaterial what particular salt be given. The hydride, carbonate, chlorid, or sulphate are all converted into bicarbonate. However, in the case of the sulphate, the sodium sulphate which is formed is, of course, also cathartic, so that the effect is doubly large. The hydride and carbonate, on the other hand, possess also the action of alkalies.

Direct Action on Peristalsis.—This is not seen when magnesium is given by mouth, but only when it is applied by vein or hypodermically. Its direct action then is to depress the excessive peristalsis induced by exposure of the intestines, or by ergot, phystigmine or barium chlorid (Meltzer and Auer, 1906).

Meltzer, 1914, believed that magnesium also inhibits the intestine with the ordinary intestinal administration; and that this somehow renders the contractions more effective by leaving freer scope to the “contrary innervation.”

Normal Occurrence of Magnesium.—Magnesium occurs in the body mainly as phosphatid and in association with calcium, in the bones, and in larger absolute quantity in the other tissues. The red corpuscles (Abderhalden, 1898) and striped muscle (Kats, 1896; Hertig, 1902) contain more Mg than Ca. The daily requirement is estimated as 0.6 Gm. The ordinary diet contains 0.10 to 1.2 Gm. (H. C. Sherman, Metter and Sinclair, 1910).

Cows, during lactation, lose considerable Mg. Ca and P, even on a liberal diet. The Mg and Ca loss can not be corrected by the addition of these elements to the feed (Forbes et al, 1917).

Absorption.—This occurs mainly from the small intestines. Metallic magnesium is also absorbed from the subcutaneous tissue (Fromherz, 1909).

Excretion.—After absorption, and with parenteral administration, the excretion occurs practically exclusively by the kidneys (Meltzer and Lucas, 1907), only in small part from the large intestine. The toxicity is therefore diminished by inducing diurese (Meltzer, 1907). A considerable quantity may be retained in the body over two weeks. The urinary excretion of calcium is increased (Mendel and Benedict, 1906). This lessens the lime-deposition in young animals (Malcolm, 1903). The normal human urine contains 0.2 to 0.3 Gm. of Mg per day (Nelson and Burns, 1916).

(M. Jacoby claims that in the human subject after parenteral injection of large doses of magnesium against tetanus, the greater part is excreted by the intestines, although its concentration in the urine exceeds that of calcium.)

The administration of hydrochloric acid increases the urinary excretion of magnesium, and still more that of calcium (Stehe, 1917; Givens and Mendel, 1917). The total balance of Mg, Ca, or N, however, is not materially altered (Givens, 1918).

The intake of food-magnesium is also excreted mainly by the urine (Forbes et al, 1910). Effects on Other Urine Ions.—The injection of magnesium chlorid causes a marked rise of urinary acidity; the phosphatide excretion is only slightly increased (C. May, 1917).

Renal Irritation.—The intramascular or intravenous injection of magnesium salts or sulphates into dogs causes the appearance of kynina 1820 in the urine. There are no other casts, albumen or other sign of nephritis (Gates and Meltzer, 1914). The excretion also occurs when toxic doses of magnesium are injected into the ligated small intestine (Gates, 1914).

Glycosuria.—Parenteral injections produce moderate hyperglycemia and glycosuria. Underhill and Clossom ascribed these to asphyxia; E. Hirsch, 1913, to narcosis and asphyxia; but Kleiner and Meltzer, 1916, find them even with artificial respiration. On the other hand, Airila and Bardi, 1915, state that intravenous injection of magnesium inhibit epinephrin glycosuria and clinical diabetes; presumably by depression of the sympathetic system.

Toxicity by Mouth.—Only the nitrate, which is absorbed much more readily, is apt to produce typical Mg symptoms (Meltzer, 1907); but toxic effects may arise if large doses of the sulphate are given.

Intestinal injection with the stomach tied off produces death by respiratory paralysis in about twenty-five minutes with a dose of 10 c.c. of 20 per cent. magnesium chlorid. When administered to rabbits by mouth, even very large doses are not fatal (Auer and Meltzer, 1914).
CATHARTIC SALTS

Intravascular Injection.—This produces immediate and severe, often fatal depression of the heart and central nervous system. It resembles potassium, but this acts more on the heart, magnesium on the respiration. The effects are seen in blood-pressure experiments, if the magnesium sulphate solution of the manometer inadvertently enters the artery. There is a sharp fall of blood pressure, and the heart may be arrested promptly. If the effect is not fatal, recovery occurs quickly, since the excretion is quite rapid.

Cardiac Effects.—These consist in slowing with moderate dilatation; then incoordinata; then sudden dilatation and standstill. The heart may be kept beating by electric stimulation, by stimulation of the accelerators, and by epinephrin (Matthews and Brooks, 1910).

Respiration.—The cessation is due mainly to the curare action, the center being ordinarily not paralyzed except with considerably larger doses (Matthews and Brooks, 1907).

Temperature.—In rabbits, this is lowered by magnesium injection, parallel to the paralytic action, but preceding the latter. It is an independent phenomenon, for it occurs also if the narcosis is prevented by calcium (Schnettler, 1915, 1916).

Magnesium Anesthesia.—Meltzer and Auer (1905) found that a general anesthesia, with abolition of reflexes, may be produced by the subcutaneous injection of magnesium salts (0.5 Gm. of crystalline magnesium sulphate per kilogram of body-weight, used as 15 per cent. solution). The injection causes but little pain, since the magnesium is also a local anesthetic. The anesthesia is complete in half an hour or an hour, and last about two hours. The blood pressure is but little lowered; there is some diuresis, but no diarrhoea. The recovery is perfect. Somewhat larger doses are fatal, paralyzing the respiration before the heart. The effective dose approaches the fatal so closely that this method is not generally advisable for man.

Nature of the Anesthetic Action.—There has been considerable discussion whether the effects of magnesium consist in a true abolition of sensation (Meltzer); or whether they consist mainly in a paralyzation of muscular response by the curare action (Guthrie), and a asphyxia. There is no doubt that the muscular and possibly the asphybital factors may play a part; but that magnesium produces direct sensory paralysis, both central and peripheral.

Evidence for Sensory Paralysis.—Guthrie and Ryan, 1910, and Matthews and Brooks, 1910, brought evidence that paralysis may occur by the curare and asphybital action of magnesium, when the sensation is still preserved. However, Meltzer and Auer claim that, with proper dosage, it is possible to secure anesthesia when the asphybital factor is entirely excluded and the muscles are still responsive. Indubitable proof of direct central anesthesia is furnished by the results of careful intravenous injection in human subjects, reported by Peck and Meltzer, 1916. This produced unconsciousness and complete surgical anesthesia, with incomplete motor paralysis.

The immediate revival of the animals by the intravenous injection of calcium chloride (Meltzer, 1900) also speaks for a direct central action. Further, they find (1915) that small intracerebral injections produce central anesthesia (also V. E. Henderson, 1900); and that the effects of magnesium and ether are additive. Gensler, 1915, and V. Inoue, 1915, also find additive effects with the aliphatic hypnotics.

Mansfeld and Hamburger, 1915, conclude that magnesium increases the anesthetic action of urethane by altering its distribution; for calcium does not remove the summation if the magnesium has been administered with the urethane; but does remove the narcosis if the magnesium was injected some time after the urethane.

Distribution of Magnesium.—Mansfeld and Bonnay, 1915 and Gensler, 1915, find that the magnesium and calcium of the brain substance are not changed during the narcotics or calcium recovery, and therefore conclude that the altered Mg-Ca ratio acts on the plasma membrane. Strong, 1912, also found that the Mg content of the plasma increased, and the Ca diminished, during the narcosis; while the organs were unchanged. The urinary excretion of both Mg and Ca was increased. J. Schütz, 1915, reports accumulation of magnesium in the brains of rabbits subjected to repeated magnesium narcotics.

Deglutition.—Graded doses paralyze the central mechanism before the peripheral (Auer and Meltzer, 1916).

Local Anesthesia.—The effects of direct application of magnesium solutions to exposed nerve are described rather differently. Meltzer and Auer, 1906, maintain that concentrated solutions paralyze without previous stimulation, having a selective action on the different functional fibers somewhat analogous to cocain. Liljestrand, 1900, and Guthrie and Ryan, 1910, claim that the paralysis is preceded by stimulation and that the Mg action is not specific, but very similar that to of NaCl, while Ca salts are much more effective. However, Wik, 1911, found that the hypodermic injection of 15 to
25 per cent. MgSO₄ into quinea pigs produces much more local anesthesia than equivalent solutions of other salts. It seems therefore that the local anesthetic action of magnesium is relatively, if not absolutely, specific.

**Curare Action.**—This was discovered by Jolyet and Cahours, 1890; and has been confirmed by Guthrie, Meltzer, and others. Meltzer and Auer, 1909, also find that, like curare, it antagonizes the phystostigmin twitchings. Further antagonisms to physostigmin were studied by Joseph, 1909. Isolated *bronchial muscle* is slightly diluted (Trendelenburg, 1912).

**Rigor Mortis.**—Meltzer and Auer, 1908, found that the hypodermic injection of calcium hastens, and magnesium delays the development of rigor in skeletal muscles and heart. In calcium rigor, the extensor muscles prevail; in magnesium, either the flexors, or the position at the time of death.

**Subcutaneous Injection of Magnesium.**—The hypodermic use of magnesium being to date not generally recommended, Meltzer and Auer, 1909, introduced and in a single injection, using 1 c.c. of the 25 per cent. solution. This produces sensory and motor paralysis of the legs and pelvic region, occurring in three to four hours, and lasting eight to twenty-four hours. There is also retention of urine for one or two days. *Inward results* are cited in Merck's Report, 26:156.

**Magnesium in Tetanus.**—This has been found highly useful, at least symptomatically and in conjunction with antitoxin. Kocher considers it the best remedy in developed cases. The spasms are temporarily relieved, but return, requiring repeated (at least daily) injections. The dosage presents serious difficulty; the dose that paralyzes the respiratory center being but little above dose required for the therapeutic effect.

**Lazarus also reports success in strychnin poisoning.**

**Administration in Tetanus.**—The doses refer to crystalline Magnesium sulphate (Kocher, 1915; Meltzer, 1916).

**For slight initial symptoms, hypodermic injections may be used, 1.2 c.c. of a 25 per cent. solution, per kilogram body weight, 3 to 5 times daily. This has been continued for 6 to 12 days without damage. It causes but little irritation. It is safe, but not sufficiently effective for severe cases. In these, the salt may be used intramuscularly, 0.6 c.c. of 25 per cent. per kilogram; six times daily.**

**In severe cases, however, it is better to proceed at once to the more effective intrathecal injection; using 1 c.c. of 25 per cent. per 20 lb. of body weight (0.1 c.c. of 25 per cent. per kilogram), by lumbar injection. This gives prompt relief, generally lasting 24 hours, when the procedure may be repeated. If the respiration should become depressed, the solution should be washed out of the canal.**

**Intravenous Injections has also been used. It is not generally advised, the effects being short and dangerous, but it may be justified when the spasms threaten the respiration. Strabismus injects in 2 minutes a total of 100 c.c. of 2.5 per cent. solution; repeated every half hour to hour. Meltzer prefers a 0.6 per cent. solution, injected at the rate of 2 to 3 c.c. per minute, stopping as soon as the respiration becomes depressed. If the respiration does not improve 2.5 per cent. calcium chlorid must be injected slowly.**

The relaxation of the tetanus is not a complete curare action; for the respiratory movements continue with proper doses (Auer and Meltzer, 1910).

**Acidiotes.**—When using effective doses of magnesium, the physician should be prepared to combat failure of respiration, by artificial respiration, together with physostigmin (1:1 to 1 mg. hypodermically) or calcium chlorid (50 c.c. of 2 per cent., intramuscular; or 0.02 c.c. per cent. in normal saline, intravenous, to 500 c.c.).

In children extra caution must be used. The doses of magnesium should generally be somewhat smaller, supplementing them if necessary by ether or the alkaline hypnotics. Morphin potentiates the respiratory depression, and should therefore not be combined with magnesium (Isselkute, 1915).

**Literature.**—Cohen, 1912; Dodds, 1912; Arnd, Dryfus, 1914; Th. Kocher, 1915; H. E. Rutherford, 1915; Meltzer, 1916.

**Chorea.**—K. Schroeder, 1916, recommends the hypodermic injection of 20 per cent. magnesium sulphate, increasing slowly from 0.5 to 3 and even 5 gm. of the salt per day.

**Arteriosclerosis.**—Magnesium sulphate and magnesium chlorid.—This was mentioned by Meltzer and Auer. **Oxalates enhance the action of Mg, presumably by removing the antagonistic effect of the tissue-Calcium (Gates and Meta, 1913).** On the other hand, small doses of Mg produce a toxicity of oxalate, by diminishing the over-stimulation (Gates and Meltzer, 1913, 1917).
CATHARTIC SALTS

Magnesium Against Erysipelas and Other Inflammations.—This was introduced by H. Tucker, 1907 and 1908. He claimed that the local application subdued the inflammation, the pain, swelling and temperature, in cellulitis, arthritis, epididymitis, etc.; and suggested its use particularly for facial erysipelas. It has also been used successfully by others. Its action may be similar to the antiphlogistic effect of Ca; but it probably acts merely by its water-content, i.e., like any evaporating lotion.

Application.—A thick compress (15 layers of gauze) is immersed in a saturated solution of MgSO₄, applied to the inflamed region, covered with oiled silk, and renewed every two hours (Choksy, 1912).

Meltzer, 1910, describes a beneficial effect of 25 per cent. magnesium sulphate on experimental burns, but demonstrable only within a narrow range of injury. Sollmann has been unable to obtain this effect.

Ineffectiveness in Cancer.—Inai, 1919, failed to confirm any effect on experimental tumors.

Phagocytosis.—Delbet and Karajanopoulos, 1915, claim that the intravenous injection of magnesium chloride (dogs, about 15 c.c. of 1:25 per cent. anhydrous, per kilogram) greatly increases phagocytosis. It does not inhibit the migration of leucocytes from the inflamed mesentery of frogs (Keda, 1916).

PREPARATIONS—MAGNESIUM

*Magnesii Carbonas (Mag. Carb.), U.S.P., B.P.—A mixture of hydrated magnesia carbonate and hydroxid. According to its preparation, it occurs as a more or less bulky powder (Mag. Carb. Less and Ponderosa), or as white, friable masses, of slightly earthy taste. Practically insol. in water. Dose, 3 Gm., 45 Gm., U.S.P.; 0.3 to 1.2 Gm., 2 to 20 Gm., repeated; single, 2 to 4 Gm., 5 to 1 dram, B.P.

*Liquor Magnesii Citratus (Liq. Mag. Cit.), U.S.P.—An effervescent solution containing 25 per cent. of a mixture of neutral and acid magnesium citrate; prepared in bottles of 350 to 1,200 ounces, which may be taken as a single dose or divided.

*Magnesii Carbonas (Mag. Mag.), U.S.P., P.C. (Milk of Magnesia)—A creamy, smooth suspension of the hydroxid, Mg(OH)₂. Dose, 10 c.c., 214 drams, U.S.P.

*Magnesii Oxiuim Dribendum (Mag. Oxid. Pond.), U.S.P.; Magnesia Ponderosa (Mag. Pond.), B.P. (Heavy Magnesia); MgO—White, very bulky, and very fine powder, without odor; earthy taste. Almost insol. in water; insol in alc. Dose, as Mag. Oxid. Pond.

*Magnesii Sulphas (Mag. Sulph.), U.S.P., B.P. (Epsom Salts), MgSO₄ + H₂O.—Small prismatic crystals, of cooling, saline and bitter taste. Very sol. in water (2:1.5); practically insol. in alc. It contains about 50 per cent. of water of crystallization. A saturated solution contains about 50 per cent. of the crystals, or 25 per cent. of the absolute MgSO₄. Dose, 15 Gm., 4 drams, U.S.P.; 2 to 6 Gm., 30 to 90 Gm., repeated; single, 8 to 16 Gm., 2 to 4 drams, B.P.

*Magn. Sulph. Eff., U.S.P., B.P.—per cent. Dose, 4 to 12 Gm., 1 to 3 drams, repeated; single, 16 to 32 Gm., 4 to 8 drams, B.P.

WATER

General Statement.—The direct application of water to semipermeable cells produces osmotic changes. If the semipermeability is imperfect or impaired, there results a leaching-out of salts, and with this, a disturbance of the ion-ratio. Instances of these deleterious actions are the water-lacking of blood; the swelling and water-rigor of muscle, etc. The surfaces which are normally exposed to contact with water are protected against these actions, either by their impermeability, as the skin and bladder; or
by the rapid passage of salts into the water, as in the alimentary tract. Even in these situations, however, the water causes more or less swelling, stimulation or irritation of the cells.

Water is, of course, an essential constituent of all protoplasma. It constitutes about two-thirds of the body-weight, 75 to 90 per cent. of the active tissues, 40 per cent. of bones. Since it is constantly lost to the body by the urine, lungs, perspiration and feces, this would lead to drying and concentration of the tissues; but before this reaches a demonstrable degree, the sensation of thirst prompts the replacement of the water. Any excess of water is promptly eliminated by the excretions, which are correspondingly increased and diluted. However, there is a temporary increase of the water content of the fluids and cells of the body; a removal of their salts; and alterations in the proportions of their ions. These changes tend to produce functional phenomena, characterized especially by increased secretions, and by changes in metabolism. The effects vary according to whether the quantity of water is normal or excessive; and according to the channel by which it is introduced.

Absorption from Alimentary Canal.—Water is rather slowly absorbed from the stomach, where it also delays the absorption of other substances. However, it passes rapidly into the duodenum, and is absorbed readily from the jejunum, small and large; and in these it favors the absorption of dissolved substances. In health, the absorption occurs mainly in the upper portions of the small intestine (v. Mering, 1893; Monti, 1891).

Absorption by the Skin.—Water is not appreciably absorbed through the normal skin. Bathing in cold water contracts the cutaneous vessels, and will in this way diminish the loss of water by perspiration; while hot water will increase the loss by favoring diaphoresis.

Digestion-and Absorption of Food.—The ingestion of water with meals has decidedly beneficial effects upon all the digestive functions, even when the quantity of water is quite large (a liter with each meal); provided that the food is thoroughly masticated. It aids the digestive action of the saliva; increases the flow of gastric juice, its pepsin and acidity, and thus presumably the flow of pancreatic juice. It secures better absorption of the food, thus leaving less material for the intestinal bacteria, decreasing their number and the putrefactive processes. The same beneficial effects are secured with distilled water, which has no detrimental effects even in prolonged fasting experiments (Hawk, 1914).

These effects are utilized in the treatment of certain dyspepsias. Water is often useful in nausea. It is also valuable as a diluent for irritable drugs. Excessive water consumption would probably be harmful in gastric atony.

The secretion of acid gastric juice is increased (Heidenhain, 1879; Pawlow; Foster and Lambert, 1908; Sawitsch and Zelloy, 1913; and others). Even 50 c.c. increases the acidity and peptic activity quite strongly. The degree of action is not influenced materially by the quantity, temperature, or by the presence of food (Bergheim, Rabours and Hawk, 1914).

The gastric stimulation does not occur in all cases. It is perhaps due to the washing of the hormone gastrin into the intestine (foy, 1918).

The flow of pancreatic juice and bile is also stimulated. The dilution would accelerate the action of the digestive enzymes. The diastatic efficiency of saliva is increased, the optimum being reached with 1:7 dilution (Bergheim and Hawk, 1913).

The discharge of the gastric contents is hastened (at least after a meal of meat, although not with potatoes; Hedbom and Cannon, 1909). The water does not actually mix with the gastric contents, but passes along a trough formed on the surface (Cohnheim).

The rate of discharge of water from the empty human stomach varies normally between 100 to 400 c.c. per minute. Older figures were higher, but misleading (Br
WATER

1908. The hunger contractions are allayed by drinking water (Carlson, 1903). Hawk and his pupils (Hove, Mattill, and Hattrim, 1911 and 1912; Batherwick and Hawk, 1924) found the feces reduced in weight and containing less nitrogen (both food and bacterial). The utilization of fats and carbohydrates is not affected (Batherwick and Hawk, 1924). Intestinal putrefaction (as judged by indican) was lessened (Sherwin and Hawk, 1912); the acidity of the feces was increased. The effects are distinct, although they are naturally not very great in healthy subjects (Spiegler, 1907).

Hydremia.—The drinking of a large quantity of water, produces a slight but definite hydremia, as shown by a slight decrease in the electric conductivity of the serum (T. M. Wilson, 1909).

Haldane and Priestly, 1916, attribute this to the passage of salts into the intestines. Blix, 1915, found that the administration of water to well-fed rabbits could increase the water-content of their blood by a maximum of 12 per cent. Fasting and withholding water diminished it, also by a maximum of 11 per cent. on the second day. After that, it remained constant. Sublimate nephritis also produced hydremia.

Water in Traumatic Shock and Hemorrhage.—The oral administration of plenty of fluid is advised, to keep up the volume of the blood (Cannon, 1919).

The Excretion of Water.—This occurs by the kidneys, lungs, skin, and intestine. The relative importance of these channels varies with conditions. If, for instance, the water is taken hot (so as to favor dilation of the cutaneous vessels), it will act as a diaphoretic. If the conditions are not favorable to diaphoresis, it will be excreted mainly by the kidneys. Excessive quantities of water may also be excreted by the intestine, if the conditions are favorable, and may thus lead to diarrhea.

The Diuretic Effect of Water.—When water is absorbed from the alimentary tract, the diuresis is prompt, strong, and certain so long as the kidneys are normal. Three to 5, and even 10 liters may be taken and absorbed in the day, in man, without altering the consistency of the feces. If a large quantity is ingested, a half to three-fourths may be excreted by the urine within forty-five to ninety minutes (Mattill and Hawk, 1911). The excretion may be forced above 10 liters per day, and continued for several weeks, apparently without deleterious effects to the kidneys or otherwise; this does not even create salt-hunger (Sollmann and Hoffmann, 1905). The diuretic action of moderate quantities of water can be greatly enhanced by the addition of other diuretics, but if very large quantities of water are given, the addition of diuretics has no further effect.

Haldane and Priestly, 1916, found no definite relation between the diuretic response to water, and hydremia, as judged by the hemoglobin concentration of the blood. Hypodermic and intravenous injection of water produce little or no diuresis. Hashimoto, 1924, attributes this to deficiency of salts, and not to the production of any diuretic substance in the alimentary canal, as was believed by Cow, 1914.

Composition of the Urine.—The urine in water-diuresis becomes very dilute, although the total or daily excretion of the dissolved constituents is generally increased. However, there is no simple relation between the increase of the different constituents, for instance N and Cl (Heinle, 1906).

Therapeutic Use of the Diuretic Effect.—This is especially useful for diluting the urine, to lessen its irritation in inflammations of the urinary passages; and to prevent the precipitation of its constituents in urinary calculus.

Diuresis for Removal of Poisons.—This has only a very limited efficiency. Very energetic diuresis, by water or by intravenous saline or glucose, is able to save animals from lightly superfatal doses of strychnin (Eggleston and Hatchet, 1917; Kleiner and Meltzer, 1917); but is quite inefficient against diphtheria toxin (Sansum, 1917).

Use in Fever.—Cushing (1905) found the administration of very large quantities of cold water (4 ounces every fifteen minutes while awake) of marked benefit in 1896.
typhoid fever. It serves to keep the mouth clean; it must have a distinct antipyretic effect; and it may aid by eliminating toxins and waste products.

The water would act as an antipyretic, by its own temperature, and by facilitating perspiration and heat loss. If allowed to keep the mouth clean, Balcar et al., 1910, found that "salt-fever" can be prevented by giving plenty of water. The effect of water in fever has also been investigated by Schwenkenbecher and Inagaki, 1906.

**Metabolism.**—Increased ingestion of water flushes salts and metabolites from the tissues and tends to increase protein metabolism and oxidative changes.

*Increased Nitrogen Excretion.*—The administration of large quantities of water causes a considerable temporary increase in the urinary nitrogen, as much as 54 per cent. (Neumann, 1890). The excess is excreted mainly as urea; the uric acid being often unchanged. Fairhall and Hawk, 1912, found the uric acid output in man decreased, while the allantoin was increased. The excretion of the phosphates and sulphates is also increased. The removal of chlorides is so extensive that their percentage in the urine soon falls to a very low figure.

*Other Urinary Constituents.*—Wilson and Hawk, 1914, report that the ingestion of additional water, moderate or abundant, causes a temporary decrease in the daily output of chlorides; presumably through the need of equalizing the osmotic pressure of the retained water. The ammonium is increased (presumably as a consequence of the heightened gastric acidity), the phosphate unchanged, the acidity variable.

*Increased Metabolism.*—The excessive excretion of metabolites is mainly due, beyond doubt, to the "flushing out" of the tissues by the diuresis (Haas, 1906). But if this were the only cause, the continued excessive administration of water would soon exhaust the stored waste products, and their excretion would fall rather below the normal figure. Actual results show that this holds for the chlorides, but not for N, P or S; this excretion remains permanently increased, although it does not remain at the original high figure (T. Dahl, 1909). There must therefore be an increased production of these metabolites.

**Metabolism in Animals.**—This conclusion is supported by the results on animals, although there is somewhat of a difference from those obtained on man. Equilibrium do not show any permanent changes in their nitrogen excretion when four times the normal quantity of water is administered, notwithstanding the increased diuresis. In starving dogs, however, it may be increased by 50 per cent. The explanation of these discordant results is probably that the removal of the water by diuresis keeps step with the absorption in the feed animals; so that it never comes to any considerable increase in the water content of the body, and the metabolism is therefore not increased.

*Nitrogen Retention in Nephritis.*—The increased N elimination following liberal water administration lowers the abnormally high N figures of the blood. However, to reduce these to the normal level, it is necessary to employ both water administration and limitation of N intake (N. B. Foster and Davies, 1916).

*"Alternative Effect" and Use in Obesity.*—Water, especially in the form of mineral waters, is employed for its metabolic effects in a variety of obscure conditions, particularly in obesity, but the results are uncertain. It is difficult to predict whether the breaking down of protein molecules will increase or diminish the body fat. If it is only partial, it may result in the formation of fat from the proteins; if carried further, it may lead to the destruction of fat as well.

**Local Actions.**—Water is mildly stimulant and irritant to sensitive surfaces. The growth of artificial cultures of frog's tissues is hastened by diluting the serum of the culture fluid (Ruth, 1913).

The effects of baths and similar hydrotherapeutic measures depend upon reactions due to the physical action of temperature, etc.

**Distilled Water.**—This is more injurious than ordinary water to the lower animals and to excised tissues; partly because of the total absence of salts (especially of calcium, thus probably altering the permeability of the plasmic membranes; R. H. True, 1914); and partly because it often contains traces of copper and ammonium compounds. This toxic action can not occur by the drinking of distilled water by higher animals, which obtain their salts from food rather than from water: The salts of the food would in all ordinary cases be more than sufficient to cover the deficiency
of salts in the water. The statements, which are occasionally made, that the drinking of distilled water leads to toxic effects, are therefore entirely groundless: Distilled water is often drunk exclusively on ships, without any bad results. Nor is distilled water detrimental in nephritis (Marcus, 1907).

**Effects of Water by Intravenous Injection.**—The immediate effects of small amounts, slowly introduced (and especially of hypodermic injections) bear a general resemblance to those following the injection of isotonic salt solutions. The changes in metabolism and urine are probably similar to those which occur on taking water by mouth. Larger doses and rapid injection introduce important modifications. Hemoglobin appears in the urine, from the laking of the blood corpuscles. The respiration is slowed and the blood pressure is lowered. The central nervous system shows rather late paralysis and convulsions. The diuresis is quite small, since the hypostolic condition of the blood slows the renal circulation by the swelling of the kidney cells. The excretion of water occurs mainly by other channels, so that there is usually a serious diarrhea, increased salivation, etc. The fatal dose of water (by intravenous injection) is somewhat smaller than that of normal saline solution; distilled water is again somewhat more toxic than well water.

**The Withholding of Water.**—This affects the metabolism in much the same way as the administration of salts in hyperstolic solution: The excretion of metabolites is at first lowered, by the lessened diuresis; but as the destruction of proteins is at the same time increased, the excretion of metabolites is also increased after a time. When water is given, the stored metabolites are washed out, leading to a very greatly increased excretion (Landauer, 1853; Straub, 1894; Spiegler, 1901).

**Thirst.**—This is a very delicate reaction to concentration of the tissues. Cannon, 1910 conceives the mechanism as drying of the mucosa of the mouth and pharynx, attributable to diminished output of saliva; this in turn, being conditioned on the limitation of water in the system. However, further investigation is needed.

**PREPARATIONS—WATER**

*Agua, U.S.P.*—The purest natural potable water obtainable.

*Agua Distillata (Ag. Dest.), U.S.P., B.P.; Distilled water.*

*Agua Distillata Sterilata (Ag. Dest. Steril.), U.S.P.—Sterilized Distilled Water for injections should, if possible, he used within forty-eight hours after its preparation; for old distilled water is seriously contaminated with bacterial products.

**MINERAL WATERS**

These will be discussed more in detail in other places, according to their ingredients, but the whole subject may be very briefly summarized in the following compilation: The action of natural mineral waters has been known empirically since remote times. Their use came about probably by accidental observation and also through the marked taste which they possess.

**Spring and Artificial Mineral Waters.**—A very striking observation was early made, namely, that these mineral waters, when used at their source, appear to be more effectual than artificial compounds of practically the same composition, or even than the same water when used at a distance. The most diverse explanations for this have been advanced. Especially in the case of thermal waters, so-called thermal forces, some mysterious property imparted to them by the earth, have been invoked. Since the discovery of radium, it has been found that some mineral waters are slightly radioactive, and this has been used to explain their action. Others, again, have laid great stress upon the presence of minimal traces of rare elements, somewhat upon the homoeopathic principle. Still others believe that the artificial waters—even if they contain the same elements in the same proportion—do not contain them in the same state of combination; for instance, that the artificial water would contain NaCl and MgSO₄, the natural water MgCl₂ and Na₂SO₄. This is, of course, contrary to the demonstrated facts; all solutions containing the same proportions of the same ions, will give these ions present in the same state of combination, no matter what particular salts were used to introduce these ions. There is nothing in any of these theories. Mineral waters are simply solutions of the ingredients of the soil, and possess only the action of those ingredients which are present in notable amount.
The difference between the water of natural sources and the artificial solutions rests upon other causes, which are sufficiently easy to appreciate, but difficult to reproduce. These factors refer largely to hygiene and climate. A large proportion of the effects must be attributed to the rest, the freedom from care and business pursuits, the exhilarating effect of improved hygiene; atmospheric, and scenic conditions, better regulation of all the habits, of diet, exercise, etc. The mere drinking of large quantities of fluid is also something which it is difficult to enforce at home, but which the patient does regularly in watering-places. Added to these comes finally the specific action of the dissolved salts.

The effect of mineral baths is purely local and reflex. There is practically no absorption of the dissolved salts through the skin. The effects are in general the same as with hydrotherapy, excepting that they are somewhat stronger.

The waters of mineral springs vary in temperature; those below 25°C. are called cold; 25 to 37.5°C. warm; above this, hot.

The molecular concentration of mineral waters varies considerably; the depression of freezing-point is 1.0130 for Hunyadi and Apenta; 0.970 for Vichy; 0.975 for Carlsbad; 0.840 for Apollinaris, etc. (Kostkiewicz, 1190).

Classification.—These waters are usually classified according to the contained salts. Various classifications are current. The following will be used here:

1. Plain Saline (NaCl).
   (a) Plain.
2. Carbonated: (b) Alkaline (NaHCO₃).
   (c) Saline (Na₂SO₄).
3. Magnesia.
4. Sulphur.
5. Chalybeate.

Occasional constituents of small importance are Ca, I, Br, Li, and As. The physiologic effects of the majority of these constituents will be discussed under their respective headings, and will only be very briefly alluded to in this place. It will also be impossible to take up the composition and special indications of the different mineral waters in any exhaustive manner. It will be necessary to illustrate these classes on only a few well-known waters. It need scarcely be mentioned that the above classification is not an absolutely sharp one, but that many mineral waters belong rather to several classes.

The composition of American Mineral Waters may be ascertained from the publications of the U. S. Bureau of Chemistry.

1. Plain Saline Waters.—These are used mainly externally for baths. The most typical is sea-water (see Index).

Artificial sea-baths may be made by dissolving a percent of sea or rock salt in water. Some of the important saline sources are the following:

European:

<table>
<thead>
<tr>
<th></th>
<th>Per 1,000:</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Fixed salts NaCl Temperature (°C)</td>
</tr>
<tr>
<td>Kissingen</td>
<td>15 11 18.5</td>
</tr>
<tr>
<td>Baden-Baden</td>
<td>28 21 18.5</td>
</tr>
<tr>
<td>Naumburg</td>
<td>30 25 33.5</td>
</tr>
</tbody>
</table>

2. Carbonated Waters.—(a) Plain.—In these the CO₂ is the main constituent. The aid digestion, and these waters are used mainly as plain table waters. The most used is the artificial soda-water.

An example of a natural carbonated water is Apollinaris:

<table>
<thead>
<tr>
<th>Per 1,000 Gm.</th>
<th>NaCHO₃</th>
<th>NaCl</th>
<th>Na₂SO₄</th>
<th>CO₂</th>
<th>Temp.</th>
</tr>
</thead>
</table>
| (b) Alkaline.—These contain a notable amount of NaHCO₃. They have the alkaline effects and are therefore useful in gastric catarrh, hyperacidity, hypescreeton of mcn, and as diuretics, in obesity, gout, urate stones, and diabetes. They are most useful when taken hot and drunk very slowly, since in this way they cause the least irritation in the stomach.

1 Formula for Artificial Kissingen (N. P.):

<table>
<thead>
<tr>
<th>Potassium Chloride</th>
<th>Sodium Chlorate</th>
<th>Magnesium Sulphate</th>
<th>Sodium Bicarbonate</th>
</tr>
</thead>
<tbody>
<tr>
<td>17</td>
<td>237</td>
<td>52</td>
<td>77</td>
</tr>
</tbody>
</table>

Twenty-four grains of this to 6 ounces of water (3/4 teaspoon to a tumbler) is the usual dose.
(c) Alkaline Saline Waters.—These waters usually contain in addition some Na₂SO₄. The indications for use are the same as for the preceding. The cold waters contain more CO₂ (Marienbad and Franzenbad). The hot alkaline waters are very numerous. The following may be taken as examples:

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

Hunyadi János

Sedlitzia 13.5 1.4

Epsom and Friedrichshall belong to the same class.

American: Crab Orchard, Kentucky; and Bedford Springs, Pennsylvania.

4. Sulphur Waters.—These contain free H₂S and sulphides. Externally they stimulate the skin and soften the epidermis; internally they act as cathartics. They have considerable reputation in the treatment of chronic rheumatism. Some examples are: Aix-la-Chapelle, Harrogate, Virginia Sulphur Springs. The following will give an idea of their composition.

In 1,000 Gm.:

<table>
<thead>
<tr>
<th>Free H₂S</th>
<th>Na₂SO₄</th>
<th>NaCl</th>

</tr>
</tbody>
</table>

Aix-les-Bains

5. Chalybeate Waters.—These contain Fe, usually as bicarbonate, also NaCl and Na₂SO₄. The amount of iron is from 0.01 to 0.12 of FeO per liter. The most famous springs are: Tunbridge and Brighton in England; Pyrmont, Wiesbaden, and Spa on the Continent; Bedford, Pittsburg, Bradywine, and several Virginia springs, in the United States.

CLIMATE

This is of such great importance in the action of mineral waters that it may be discussed in this place. Only the roughest sketch can be given, and the student must refer to special text-books for further description.

The principal elements which enter into the climate are the following:

1. Purity.²
2. Density (Altitude).
3. Air: Moisture.
4. Temperature.
5. Special Constituents.⁸

¹ Formula for Artificial Vichy (S.P.):
² Purity: This refers especially to the absence of bacteria, but other fixed impurities may also be of importance; e.g., the causation of hay fever by pollen. In others, various chemical gases may also be deleterious impurities.
³ Of such special constituents, the aromatic oils given off by needle-trees may be of considerable value as antiseptic and stimulants in phthisis. The presence of oxides, if it is of any importance, serves mainly to indicate the general purity of the atmosphere.
2. Sunlight.
4. Conditions of Life—comfort, hygiene, rest, diversion, pleasant surroundings, out-of-door life, etc.

The subject of climatology is very largely empirical. The work which has been done on the effect of the different climates upon metabolism, nutrition, etc., is as yet too limited to be of great value.

The principal climates used in therapeutics are:

1. Sea.
2. Dry and Warm.
3. Elevated.

1. Sea Climate (Including Islands and Sea Voyage).—The important effects of this are on the circulatory temperature, humidity, and purity of the atmosphere, and to general surrounding conditions.

This climate, being very restful, is especially useful in cases of overwork. The freedom from smoke of Mediterranean shores also renders it valuable in hay fever and phthisis.

2. Dry and warm climate, such as in deserts and Egypt, southwestern Texas, inland Southern California, or in the pine sections of Georgia and the Carolinas.

The special advantage of this climate consists in its permitting outdoor life in winter. It is peculiarly valuable in lung disorders which do not stand a northern temperature.

3. Elevated Climates. These are generally arid, and the air is cool and dry. What importance can be given to the rarefraction of the atmosphere is not at present clear, still less the manner in which this acts.

The rate of the heart and respiration is at first increased, but later it returns to normal.

The quantity of urine is increased, as also the gaseous metabolism and respiratory quotient. The nitrogen excretion is diminished (Jacquet and Stähelin, 1902). The blood becomes rapidly more concentrated in corpuscles, and the serum in protein. The absolute amount of corpuscles and of hemoglobin is not, however, much increased at first, but very probably so later (Jacquet, 1904).

These climates cause improvement in a number of conditions, probably in part due to a greater exercise of the organs from climbing, etc. They are useful in dyspepsia, anemia, chlorosis, insomnia, asthma, and consumption.

High climates are unfavorable to feeble conditions of the heart and vessels, which cases should be sent to the seashore.

DIURETICS

Diuresis (increase of the quantity of urine) is produced by many substances acting by various mechanisms, and belonging to different groups. The whole subject is, however, be summarized in this place as a considerable proportion of the diuretics act at least in part, by salt action.

The details of the actions of diuretics will not be discussed in this summary. They may be found by referring to the individual drugs.

Diuretics may be divided into the following classes:
1. Acting through changes in the general circulation.
2. Acting purely by local, irritant stimulation of the kidney cells.
3. Acting by non-irritant stimulation of the kidney cells.

1. Diuretics Which Act by Influencing the General Circulation. The secretion of urine is roughly proportional to the glomerular blood pressure. This may be raised by increasing the work of the heart, as by Digitalis (which acts also by increasing the pulse wave, lessening venous congestion, and rendering the blood hydrenic). Vasomotor-tors generally act very powerfully on the renal arterioles, so that they tend to lower the glomerular pressure, notwithstanding the rise of general blood pressure. Vasodilatation also tend to lower the glomerular pressure. They are useful, however, when a vasocostriction is to be counteracted.

2. Diuretics Which Act by Influencing the General Circulation. Moderate irritation raises the glomerular pressure by dilating the renal arterioles. It is conceivable that it also stimulates the vital secretory activity of the cell. Excessive irritation, on the other hand, produces venous congestion, which hinders the filtration of urine by compressing the tubules. The cells are also injured as shown by the appearance of albuminuria; and their permeability is thereby lessened.
DIURETICS

Irritant diuretics are very numerous and only a few of the more important can be mentioned.

(a) Essential Oils.—Especially turpentine, juniper, cubeba, etc.
(b) Hydrocarbons.—Alcohol, ethyl carbamate, hexamethyleneamin, etc. These produce moderate irritation. (The diuretic action of beer is due mainly to the rapid ingestion of its water; at least, Raphanel (1804) failed to discover any difference in the daily excretion, whether a liter of water or of beer was taken.)
(c) Absorbable Metals.—Especially Calomel.
(d) Glucosides.—These are closely related to the aromatic series. Here belong: Ipecacuanha (Ipecacuanha). These owe their diuretic action to Scoparin. The alkaloid Spartalin (see Index) does not contribute to it. Asparagus tops seem to act similarly. They are given in 5 c.c. doses of the fluid extract.

Corn Silk, Triticum, Guaiac, etc., may be counted in this group.

Compositae, Aloe, etc., are too powerful for therapeutic use.

(c) Phosphates and Some Salts (notably Nitrates) are also mildly irritant.

3. Stimulant Diuretics.—This is the place generally assigned to caffeine and theobromin; part of their effect, however, is due to peripheral dilation of the renal arteries. No irritant action has been described for caffeine and theobromin even for large doses; but it has been noted with theobin.

4. Saline Diuretics.—Water, salts, sugars, urea, etc., act by lessening the viscosity of the blood, thereby increasing its filtrability and raising the glomerular pressure; by shrinking the renal cells; and by preventing the reabsorption of water from the tubules. Excised renal artery is markedly dilated by urea or sodium sulphate, while these have no effect on carotid artery (Cow, 1911). In addition, it is rather probable that they cause the stimulation of the vital activity of the kidney cells. This is most pronounced in the case of milk-sugar; urea; iodides; nitrates; alkalis; and acids. Water may be rendered more palatable by carbonic acid, or by giving it as lemonade, or as tea. These additions enhance its diuretic effect.

Normal Saline solution may be injected hypodermically or by rectum. Milk is a very efficient diuretic, acting partly by its water, partly by its sugar. Milk-sugar and Urea are given in doses of 10 to 30 Gm. Diluted Inorganic Acids (in the form of lemonade) are rather too irritant to the stomach and kidneys, and are to be used only if an acid action is distinctly indicated. Alkalies are quite effective; they also render the urine alkaline. Free alkalies and carbonates are not used, since they interfere with digestion. The effect is obtained from organic acids and their salts (especially the acetate or citrate of potassium), which are oxidized to carbonates in the body.

Water and carbonic acid are given as the potassium salts. The iodide acts too powerfully on other functions to be used as a pure diuretic. The reputation of lithium is unmerited.

The comparative diuretic effect of these drugs on normal man was investigated by Raphanel (1804), who placed himself on a uniform diet for prolonged periods. He consumed daily 1,780 c.c. of fluid; the quantity of urine on this diet amounted to 750 to 960 c.c. Under the influence of drugs, it was increased by the following percentage:

<table>
<thead>
<tr>
<th>Drug</th>
<th>Increase in Urine (in c.c.)</th>
</tr>
</thead>
<tbody>
<tr>
<td>1,000 c.c. water</td>
<td>100 per cent</td>
</tr>

<tr>
<td>0.5 Gm. Ol. Junip.</td>
<td>1,000 c.c. water—111</td>
</tr>
</tbody>
</table>

In disease, the results would probably not be quite the same. The choice of the diuretic must be determined by the condition of the kidneys, and by the object to be accomplished. (In dogs with vesical fistula, Ginsberg, 1912, found milk less effective than water.)

Combination of Diuretics.—A combination of several diuretics is often most effective; they are generally administered with plenty of water. Schloesser, 1913, found that the combination of caffeine and intravenous sodium sulphate gave a potentiated synergistic effect, while the combination of caffeine with theobromin or theophyllin gave only a simple addition of their action.
The indications for diuretics are as follows:

1. The removal of liquid from the body, in the various forms of dropsy. In this case it is well to employ them with as little fluid as possible.

2. To remove toxic substances from the organism, whether these have been introduced from without or formed within the body, a free supply of water, in the form of infusions, supported by the irritants, salts, or theobromin, fulfils the indication; or the hypodermic injection of large amounts of normal salt solution. Irritants must be avoided if the kidneys are inflamed, or if the poison is itself irritant.

3. To Dilute the Urine.—This may be useful (a) to render it less irritant to the urinary passages in nephritis or inflammation of the bladder or urethra; it also serves a useful purpose in frequently washing out the pus and bacteria.

(b) To prevent the formation of calculi, or to remove concretions formed in the urinary tubules (as in oxalate-poisoning).

(c) To dilute irritant poisons, whose action on the kidneys is proportional to their concentration.

For the dilution of the urine, water supported if necessary by theobromin is of the greatest service.

Nephritis contraindicates irritant diuretics, and such as will become poisonous if they are not excreted (potassium, digitalis, mercury).

SODIUM CHLORID

General Statement.—This constitutes the greater part of the electrolytes of the tissues (with certain exceptions), and especially of the fluids, of vertebrates. Its ions are essential for the functionation of most cells. Since the ions are constantly excreted, especially by the urine, they must be constantly replenished, leading to the instinctive use of salt in food. Its administration to mammals, even by intravenous injection, produces practically only osmotic effects; but marked ion-actions may be observed by exposing excised tissues to solutions with or without the sodium and chlorid ions.

The therapeutic uses of salt depend mainly on its osmotic effects. These result in stimulation of the gastric mucous membrane, leading to its use as condiment and in some indigestions; under suitable conditions, a laxative action; irritation of the skin, with attending reflex stimulation,
utilized as salt-water baths. After absorption, it leads to diuresis and slight metabolic changes. Isotonic solution is used as vehicle or for cleansing sensitive mucous membranes, e.g., the nose; and for hypodermic and intravenous injections. These saline infusions are employed in hemorrhages, shock, and for the dilution or removal of systemic poisons.

The intravenous injection of strongly hypotonic solutions is fatal, with stimulation and paralysis of the central nervous system.

Retention of chloride occurs in certain pathologic conditions, especially pneumonia and other fevers, nephritis, cancer, etc. Its mechanism is not explained. In favor of the formation of edemas, against which salt-poor diet is sometimes efficient.

**NaCl Incons.**—With ordinary diets, this ranges between 10 and 15 Gm. per day; but its reduction to 5 Gm., or even to 2 Gm., causes no disturbance. Carnivorous animals obtain a sufficient supply in their food. But since K predominates over Na in the salt of plants, herbivores and animals feeding on a mixed diet require additional NaCl. This need has led to the instruction use of this salt: in regions remote from deposits of this salt, ashes of plants which are rich in Na have been used by peoples as ignorant as the negroes of the interior of Africa. A table of the salt content of food is given by Levy, Arch. f. Verdi, Kranzh. 16:267.

**Distribution of NaCl in the Body.**—The most exact and comprehensive determinations are those of Wahlgren, 1909, and Putberg, 1919, on dogs. Similar relations probably hold for man and other animals: The entire body contains about 0.17 per cent., expressed as Cl (0.11 per cent., Rosenmann, 1912). Of this, about a third is in the skin; the remainder chiefly in the blood, muscles, bones and intestines. The highest percentage of Cl exists in the skin (0.38 per cent.); then the blood (0.31 per cent.); kidneys (0.76 per cent.); and lungs (0.24 per cent.). The brain, bones and intestines contain 0.17 to 0.18 per cent.; the liver, 0.13 per cent.; the muscles only 0.07 per cent. According to other determinations, blood serum contains 0.16 to 0.24 per cent. (equivalent to 0.9 to 1.1 per cent. NaCl); saliva, 0.16 to 0.24 per cent; Cl; the human intestinal juice 0.88 to 0.87 per cent. NaCl; sweat, 0.86 per cent. (Kovace); human gastric "appetite" juice 0.49 to 0.50 per cent Cl (Carlson, 1915). The red blood corpuscles contain 0.12 to 0.18 per cent. of Cl, and 0.21 to 0.28 per cent. of NaCl; except in some animals (horse, pig and rabbit), whose corpuscles contain practically no Na (see Potassium). The chloride content of the entire human body is estimated at 60 to 135 Gm., equivalent to 250 to 300 Gm. of NaCl (Magnus-Levy, 1906).

**Artificial Variations of Chlorid Content.**—Putberg studied the changes following the intravenous injection of NaCl. Here, also, the skin maintains the highest percentage; but because of their greater mass, the muscles and intestines take up the greater absolute amount. With Cl-poor food, the total Cl content sinks to 0.137 per cent., the loss being greatest from the skin. The skin therefore acts as a chloride depot, storing and giving off most of the excessive or deficient Cl. Rosenmann, 1917, found the entire Cl content increased by 300 per cent. when dogs were given highly salted food. With the return to normal diet, the Cl content returned to one and one-half times the ordinary level within five days; the further fall to normal occurred much more slowly.

Austin and Jonas, 1918, confirm that the chloride content of the blood is not materially and persistently altered even by prolonged diets of either high or low chloride content.

**Chlorid Content in Disease.**—Biermack, 1904, found the Cl of the blood constant in numerous diseases. Javal and Adler, 1906, determined the percentage of Cl and water in the organs after death from various diseases, with a special reference to edema; but the results were not decisive.

Levy, 1915, states that human organs in renal, cardiac and vascular disease may contain twice the skin even three times, the normal amount of Cl, without material increase of their fluid. Similar results were obtained on uranium rabbits. F. C. McLean, 1915, found the chloride of the plasma increased, clinically, in cardiac and renal disturbances, and in pneumonia; diminished in diabetes and with diuretics. The chloride and urea content of the plasma do not go parallel. In uremia, the diminution of blood-chlorid is concomitant with increased hydrogen ion concentration (McLean, 1916).

**Microscopic Distribution.**—A. B. Macallum, 1905 and 1908, found the chloride most abundant in the inactive tissues, especially in the intercellular spaces and in degenerating cells. It is absent from the nuclei (as also PO, and K, and probably all other inorganic ions); but it occurs abundantly in the cytoplasm. Nerve fibers are rich in Cl,
especially the axons; but the myelin sheaths are free from it, and nerve cells contain very little (Macalium and Menlen, 1906).

**Excretion of Chloride.**—This occurs mainly by the urine, chiefly as KCl; only a small part being lost by the feces and perspiration. The excretion varies with the titration of the salt in the diet, the general salt intake being somewhat behind in time. The administration of salt therefore produces a temporary accumulation in the tissues. With a steady income of salt and water, equilibrium is reached, in normal man, in three or four days (Borelli and Girardi, 1912). If the supply of salt is stopped, the excretion falls to a very low level within three days, the tissues retaining their normal salt content with very great avidity. A small excretion (0.6 to 0.9 Gm. daily in man) continues, however, so that the tissues finally lose salt. This leads to the phenomena of "salt-hunger."

**Feces.**—The fecal chloride excretion is normally insignificant, but in nephritis it may reach 3 to 5 Gm. NaCl per day (Javal, 1903; Halpern, 1905).

**Diurnal Variations.**—In man, the urinary chloride excretion is always greater in the forearm than in the night, independently of meals. The midday meal has an influence, the excretion being decreased half an hour after eating, due to the gastric excretion of HCl. This lasts an hour, and is followed by marked increase (Herrmannsdorfer, 1914).

**Time of Excretion.**—Giving 20 Gm. by mouth, the additional chloride should be excreted within twenty-four to forty-eight hours, either by diuresis, or by increased salt concentration. A longer delay indicates impaired permeability of the kidney. Schlayter and Takayasu, 1915, consider the salt and iodide excretion as an index of tubular activity; whereas water and lactose excretion indicate the renal vascular function. This classification is based on rather ill-established assumptions.

**Influence of Other Salts and Diuretics.**—The excretion of Cl can be hastened by the administration of related salts (bromides, iodides, nitrates, sulphocyanides). Conversely, the administration of Cl hastens the elimination of these salts, and may be useful against iodium and bromism. Diuretics have little effect; the drinking of large quantities of water reduces the percentage of Cl in the urine; the absolute quantity may be unchanged or moderately increased (Kulun and Hawk, 1911). With dogs, theophyllin and caffeine diminish the Cl, both absolute and percentage, independently of any diuretic effect (Saxone, 1911). In rabbits, however, these and other diuretics tend to increase the Cl excretion proportional to the diuresis (Boismoun and Imbert, 1912).

**Chlorid Retention.**—The chloride excretion is greatly diminished in some cases of nephritis; in fevers, particularly in pneumonia (where much salt is retained in the effusion); and during the rapid development of new tissue (cancer).

**Retention in Fever.**—This was first described by Redtenbacher, 1850, and has been extensively investigated, especially by Roehmann, 1880. The low Cl excretion is partly due to the low Cl income; but even when this is taken into account, there is considerable deficit in the output, i.e., a true retention (Garratt, 1904). This is especially marked in pneumonia; and the Cl in the exudate is not sufficient to account for the difference. The retained Cl seems to be distributed indiscriminately through all tissues. The Na and Ca are also retained, while K and Mg are excreted normally or in excess (Peabody, 1913). Mediguecoureau, 1911, found a comparatively slight Cl retention in turpentine pleurisy, and none in pneumococcic septicaemia in rabbits. This indicates that the retention is connected with the pulmonary changes. Snapper, 1913, attributes the retention to altered cell permeability; for he claims that the addition of sodium sulphate to blood causes the passage of NaCl into the corpuscles in fever; whereas normally it causes the passage of Cl out of the corpuscles. The whole subject is still very obscure.

McLean, 1915, finds that the diminished excretion in pneumonia is associated with lowered Cl content of the plasma. At the crisis, the Cl increases both in the plasma and in the urine.

**Retention in Cancer.**—The diminished excretion is probably explainable entirely by the deficient Cl intake, and its need for the formation of new tissues and transudate (Gaertig, 1850; Lautenheimer, 1892).

**Retention in Nephritis.**—This was mentioned in connection with edema. It is not apt to occur in acute glomerular nephritis (Borchardt, 1912). However, in chronic
nephritis the ability to excrete chlorid is generally impaired before the nitrogen excretion (O’Hare, 1916).

The Cl excretion is increased in the early diuretic stage of uraemia and cyanidraic nephritis; it is usually diminished with large doses of uranium or chromate. The Cl excretion bears no simple relation to the anatomic changes (Austin and Eisenbrey, 1912).

Salt Test for Nephritis.—Schlager, 1911, keeps the patient on a constant diet for several days, then adds 10 Gm. of NaCl in one dose. This excess is normally excreted within twenty-four or at most forty-eight hours. A delay beyond this indicates diminished permeability of the kidneys to chlorids. Frothingham, 1915, classifies the excess excretion, within forty-eight hours, of 8.5 Gm. as no retention; 9.5 Gm. as slight retention; less than 4.5 Gm. as considerable retention. Hedinger and Schäfer, 1912, 1913, now employ a ‘nephritic test meal.’ A strictly similar test may be made with urea, 10 Gm. of which should also be excreted within forty-eight hours (Monakov, 1914).

In pancreatic-necrotic dogs, Lebosohn found the chlorid metabolism quite normal, but Rubens, 1915, claimed that such dogs excrete only 1/3 to 1/4 of the chlorid of normal dogs on the same diet.

Beard and Rowntree, 1917, report that diabetic patients when permitted, often consume large quantities of sodium chlorid with their diet, and develop retention-edema. They are also subject to ‘salt edema’ from sodium bicarbonate administration.

Mechanism of Chlorid Regulation.—The blood maintains its chlorid concentration remarkably constant, and even the tissues undergo only temporary changes. The regulation is accomplished through the adjustment of the urinary excretion; but the mechanism by which this is controlled is not understood, notwithstanding extensive investigations. The problem is probably analogous to that of the regulation of the sugar content of the blood.

Colloid-Chlorid Combination.—One theory (Forster, 1871) assumes that the greater quantity of the salt exists in the body in a form (perhaps as a combination with the protein) in which it can not pass through the living kidneys. This salt is therefore retained with great tenacity. Any excess, over this, such as is normally present, is free and filters very readily into the urine. This theory agrees with the observation of Sollmann (1901) that the injection of these ions which are closely related to chlorid (v.e., Br, I, NO3, SCN) increases the chlorid percentage in the urine, while other ions do not have this effect: it may be assumed that the related ions can displace the chlorid from its protein compound. All attempts to prove by chemical or physical methods the existence of such compounds in the blood have failed. Roma, 1910, f.t., showed by ‘compensated osmosis’ that the CI of the blood diffuses exactly as if it were in the ordinary ionic condition. However, it is still conceivable, that the adsorption of the colloids may modify the filtrability of dissolved substances. M. Fischer, 1915, believes that retention of salt and water are both due to inhibition of body colloids, which is increased by acids, and therefore he thinks by acidosis.

Cushny (1902), attributes the chlorid regulation to the absorbing mechanism of the tubules.

Chlorid Threshold.—Ambard and Weil assert that there is a certain threshold of the NaCl concentration of the plasma—normally 3.62 Gm. per liter. If the concentration falls below this, the chlorid is excreted; if it rises above, the excretion varies as the square of the excess (McLean, 1912).

Limited Salt Income.—The maintenance of a certain salt content is indispensable to the body; sodium chlorid being especially important. Animal food appears to contain a sufficiency of this salt; while a herbivorous and omnivorous diet is insufficient in this respect. Under ordinary conditions, the excretion of salt keeps perfectly parallel with the salt intake (Falk, 1848), so that a moderate excess of salt income is practically without effect, except on the urine. A very limited salt income (as by an exclusive milk diet) can also be borne for a considerable time, being met by a corresponding decrease of chlorid excretion, so that the percentage of the salt in the blood is scarcely altered, and no general symptoms whatever result. Dogs on a CI-poor diet retain CI or I more efficiently than on ordinary food (Sarvonat and Cramien, 1911). The diminished intake of salt may have no deleterious effect. Even when the excretion is further increased by liberal water-diuresis, the patients show no particular craving for

SODIUM CHLORID 779
salt. Complete abstinence from food also does not produce any effects referable to the absence of salt. After a ten to fifteen-hour fast, the total quantity of Cl in the body is reduced by only 2 per cent.; and the percentage of Cl is even above the normal, because the tissues disappear more rapidly in starvation than does the Cl (Rosemann, 1912). D'Ercole, in 1908, found no change in the freezing-point or conductivity of the blood plasma. The inorganic metabolism in starvation has also been studied by Cathcart and Fawcett, 1907.

Salt Starvation.—This may be produced by feeding food deprived of all its salts (J. Forster, 1873); or by "deceptive feeding," abstracting the gastric juice through a fistula (Rosemann, 1912). Forster found that pigeons died in thirteen to twenty-nine days; dogs in twenty-six to thirty-six days. In man, an abstinence of nine days is serious, but not dangerous. The subject does not return to normal for a week or two after resuming the consumption of salt (E. Taylor, 1904).

Salt-poor Diet. —The use of NaCl-poor food in edema, etc., was discussed previously. Javal, 1912, suggests the addition of sodium iodid or bromid to improve the taste of the unsalted bread. Cl-poor diet has also been employed to enhance the retention of the bromid ion in epilepsy (Toulouse and Richet, 1900). Indeed, the efficiency of the bromid treatment has been referred to de-chloruration; but this is probably erroneous (see Bromide, Januschke, 1911). Tables of the content of the various salts in foods are given by Allbu and Neunberg, Mineralstoffwechsel.

Effects of Excessive Consumption of Salt.—By means of the regulating mechanisms, an excess of the Na or Cl ions is eliminated very promptly, and could not produce any very large effect. But even when they are retained, these ions produce only very small actions; for the amounts normally present are so large that the artificial introduction of ordinary amounts will not increase their ratio to a considerable extent. Na and Cl are therefore the most indifferent of the ions, and their salts are used when the effects of other ions are to be tested. It is important to remember, however, that they are really very essential to the protoplasm, and that the absence of effects is due only to the fact that the variations which are introduced are relatively small.

Local Actions of Salts. —Salts in isotonic or hypotonic solutions have little local action; in substance or in hyperisotonic solutions they act as rather mild irritants, without destroying the tissues.

Action on the Skin; Salt-baths. — Sodium chloride and other neutral salts, e.g., in the form of sea baths, produce a mild but extensive stimulation of the skin, and thereby reflex tonic effects. The mechanical irritation of the dried salt crystals contributes to the result. They possess an advantage over most other irritants in that they do not injure the epidermis.

Alimentary Canal. — Salt produces a similar stimulation of the mucosa of the alimentary canal, especially in the stomach, i.e., before the salt is diluted.

The action is deep since the salt will stimulate all the cells with which it comes into contact in the course of its absorption. Since the salt is quickly removed by further absorption, it does not cause any permanent change. In this way it differs from the majority of gastric irritants, which produce a superficial but persistent action. The stimulation by salts may therefore be continued for a considerable time, and is frequently very useful in the treatment of certain cases of "atonic" dyspepsia. Salt also often aids the digestion of otherwise difficultly digestible articles. Rosenblatt, 1907, observed markedly increased secretion in the Pavlov miniature stomach, depending on the concentration; 1 per cent. was indifferent; greater dilutions were slightly stimulant. Pepsin was, with Hamburger, 1915, found that neutral salt, even in the concentration of serum, rapidly destroy pepsin. The inhibition is complete with

SODIUM CHLORIDE

2.5 per cent. NaCl; scarcely perceptible with 0.25 per cent. Other inorganic salts act similarly, probably by liberation of OH ions (Hamburger, and Halpern, 1925). The destruction does not occur in the presence of free acid; but once destroyed, the ferment cannot be re-activated by acidulation. This reaction is probably the explanation of the "antipepsin" of the serum. Neutralization of gastric juice likewise destroys its pepsin, since NaCl is formed. This would contribute to the action of alkalies, for instance in gastric ulcer.

Laxative Action.—A teaspoon of salt in a pint of water, taken before breakfast, is often laxative.

Saline Diuresis on Milk Flow.—In lactating goats, with limited water income, diuretic doses of salt or urea decrease the yield of milk and increase its fat-content, presumably by diminishing the available amount of water. The nitrogen of the milk is not increased (Stenbock, 1915).

Toxic Action.—If salt is given in large amounts and concentrated form, the irritation may lead to a strong inflammation—to severe gastroenteritis, which may be fatal. Poisoning by enema was reported by Brooks, 1910. A pint of saturated solution had been injected, and repeated twice at hour intervals. The symptoms were restlessness, thirst, rapid pulse, coma, fever (107° F.), frequent micturition, dyspnea. Death occurred eight hours after the first injection, preceded by convulsions and bloody discharge from the rectum.

After Absorption.—The ingression of salts, without sufficient water to render them isotonic, must tend to increase the salt concentration of the body. This increase affects mainly the tissues, the molecular concentration of the blood remaining practically unaltered. This increased salt concentration is counteracted by the stimulation of two mechanisms: a desire for water (thirst); and the elimination of highly hypertonic urine. If water is given freely, the salts are powerfully diuretic. This leads to an increased excretion of metabolites, partly by the flushing out of stored waste products, but also by direct stimulation of metabolism. If the water income is restricted, the urine flow decreases the N excretion temporarily (Desgrez and Guencke, 1911).

The effect upon the metabolism is uncertain in its outcome, as is the case with all alteratives. It may be useful especially in obesity.

Saline Diuresis.—When extra salt is administered by mouth, it may increase the urine flow, or the percentage of urinary chlorid, or both. This probably depends on the state of the tissues more than on the kidneys.

Respiratory Metabolism.—This is increased by saline injections, especially if hypertonic (Raeder, 1915).

Salt Glycosuria.—Bock and Hoffmann, 1871, observed that intravenous injection of NaCl solution into rabbits produces glycosuria. This was confirmed by Kuehle, 1872 (who also found that it does not seem to occur in dogs) and later by M. Fischer, O. H. Brown and others. The glycosuria is greater with rapid injection or higher concentrations, and may be abolished by the addition of Ca ions.

The mechanism of the salt glycosuria is in dispute. Underhill and Closson, 1908, claim that it is accompanied by hypoglycemia, and therefore attribute it to increased permeability of the blood-vessels. E. Frank, 1914, failed to find the hypoglycemia and attributes it to polyuria. Willenkow, 1912, states that it does not occur after section of the splanchics and refers it to stimulation of the central nervous system. Further work is evidently needed.

E. Hirsch, 1915, reports hyperglycemia from intravenous injection of 10 per cent. NaCl. The action is central, presumably on the glycogenic center. Solutions of 2.5 per cent. or more dilute, even in large quantities, do not increase the blood-sugar; nor does sodium carbonate or acetate, nor calcium chloride. Sodium sulphate also does not produce hyperglycemia (Kleiner and Meltzer, 1916). Magnesium sulphate, however, does so.

It is interesting that diabetic puncture and puncture of the funiculus teres in rabbits increases the urine and the percentage of chlorid ("Salt puncture"). The urinary effect is independent of the glycemia, but depends on nervous impulses carried by the splanchics (Jungmann, 1914).

Salt Fever.—Finkelstein, 1908, and Schap, observed that the administration of salt to infants by mouth or hypodermically, may produce fever. A slight rise of temperature is also observed in adults, if at least a liter of 0.9 per cent. NaCl is injected hypodermically (Ringl, 1910), but is prevented if Ca is added, as in Ringer's solution (Meyer and Bietschel; Bock, 1912; Biebert and Martin, 1910). The rise is accompanied by an increased N metabolism and heat production (Freund and Graf, 1911). Hyper- tonic salt solution (5 per cent. NaCl) is much more effective (Kolby and Christjasen, 1914). A similar rise is produced by the injection of isotonic dextrose or lactose, and by indifferent particles (paraffin, colloid metals, etc., Bock); but these may have a differ-
ent origin. The salt fever is not due to infection, for it occurs with absolutely sterile solutions and with oral administration (Bingi; Freund, 1913). It is therefore quite distinct from the "water infection," the "wasserfieber" of Wechselsman, 1912; i.e., the fever that occurs after the injection of solutions made with stale distilled water. Finkelstein and Bingi assumed that the salt fever is caused by irritation of the heat centers by the chemic products resulting from the action of the Na ions on the tissues.

An apparently different type of salt fever is produced by the injection of hypertonic solutions of salt, glucose etc. This can be prevented by the administration of water and is attributed by Balcer et al, 1919, to the dryness of the tissues, limiting perspiration and to the sudden increase in blood pressure.

Wright's Surgical Solution.—A. Wright, 1917, recommends the saturation of wounds with a hypertonic saline solution, aiming to keep the surface irrigated with lymph. He employed 4 per cent. of sodium chloride and 1 per cent. of sodium citrate in distilled water, sterilized by boiling for half an hour.

Fackenheim, 1915, uses the same principle by dressing the wound daily with granulated sugar.

PREPARATIONS—SODIUM CHLORID

*Sodi chloridum (Sod. Chlorid.). U.S.P.; (Sod. Chlor.). B.P.; (Common Salt). NaCl. White, crystalline, powder of purely saline taste. freely sol. in water (1:3), nearly insol. in alc.; sol. in glyc. (1:10). Chlorids are incompatible with salts of silver and lead. Dose, 14 Grms. by ounce, U.S.P.

SALINE INFUSIONS AND TRANSFUSION

The injection of saline solutions, of blood serum, washed corpuscles, non-coagulable blood, or direct transfusion of blood produced very similar results and are merely minor modifications of the same general procedure.

General Effects of Saline Infusions.—The general effects of hypodermic or intravenous injections of saline solutions on the quantity of blood, lymph and urine, and the fate of these solutions were discussed under "Salt Action." It may be recalled that the quantity of fluid in the blood is temporarily increased. This produces a moderate rise of blood pressure; and this, perhaps with some direct salt action, results in an increased excitability of the respiratory, vagus (H. C. Jackson and Ewing, 1914) and vasomotor centers. With normal animals, the rise of capillary pressure is large and persistent; while the rise of arterial pressure and the medullary stimulations pass off quickly, but without noticeable fatiguet. In animals whose blood pressure is low—particularly if this is due to hemorrhage, saline infusions bring the pressure toward normal, and maintain it much better (see figure). Excessive injections of saline solutions may cause death from pulmonary edema, or from overdistention of the heart. Even therapeutic injections may produce glycosuria, slight fever, and rarely albuminuria.

Vasomotor Center.—In normal animals, injections of 40 to 50 c.c. per kilogram produce only slight stimulation or no change. Occasionally, i.e., when there is maintained rise of blood pressure, the vasoconstriction is quite marked (Pilcher and Sollmann, 1914). Quantitative Relations.—These effects are produced by all salts whose ions are not specifically toxic, i.e., by most sodium salts. To have any effect, these must be used in rather large amounts, i.e., from 25 to 50 c.c. of the eighth-molecular solution per gram of body weight. Solutions which contain all the salts of the serum in the proper proportion (i.e., Locke's Fluid) are somewhat better than the normal (0.9 per cent.) sodium chlorid solution, but the latter suffices for all practical purposes.

Even small doses of isotonic NaCl may produce changes in blood pressure, while Ringer's solution or glucose has much less effect (Selig, 1921) so that the action is probably not wholly osmotic. Frogs' vessels are dilated by perfusion with NaCl (Hooker, 1912).
Factors Involved.—The effects produced by injections of sodium salts depend on the interaction of a number of factors, especially:

1. Hydric plethora
2. Osmotic changes
3. Changes in the alkal reserve, by selective retention of the cation
4. Altered ion ratio in the blood.

The nature of the anion. This, however, probably acts mainly by altering the permeability of the cells to sodium (Gruenwald, 1918).

Toxic Doses of Different Cathions.—Joseph and Meitzen, 1907, found that MgCl was fatal for mammals with 0.22 Gm. per kilogram (1 c.c. M/5 per kilogram per minute); Ca and K required about double, Na twenty times as much.

Hypotonic Solutions.—These act very much like isotonic solutions, but are somewhat more injurious and may lake the blood.

Hyperosmotic Solutions.—These, by abstracting water from the tissues, produce a much more violent stimulation of the central nervous system, passing on to convulsions, but always followed by depression. Small intravenous injections raise the blood pressure partly by direct stimulation of the heart (Retzius, 1912). With larger injections, the blood pressure shows a progressive fall, with temporary rise during the spasms. The respiration is at first quickened, but becomes slow and shallow as the blood pressure falls. The heart is quickened, feeble, and arrhythmic. In the later stages it may be slowed by stimulation of the vagus center. The temperature rises.

The diuretic effect and the local irritation are also much greater.

It is probable that some of the phenomena of arexia are due to a hyperosmotic condition of the blood, which may reach almost double the normal concentration in this condition.

Restoration of Normal Blood Volume.—The circulation rapidly dispose of injected solutions by exchange with the tissues. As has been explained more fully under General Salt Action, the total molecular concentration, the ratio of ions, and the total volume of blood are restored to nearly normal within half an hour.

Conditions Delaying the Restoration of the Blood Volume.—Rogert, Underhill and Mendel, 1916, confirm that in normal dogs and rabbits, the blood-volume returns to normal within half an hour after the intravenous injection of warm Ringer's fluid, equivalent to the total blood-volume. This is delayed by morphin, and by nephritis (uranium, chromate or tartrate), but not by ligation of the kidney vessels. The restoration is not affected by the addition of 0.4 per cent. sodium carbonate, either in normal or in nephritic animals. Gelatin solutions (1 per cent.) may leave the blood as rapidly as plain saline, although more commonly from 11 to 27 per cent., are still present in the blood after half an hour. The gelatin leaves the blood in the same ratio as the fluid (Boycott, 1914) and is partly excreted in the urine.

Balanced Solutions.—It has been pointed out that even isotonic sodium chloride solutions are injurious to isolated tissues; that the function of isolated tissues requires exactly “balanced,” solutions, of the type of Ringer's, Locke's or Tyrode's solutions; but that this is not necessary in the intact animals, because the regulating mechanisms of the body rapidly restore the normal concentration and ion-ratio of the blood. Solutions of sodium chloride of 0.6 to 1 per cent. may therefore be used for hypodermic, and even for intravenous injections, although Locke's fluid is probably more desirable.

Special Ingredients.—Saline infusions are used mainly for the mechanical result of increasing the quantity of circulating fluid. Any indifferent solute could therefore be substituted for isotonic quantities of sodium chloride. Most substitutes, however, are too toxic for large intravenous injections.

The only substitutes for, or additions to, salt that have reached some practical importance are: glucose, sodium bicarbonate, acacia and gelatin.

Glucose.—This may have advantages, especially in impeding acidosis, and in cardiac collapse, where it acts as a nutrient; in nephritis; or in
fever, because the oxidation of the sugar leaves the water at the disposal of the tissues. It is often used in strongly hypertonic solutions, although it is probable that approximately isotonic solutions (5 per cent.) should be preferred. It is also injected with acacia, especially in shock. In any case, it should be aimed to graduate the injections, so as to avoid marked hyperglycemia.

Enriquez, 1914, recommends a 10 per cent. solution, injected at the rate of 250 to 300 c.c. per hour, to a total of one liter.

Elranger and Woodyatt, 1917, claimed fair results with dogs in shock.

H. J. John used it with good results in pneumonia (250 c.c. of 10 per cent., by vein, 2 or 3 times a day).

Antipyretic Effect.—Barbour, 1919, observed in man under suitable conditions a very slight lowering of temperature by increased heat dissipation, after oral administration of 10 to 100 grams of glucose in 250 c.c. of water.

Colloid Infusions.—The attempt has been made to prolong the stay of the saline in the vessels by the addition of gelatin (Hogan, 1913) or other colloids. Bayliss, 1910 confirmed that the addition of 5 per cent. of gelatin or acacia to Ringer's fluid maintains the blood pressure longer. These solutions produce less diuresis (Knowlton, 1911) and are generally retained much longer; but this prolonged sojourn of the colloid may be inadvisable.

Colloids on Diuresis.—Knowlton observed that 5 per cent. of gelatin or of acacia, added to Ringer's fluid, practically prevented a diuretic response; whereas soluble starch, which is at least equally viscous, did not inhibit diuresis. The effect of gelatin is probably due to its water-affinity.

In the experiments of Bogert, Underhill and Mendel, 1916, the urine-flow was as great with 2 per cent. gelatin as with plain saline. The gelatin solution generally left the circulation somewhat more slowly than plain saline; but not always. The gelatin was eliminated from the blood at the same rate as the fluid, being partly excreted by the kidneys (Boycott, 1914).

In rabbits, J. Clark, 1918, found that the gelatin begins to leave the blood immediately after injection, its elimination being completed in 6 to 24 hours.

Hogan, 1915, advised the following solution: Gelatin, 1.5 Gm., dissolved in 100 c.c. of water, and added to 1,000 c.c. of 0.9 per cent. NaCl with 2 Gm. of Na2CO3 10H2O. This is injected (about 500 to 750 c.c.) until the blood pressure is satisfactory.

Acacia.—S. H. Hurwitz, 1917, recommended a 5 per cent. solution of acacia in 25 per cent. fluid, as being more easily sterilized than gelatin and non-toxic. Its viscosity is slightly higher than that of plasma. Bayliss, 1917, also found the addition of 6 per cent. of acacia to Ringer's fluid counteracted low-blood pressure in animals much more effectively than plain Ringer's.

Acacia in Traumatic Shock.—This solution has been extensively tried against the shock of war wounds. The British Baylis solution contains 5 per cent. of acacia and 0.9 per cent. of sodium chloride. Elranger advised 2.5 per cent. of acacia and 1.8 per cent. of glucose, injected very slowly separately or together, in the ratio of 5 c.c. per kg. In animals and in many clinical cases, the injection was followed by some improvement; although it is not clear that the ultimate results were any better than with simple saline.

Dangers of Acacia Infusions.—Serious collapse, sometimes fatal, has followed the injection of the Baylis solution on several occasions (Engl. Med. Rec. Com. 1919). Simple chills are more common.

The cause of the accidents has not been completely explained. Faulty preparation of the solutions may be one element. However, acacia produced agglutination of the blood-corpuses and like other colloids, it may cause anaphyacloid phenomena in animals, which resembles the clinical accidents (Kruse, 1910; Hanfick and Kasten, 1910).

Some specimens are much more dangerous than others (De Kruif, 1918).

Alkali.—The addition of 0.5 per cent. sodium bicarbonate to the physiologic saline solution (Howell, 1900; Dawson, 1904) approaches more closely the normal reaction of the blood, counteracts acidosis (Milroy,
1917) and often causes more lasting restoration of the blood pressure (compare "Milk Alkalies"). However, in simple hemorrhage or mild collapse, it is a needless complication.

**Therapeutic Uses.**—Saline infusions are employed to tide the patient over acute anemia from hemorrhage; in collapse; or in alternation with bleeding for the removal of poisons (uremia, CO, etc.). Direct transfusion of blood is more efficient, but more inconvenient and often inadvisable.

**Use in Hemorrhage.**—Saline injections are made with the object of restoring the fluid needed for effective work of the heart. The restoration of the blood pressure succeeds, at least temporarily, unless the hemorrhage has reduced the pressure to the level of shock (Pilcher and Sollmann, 1914; Downs, 1916). Short of this, the temporary benefits are often striking; but since the solution does not stay long in the vessels, the final fatality is not greatly influenced.

**Influence of Saline Infusion on Hemorrhage Fatality.**—Kwan, 1913, states, found that rabbits die from acute hemorrhage when 20.7 to 33.2 c.c. of blood are lost per kilogram. When the blood was replaced at once by simple saline, the fatal limit was 33.5 to 37.3; when replaced by Ringer's solution 25.5 to 37.3 c.c. per kilogram.

**Efficiency of Modificatons.**—This was investigated by Penfield, 1928. By repeated hemorrhage, he kept the blood pressure of dogs about 40 mm. Hg for 4 to 174 hour. Then a saline injection was made, equal in volume to the blood withdrawn. Survived animals were observed for a week:

About half of the animals survived, the ratio being the same for plain 0.9 per cent. sodium chloride, for the Bayliss gum-bicarbonate solution and for the Erlanger gum-deastrose solution.

**Extravas of Hemorrhage.**—Richet, 1918, found that the minimum of blood compatible with life (in dogs) is 4 per cent. of the normal number of corpuscles, and 27 per cent. of the normal blood mass. This meant that considerable blood may be replaced by saline. For instance, with simple gradual hemorrhage, death occurs when 77 per cent. of the blood corpuscles have been lost; but if saline is injected, life persists until the blood corpuscles loss has reached 87 to 99 per cent.

**Traumatic Shock.**—The low blood pressure that is characteristic for shock, early suggested the use of saline solution. The results, however, have been uniformly disappointing. Normal saline solution does not raise the pressure materially. Excessive injection easily produces fatal dilation of the heart. If acacia or epinephrin are added, the blood pressure can be maintained longer, but only at the expense of overloading the heart. The ultimate mortality is practically the same as in untreated animals.

**Saline Infusion in Collapse.**—This may hasten recovery in temporary collapse, as with phenol and other poisons. It is of little use in the lasting collapse of fever or severe shock.

**Use in Uremia and Other Intoxications.**—Saline solutions were extensively employed as diuretics; but it is now recognized that simple injection does not increase the elimination of the toxic substances sufficiently to be of much value. (Their influence has been studied by Lenhartz, 1890).

A limited diastactosis occurs with strychnin (Hatcher and Smith, 1917; Kleiner and Meltzer, 1917). The recognition of the impermeability of the kidney to chloirid in some nephrites enjoins special caution. Mosenthal and Schlapper, 1913, claim that the kidneys of experimental nephritis do not respond well to NaCl. In any case, saline injections must be used cautiously in anuria, and must not be persisted in if a moderate injection does not cause distress.

**Plasmapheresis.**—This term was introduced by Abel to designate the replacement of the plasma with saline solution. The blood is withdrawn, the corpuscles separated and washed by centrifugation, suspended in 0.6 per cent. NaCl, and reinjected. In this way much larger amounts of plasma may be withdrawn without damage, especially if the process is several times repeated. The number of red corpuscles rises at
first (i.e., the volume of liquid in the vessels is reduced); but ultimately they decline slowly. The plasma proteins may be reduced to a third. The urea and non-protein nitrogen of the blood are increased. The temperature rises slightly (Abel, Rowntree and Turner, 1914; Turner, Marshall and Lannon, 1915).

Hepatic degeneration (phosphorous or chloriform) delays regeneration of the blood proteins after plasmapharesis (Herr et al., 1918).

Transfusion of Blood.—This was tried clinically in very early times, but with disastrous results, since foreign species were generally used. Worms-Mueller, 1874, investigated the acute and late effects of the transfusion of the blood of the same species, the fowl of the blood, the therapeutic field, etc., and practically stated our modern knowledge of the subject, except some technical details (Sollmann, 1915). He showed that clamps of the blood volume between 25 per cent. below the normal, to 30 or 50 per cent. above normal do not materially alter the normal blood pressure; attributing the adjustment to vasomotor changes. The pressure remains practically unaltered even with extreme plethora; but other acute central symptoms supervene.

As the further fate of the animals, Mueller showed that increasing the normal quantity of blood by 50 per cent., by slow transfusion, does no damage. Of the injected plasma, about half the water has disappeared from the blood within two hours; the remainder leaves more slowly, requiring several days. The plasma protein also disappears promptly; and increased urea excretion indicates that it has been metabolized. The injected corpuscles persist much longer, the normal ratio being restored in three to four weeks. He therefore concluded that the usefulness of transfusion is due solely to the injected corpuscles. No differences were found between fresh or delbrinized blood and blood that had been kept on ice for a day.

These observations have been confirmed by the modern investigators. For instance, Weinberger, 1907, found in dogs that the water leaves the blood vessels very rapidly, causing diuresis, but not nearly as great as with NaCl solution. The red corpuscles can thus be raised temporarily to over 15,000,000; but they gradually decline during the succeeding days. The specific gravity rises still more. Animals invariably die after four or five transfusions, with hemoglobinuria and nephritis. The injected blood protein is of no nutritive value, the nitrogen being rapidly eliminated.

The transferred corpuscles persist over 30 days, as judged by the agglutination reaction (Ashby, 1915).

Transfusion of Citrated Blood.—This is discussed under Sodium Citrate.

Indications for Transfusion.—These were stated by Mueller: excessive hemorrhage; carbon monoxide poisoning; and some chronic anemias, for instance, leukemia. They are practically the modern indications, (if), Ottenberg and Libman, 1915.

Transfusion is also used to overcome the hemorrhagic tendencies of purpura and similar diseases.

UREA

Urea, CO(NH₂)₂, is an effective diuretic, acting probably by simple osmosis. It is little if at all toxic.

Hewlett et al., 1916, find that the administration of 100 Gm. of urea by mouth to man increases in a few hours the blood urea to 160 to 242 mg. per 100 c.c.; and this is accompanied by prostration, apathy and somnolence. These symptoms resemble those occurring in pure retention-uremia, when the blood urea rises to 100 to 200 mg. per 100 c.c. (However, nephritis may not show any uremic symptoms with 250 mg. McLean, 1917).

The beneficial effects of urea on perfunctions were discussed previously. It is excreted mainly by the kidneys; a small amount also by the sweat (0.24 per cent., Kovacs). The urea content of the milk is not increased by urea administration (Steenbock, 1915).

Urea is not utilized in nutrition (Hemisphere and Anderson, 1914).

Urea occurs as colorless crystals of cooling, salias taste, freely soluble in water (1:7). The effective diuretic dose would be 30 to 40 Gm. per day.

SACCHARUM LACTIS (MILK-SUGAR)

This also produces osmotic effects. Nine to 12 Gm. (2 to 4 drams), in warm milk 30 hours before breakfast, causes a soft stool. Smaller doses (pure or as milk) are efficient for diuresis (the effective dose would be 100 to 200 Gm. per day). Milk-sugar is also used to stimulate the combustion of sugars, on account of its laxative. It is also employed as sweetening agent, especially for powders; and as a carbohydrate food, especially for infants.
POTASSIUM SALTS

General Statement.—Potassium is widely distributed through the body and is essential to the vital functions. It acts as a depressant to the central nervous system, and is mutually antagonistic with Na.

With intravenous or hypodermic injections, the ion-actions manifest themselves by depression of the heart and other muscles, and of the central nervous system. These effects may also be secured from toxic doses by mouth; but not by ordinary doses, since the rapid excretion prevents the accumulation of excessive potassium in the tissues. The therapeutic use of potassium in myocardial and muscular depressant was a faulty deduction from the laboratory experiments. The oral administration of moderate quantities of potassium has practically only osmotic effects—diuresis, slight changes in metabolism, etc. The therapeutic actions of potassium salts are therefore attributable to their anions, and are practically equivalent to the corresponding sodium salts. The potassium salts perhaps produce somewhat more local irritation. They are contraindicated in renal insufficiency, since the deficient excretion could lead to the development of toxic potassium effects.

Income of Potassium.—The daily diet of man contains about 3 to 4 Gm. of K₂O and 5 to 8 Gm. of Na₂O; but there are great variations. A vegetable diet contains relatively more K.

Distribution of Potassium.—This is in many respects converse to that of sodium. The K is generally more abundant within the cells; the Na in the extracellular juices, serum and lymph. The serum of all mammals contains about 0.15 per cent. of K₂O as against 0.44 per cent. of Na₂O. The percentage in the blood corpuscles differs markedly in different species, being generally inverse to the percentage of Na. The corpuscles of the horse, pig and rabbit contain 0.33 to 0.52 per cent. of K₂O and no Na₂O; in man, the ratio of K₂O:Na₂O is 0.42:0.075; in the beef, sheep and goat, it is 0.07:0.23; in dogs and cats, 0.51:0.38. In the K-rich animals, the dissolution of a fifth of the corpuscles would liberate a fatal quantity of potassium. Muscle fibers also contain K, without Na (Fahr, 1912). Macleod, 1907, found that the juice expressed from the heart or skeletal muscle produces a typical potassium effect on the heart.

The distribution of K within the cells has been investigated by A. B. Macallum, 1907. It is absent from the nuclei and from the nerve cells; but is present in the cytoplasm of most vegetable and animal cells, including the muscles, the nerve fibers, the muscula of the pancreatic cells, etc.

Excretion.—A considerable part of the potassium, 15 to 45 per cent., is excreted in the feces. The urine contains generally Na:K::2:1 to 5:1. In starvation, the ratio is reversed to 2:3.

The excretion of K seems to be hastened by the addition of Na (Biernecki, 1911). A few experiments by Illmenfeldt, 1913, indicate that the excretion of administered potassium is delayed by aortic insufficiency, arteriosclerosis, and intestinal nephritis.

Influence of Excretion on Effect.—The effect of potassium, as of other cations, varies greatly according to the channel of introduction, because the excretory capacity for these ions is usually much greater than the rate of their absorption from the alimentary canal. Oral administration is therefore effective only if very large doses are given; if the mucous membranes are corroded, or if the excretion is checked, as by ligature of the kidneys.

The influence of excretion is well illustrated by magnesium; after occlusion of the kidneys, the toxicity is increased 50 per cent., and the action is more lasting and cumulative.

On the other hand, some vicarious channel of excretion becomes established, so that the toxicity is less eighteen hours after operating than it is immediately (Meltzer and Lucas, 1907).

The toxicity of intravenous KCl is diminished by NaCl (Amberg and Helmholtz, 1916). A summary of the excretion of salts is given by Heffer, 1902.

Systemic Actions.—The central nervous system is paralyzed by K in its whole extent. The reflexes suffer, then the medulla. Depression of the respiratory center leads to apneustic convulsions. Absence or increase of K are both depressant to the perfused respiratory center of the frog (Hooker, 1912). With intravenous injection, the most important effect is the cardiac paralysis.
Cardiac Actions.—The relations of K to the other ions were discussed previously. The heart is stimulated by small, fatigued by medium, and paralyzed by large, doses. This is seen even in the nerve-free heart of the chick’s embryo, and is therefore muscular. In Langendorff perfusions of the excised mammalian heart, increase of K produces inhibition, followed by fibrillation. Purification occurs when the concentration of the blood reaches 0.08 per cent. (Hald, 1902). Howell and Duke, 1908, found that stimulation of the vagus causes an increased output of K in the perfused heart, especially the auricle. They attribute the vagus stoppage to the K which the stimulation of the nerve is assumed to convert from a non-diffusible to a diffusible form.

In intact mammals, the effects are somewhat different for intravenous and arterial injections (Mathison, 1911); by the vein, there is a primary fall of blood pressure, with a slight secondary rise. The fall is due to cardiac disturbance, decreased output, heart block, slowed pulse, tawn changes, suddenystolic standby, usually before the respiration stops. Slow continuous injections into dog’s produce slowing and weakening of the heart by central vagus stimulation; for if the vagi are divided, the heart is quickened and strengthened, and often shows extracystodes. The direct cardiac action of the small doses is therefore stimulant. Larger doses depress the heart muscle directly, even when the vagi are divided. Fatal doses produce ventricular and eventually auricular fibrillation (Hering, 1911). Arterial injection causes an immediate rise of blood pressure, by stimulation of the vasomotor center, and of the vessels directly (it occurs even when the central nervous system is destroyed). However, the vessels of frogs are diated by perfusion with K (Hooper, 1911).

Skeletal Muscles.—K weakens the muscles; diminishes the height of contraction; lengthens the latent period; and decreases the conductivity and excitability (Fah, 1910). In this way, potassium counteracts the effects of veratrin.

Meigs and Atwood, 1916, suggest that the changes occurring on the immersion of frog’s muscle in 0.9 per cent. KCl may be explained by the muscle-membrane being now permeable to KCl than to the NaCl and K-HP04, that are contained in the muscle. KCl and water would therefore diffuse into the muscle-cell.

Nerve.—Injection of K suspends the conductivity of nerve and potentiates the anesthesia produced by Na, NII, and Mg. It is not this effect (Zorn, 1913). Injection and the local application of lipolytic anaesthetics increases the concentration of K in medullated nerve fibers. This may play a part in the anesthetic effect (Menet, 1912).

Use as Local Anesthetic.—Under clinical conditions the local anesthetic action of potassium salts is almost insignificant, since the potassium is very rapidly absorbed or “neutralized” by other ions in the body (Sollman, 1917). However, 1 per cent potassium chloride may be used in place of normal saline for the dilution of the novocain anaesthetics.

Potassium Poisoning in Nephritis.—The administration of 5 to 10 Gm. of KCl (diluted) usually produces no symptoms, even when the permeability to NaCl is impaired, as in chronic nephritis. Occasionally, however, a nephritic patient may develop severe potassium poisoning, as in a case described by Snellie, 1915. The symptom started after seven hours and reached their maximum in twenty-one hours. They consisted of cyanosis, weak pulse, and vomiting. Rabbits with their kidneys rendered less permeable by uranium nephritis also showed markedly increased susceptibility to potassium. However, with the ordinary potassium intake, v. Limbeck, 1893, did not find increase of K in the blood of uremic dogs.

Potassium in the Toxicity of Urine and in Uremia.—The toxic action which urine possesses when injected intravenously has been variously attributed to the leukocytes to toxins, etc., and at one time even to the urea. Various theories and methods of diagnosis were built upon the variations in this toxicity. It has, however, been shown that about 85 per cent. of the toxicity of the urine is due simply to its potassium salts. The symptoms are also precisely those of the latter. What causes the other 15 per cent. of the toxicity is at the present not known. Hartman, 1913, claims to have isolated from normal urine a cyclic ketone, “Urinothiol,” which is quite toxic, and produces headache in small doses—perhaps through its disagreeable odor.

If the undiluted urine is injected, its osmotic pressure also contributes to the toxicity. The acidity, volatile products, pigments, and urea have no effect. It is quite probable that the urine contains true toxins and other toxic products in disease, but as method has so far been devised for estimating the importance of these.

The conditions are still more complicated in normal: it is very probable that the retention of potassium and ammonia, and the increased osmotic pressure of the blood contribute to the effects, but there seem to be other factors which are not understood. Foster, 1913, has isolated some unidentified crystallizable toxic substances from
the blood of uremic patients, which he failed to find in normal blood. Further investigation is needed.

Hatcher and Smith, 1916, found that the intravenous injection of urine is practically non-toxic to cats.

**PREPARATION**

Potassium Chloridum. KCl. — Readily sol. in water. **Dose**, 1 to 2 Gm. (15 to 30 gr.). Not to be confused with the toxic chlorate!

**LITHIUM SALTS**

**General Statement.**—Lithium urate is relatively soluble. By a misinterpretation of this chemical fact, the lithium salts were introduced as solvents for uric acid; and hence as remedies against gout, rheumatic conditions, etc. Since the soluble urate can not be formed in the presence of sodium or potassium ions, it can not exist in the body or in the urine. The uses of lithium salts therefore have no rational foundation, and they may be considered inefficient, and in larger doses somewhat dangerous.

The action of this cation resembles potassium quite closely, but it is somewhat less toxic to the heart, and causes a vagus stimulation. These effects are seen only on intravenous injection. A most important difference from potassium consists in a specific gastroenteritis which is produced even when the salts are given subcutaneously, or if the administration of small doses is continued for some time (1 Gm. of the carbonate in man). The action is local, the lithium being largely excreted by this channel. It is also excreted by the kidneys, but does not cause nephritis (Krumbof, 1884; Good, 1902). It is also excreted in the milk (Koldewijn, 1910).

Acute poisoning from larger doses in man (four doses of 2 Gm. of LiCl) is described by Cleveland, 1913. There were no gastro-intestinal symptoms, but marked muscular and general prostration; vertigo; and eye and ear symptoms resembling cincniosis.

**Action on Urates.**—Lipowitz, 1841, found that lithium carbonate is a better solvent for uric acid (about four times) than sodium carbonate. He suggested its therapeutic use, and this was introduced by Ure, 1844, and Binwanger, 1847. Garrod, 1861, found that gouty tophi were dissolved in lithium solution. However, the solvent action occurs only when strong solutions of lithium carbonate act on uric acid. In the presence of NH₄, Na or K, the less soluble urates of these cations are formed. The solution can therefore not occur under the conditions of the body of urine (see Index, Urate Solvents). Lithium salts have diuretic actions (Husemann), but no greater than the Na salts. The popular “Lithia waters” have been shown to be practically devoid of lithium. The best contain only 0.01 to 0.02 per cent. “Buffalo Lithia Water” contains only a fifth as much lithium as Potomac River water; 100,000 gallons would be needed to supply the ordinary therapeutic dose of lithium.

**PREPARATIONS—LITHIUM**

*Lithii Carbonas* (Lith. Carbis), U.S.P., B.P., Li₂CO₃.—Light, white powder; odorless, alkaline taste. Sol. in water (1 : 70); almost insol. in alc. **Dose**, 0.5 Gm., 8 gr., U.S.P.: 0.12 to 0.3 Gm., 2 to 5 gr., B.P.

*Lithii Citras* (Lith. Cit.); U.S.P., B.P., Li₃C₆H₇O₇ + 4H₂O.—A white powder, or in granular form; odorless; cooling, faintly alkaline taste. Deliquescent. Freely sol. in water (1 : 1.4); very slightly sol. in alc. **Dose**, 0.5 Gm., 8 gr., U.S.P.: 0.3 to 0.6 Gm., 5 to 10 gr., B.P.

*Lith. Cit. Aq.*, B.P.—5 per cent. **Dose**, 4 to 8 Gm., 2 to 3 drams, B.P.

**RUBIDIUM AND CAESIUM**

These also resemble potassium. Rubidium iodid and bromid have been introduced into therapeutics, with the improbable claim that they produce less iodism and bromism. The doses are the same as those of the potassium salts.

Caesium or rubidium may replace potassium in the excised frog heart (Zwaardemaker, 1915).
AMMONIUM COMPOUNDS

General Statement.—The ammonium ion produces rather strong stimulation and subsequent paralysis of the central nervous system, especially the medulla. The systemic effects are seen only with intravenous administration, because the ammonium ion is rapidly converted into urea and excreted. On excised muscles, it has also a weak curarizing action.

In intact animals, the effects of the ammonium compounds are strictly local. They diffuse rather rapidly, and thus exert considerable salt action, especially irritation. These local actions increase the flow of mucus, which is also rendered more fluid. Ammonium chloride is therefore used as an expectorant in the first (dry) stage of acute bronchitis and in dry chronic bronchitis. It is also somewhat diaphoretic (nauseant action?). Large doses are emetic. Ammonium acetate has been employed as a weak diaphoretic and diuretic in fevers, but is probably useless.

Ammonium hydroxide and carbonate act also as alkali, and by the liberation of the volatile and diffusible NH₃, their action extends deeply. Their vapor is used to produce reflex stimulation of the medullary centers (trigeminal reflex), in collapse, fainting, etc. When too concentrated, they produce laryngitis, bronchitis and pneumonia.

Applied to the skin, ammonia produces rubefaction, and if concentrated and confined, vesication, usually without corrosion. It is used in combination with oil (ammonia liniment) for counterirritation in rheumatism, etc. Ammonia is also applied to insect bites.

Expectorant Action.—Ammonium chloride makes the sputum subjectively “looser,” easier to raise, and perhaps more abundant. The increased secretion of mucus and saliva is mainly a reflex from the local irritant action, although there may be some direct central stimulation (V. E. Henderson, 1910). The liquefaction of the mucus may be due partly to the ammonium ion, partly to the excretion of the alkaline ammonium carbonate by the saliva. This excretion, however, is quite small, since most of the ammonium is destroyed in the body. Ammonium chloride is also said to have a primary astringent effect on the mucous membrane.

Administration.—Ammonium chloride is used in acute and chronic bronchitis in the dose of 0.3 Gm., 5 gr., repeated as needed; either as troches (0.1 Gm., 1/5 gr.), or in solution. Its disagreeable taste is less noticeable in acid mixtures (syrup of citric acid). Ammonium carbonates (same dose) is more solute for mucus, but rather nauseant.

When it is desired to extend the direct action to the trachea and bronchi, the ammonium may be administered in the form of inhalation of ammonium chloride, prepared in a finely divided state by bringing together the vapors of ammonia and hydrochloric acid.

Bronchial Secretion.—Ammonium salts, like other emetics, increase the bronchial mucus, even when they are placed in the intestines; but by this method, the dose must be much larger than therapeutic. Ammonium salts produce moderate dilatation of excited bronchial muscle (Trendelenburg, 1912).

Absorption and Excretion by the Lungs.—Magnus, 1902, and Bruckel, 1907, found that ammonia is neither absorbed nor excreted by the lungs; but Hoeber, 1912, and McGuigan, 1913, claim that the inhalation increases the percentage of ammonium in the blood. However, this insignificant absorption occurs from the trachea and bronchi and also from injured alveoli (Magnus, Sorgdrager and Leuwen, 1914). W. Coleman, 1916, states that traces of ammonium can be discerned in the urine (not in the saliva) twelve hours after discontinuing small doses of the salts (1/2 grain every two hours).
Disintoxication of Ammonium.—Ammonium is partly excreted as such by the urine; but the greater proportion is rapidly converted into urea, according to the formula:

\[
\text{CO}_\text{NH}_2 + \text{CO}_\text{NH}_2 \rightarrow \text{NH}_4^+ + \text{H}_2\text{O} + \text{NH}_3 + \text{H}_2\text{O}
\]

Two molecules of water are split off from the ammonium carbonate and urea remains. This liberates the acid ion with which the NH\(_4\) was combined; this will seize upon the free fixed alkali of the body, and lead to an diminished alkali stock of the tissues. In this way any excess of ammonium introduced into the body is very soon eliminated, or at least acts to act as ammonium.

The transformation of ammonium into urea is much more complete when the ammonium is given combined with organic acids, than in the case of its inorganic salts, or with the latter, a part of the ammonium is needed to help in the neutralization of the anions (Underhill; Caldwell and Clowworth, 1910).

There is similarly a fairly definite relation between the ammonium excretion, the action of the urine, and acidosis conditions (Hessebalch, 1906).

Ingested ammonium disappears very rapidly from the circulation, even if the Inexes are ligated (Jacobson, 1924). The conversion of ammonium carbonate into is practically complete in all mammals. Ammonium chlorid is destroyed more slowly by hereditary animals than by carnivore or man.

In man, after the administration of 5 gm. of ammonium chlorid, 52.5 per cent. were recovered from the urine in 2 days (Wolf and Osterberg, 1912).

Ammonium in Metabolism.—Arterial blood contains normally about 1.5 mg. of H\(_4\) per 100 c.c. Portal blood contains from 3.5 to 6.5 mg. (Carlson and Jacobson, 1892). Folin and Denis, 1912, believe that the excess in the portal blood comes mainly from bacterial changes in the large intestines. The ammonium is probably a normal inrumer of urea. This is formed from ammonium carbamate by the subtraction of \(\text{O}^-\):

\[
\text{CO}_\text{NH}_2 + \text{O(NH)}_2 \rightarrow \text{H}_2\text{O} = \text{CO}_\text{NH}_2 + \text{H}_2\text{O}
\]

Place of Urea Formation.—The transformation of ammonium into urea occurs in the liver (v. Schroeder, 1892; Fiske and Karasar, 1913); the urea may also be considerably higher in the hepatic than in the portal blood (Van Slyke, Cullen and Elean, 1919). The liver must therefore play a prominent part in urea formation (however, probably all organs participate, especially in its formation from amino-acids (Folin, 1914). For instance, the amount of urea in the tissues or blood, after the abundant injection of amino-acids, is smaller in animals with the liver and intestines excised from the circulation (Fiske and Sunner, 1914). Jansen, 1915, also presents evidence that the liver has a considerable role in the formation of urea from amino-acids.

Function of Ammonium in Neutrality Regulation.—The transformation of ammonium into urea is utilized for the control of the reaction of the body: when there is an excessive formation of acid (acidosis), the transformation is less complete, the acid being neutralized by the ammonium and excreted in the urine. If alkalies are administered, the ammonium is displaced from its salts, and converted more completely, so that none may appear in the urine (Janney, 1912). The ammonium-urea relation of the urine is thus an index of the acid production or alkali income.

The ammonium excretion is therefore high in diabetics (Bouisignault, 1850), where a tendency to acidosis is frequently present.

Utilization of Ammonium Nitrogen.—Grafe and Schupfer, 1912, claimed that ammonium may replace the protein in food. This was confirmed by Knoops, 1912; Grafe, 1915; and others. However, it does not prove that ammonium is converted into tissue nitrogen. It is more probable that it is utilized by the intestinal bacteria, and that these
are then digested and their nitrogen absorbed. Accordingly, Henriques and Anderson, 1914, found no retention of nitrogen after the Intravenous Injection of ammonium or urea. Taylor and Ringer, 1913, did observe considerable nitrogen retention after oral administration of ammonium carbonate. However, the associated changes in metabolism indicate that the retention is due to a toxic action of the ammonium, rather than to its utilization (Underhill and Geldschmidt, 1953).

Autoionization by Ammonia.—The symptoms of uremia, tetany and other convulsions are not due to a failure of the liver to transform the ammonium. This appears unfounded. There is no evidence that the low urea is impaired, except perhaps in extreme cases of liver degeneration. Fiske and Karstner, 1913, found the ammonia conversion by perfused livers unimpaired after acute hepatic injury by chloroform, phosphorus, etc. Even if the ammonium were not destroyed, the secretory mechanism of the kidneys could be expected to remove the excess.

In fact, the ammonium content of the blood has not been found increased in uremia or in acute yellow atrophy of the liver. An increase of 90 per cent. above the normal has been reported after complete excision of the thyroid and parathyroids (MacCallum and Voeglin, 1909; Berkeley and Beebe, 1909); and the ammonium production is increased (Underhill and Salk, 1908), or its destruction diminished (Carlson and Jacobson, 1910). A similar increase was reported in clinical tetany (Mussier and Goodman, 1909). There is also a close resemblance between the symptoms of tetany; those of animals with Eck's fistula on a meat diet (Pawlow, 1893); and ammonium poisoning. Even the concentration of NH3 in the blood required to produce true ammonium tetany, (0.008 per cent., Magnus, et al., 1914) seemed very similar (Jacobson, 1922). However, later work of Carlson and Jacobson, 1911, with improved methods, showed that the increase of ammonium is not constant and falls within the variation of normal animals, so that even these conditions can not yet be classed as ammonium intoxications.

McNeil and Levy, 1917, conclude that increase of blood ammonium above 1.85 per 100 c.c. which occurs in various diseases, is not connected with acidosis, but rather with hepatic disturbance, especially of the acute functional type.

**FIG. 28.**—Ammonium chlorid, intravenous. Carotid pressure tracing. Dog.

Intravenous Injection of Ammonium Chlorid.—The effects vary with the dose and the rate of injection. Marfori, 1893, described immediate tremors and twitchings, advancing to tetany, violent convulsions and opisthotonos; irregular respiration; salivation and emesis; somnolence and lassitude. The respiration shows momentary convulsive inspiratory standstill, followed by increased rate. This stimulation occurs even with small doses. Blood-pressure tracings (Fig. 28) show a temporary fall, then a slow but more lasting rise; with slowed rate and "vagus pulse." The rate may be quickened during the convulsions. These effects indicate stimulation of the respiratory, vasomotor, and vagus centers. If the injection is not promptly fatal the function recovers rapidly (Meneguzzi, 1923).

Cocere Action.—This is much weaker than with the organic ammonium bases (see above). Plant Tumors.—The injection of ammonium salts and a number of other substances produce tumor-like cell proliferations in plants (E. F. Smith, 1905). They are probably due to removal of growth restraining factors by lowering of surface tension, etc.

Reflexes from the Inhalation of Ammonia Vapors.—Through irritation of the sensory trigeminal endings, these produce momentary standstill, then increased breath; stimulation of the vasomotor center (str
AMMONIUM COMPOUNDS

of blood pressure); and vagus slowing of the pulse (in rabbits, vagus standstill).

Use for Medullary Stimulation.—Ammonia is one of the most effective means for stimulating the medulla reflexly. It may be used as the aromatic spirit of ammonia—15 to 30 drops in a tumbler of water; or as ammonium carbonate—smelling salts; in headache, fainting, collapse, excessive anesthesia, etc. Care must be used so that the unconscious patient is not made to inhale too concentrated a vapor.

Toxicology.—The neutral ammonium salts may produce gastritis. This would be treated by dilution and evacuation. Ammonia and the carbonate produce more violent irritation, and also inflammation of the respiratory passages. The mortality of ammonia poisoning is therefore high. If the patient recovers from the acute effects, pneumonia may set in; or the hoarseness or aphonia may last for months. The treatment consists in artificial respiration, weak acids and oils.

Preparations—AMMONIUM

*Spiritus Ammoniacus Aromaticus (Sp. Ammon. Arm.), U.S.P., B.P. (Aromatic Ammonia).—A solution of ammonium carbonate (4.4 per cent.), ammonia water (6 per cent.), and aromatic oils (lemon, lavender and nutmeg) in alcohol of about 60 per cent. (U.S.P.). The composition of the B.P. is similar. A nearly colorless liquid when freshly prepared, but gradually acquiring a yellowish color. Dose: 2 c.c., 30 minims, U.S.P.; 1 to 2 c.c., 30 to 60 minims, repeated; single, 4 to 6 c.c., 60 to 90 minims, B.P.; largely diluted.

*Ammon. Chlor., U.S.P., B.P. (Sal Ammoniaci; Salmiac), NH4Cl.—White crystalline powder; readily soluble in water; a strong odor of cooling saline taste. Dose: a minims in water (1:20), sol. in alc. (1:100); freely sol. in glyc. (1:8). Neutral or slightly acid to litmus. Incompatible with alkaline hydroxides or carbonates (liberation of ammonia); precipitates with Ag and Pb salts. Dose: 0.3 Gm. 5 gr. U.S.P. (0.3 to 1.2 Gm. 5 to 20 gr. B.P.)

Troch. Ammon. Chlor., U.S.P.—0.1 Gm., flavored with Licorice and Tolu.

Ag. Ammon. Fortior, U.S.P.; contains about 28 per cent. of ammonia; Lig. Ammon. Fortis, B.P., about 32.5 per cent.

Linimentum Ammon. (Lin. Ammon.), U.S.P., B.P.—A mixture of 1 part ammonium water and 3 parts of fatty oil (sesame, U.S.P.; almond 1, olive 2, B.P.).

Lin. Camph. Ammon. B.P. (Compound Liniment of Camphor)—12.5 per cent. of Camphor; 25 per cent. of Stronger Ammonia in alcoholic solution of Lavender.

Classification of Expectorants

These are remedies that modify expectoration and are therefore employed in the treatment of coughs. The successive stages of bronchitis present different indications, which are met by the various classes of expectorants.
The act of coughing is a coordinated reflex involving the respiratory center, and resulting in the sudden and violent expulsion of air from the lungs. It has a physiologic function in the removal of irritant substances or of accumulation of mucus from the respiratory passages. Like other reflexes, however, it tends to persist after its cause has ceased to be active; or it may become excessive. In either case it will require treatment. It must be borne in mind that cough is merely a symptom, and while it may be treated directly, as such, no treatment can be of permanent benefit unless it is also directed against the original cause, if this is still in operation. This cause lies most commonly in the respiratory passages, but there appear to be other conditions which may give rise to cough, or which at least may help in its production. The changes produced in the general circulation by drugs like digitalis, strychnine, or the strychnines are sometimes beneficial. When signs of disease are present in other organs (dyspepsia, etc.), these should receive direct treatment. General measures, such as laxatives, diaphoretics, antipyretics, analgesics, etc., must be used as the indications arise. Removal to a more suitable climate is often advisable, and sometimes necessary in chronic bronchitis. A dry climate is chosen if the secretion is profuse, and vice versa.

SEDATIVE EXpectorANTS

These are used, especially in the early stage of bronchitis, to soothe the acute inflammation, mainly by stimulating the secretion of the protective mucus. They comprise the nauseant expectorants, especially ipecac and antimony; more rarely aperomorphin, pilocarpin, lobelia, etc. (Senega, although a nauseant, is generally classed as a stimulant expectorant.) With the sedative expectorants may also be classed the demulcent expectorants, acacia, syrup, glycerin, glycyrhriza, demulcent herbs (species pectorales, breast-tea); the saline expectorants, ammonium chloride and potassium iodid; and the alkaline expectorants, ammonium carbonate, sodium bicarbonate or borate.

These saline and alkaline expectorants are also used in the other stages of bronchitis whenever the mucus requires thinning. The demulcents are useful throughout.

IRRITANT (STIMULANT) EXpectorANTS

These are employed in subacute and chronic bronchitis, to irritate the mucous membrane in such a way as to stimulate repair. They tend to diminish the excessive secretion usually present in these later stages. They are represented especially by the aromatic expectorants. The volatile oils, balsams and phenols, especially terpene hydrate, terebene, cubeta, santal, balsam of Peru, tolu, and styrex, cresote and guaiacol, tar, benzoates. The irritant senega and squill are also classed as irritant expectorants. Astringents are used when the inflammation involves the larynx or pharynx.

ANODYNE EXpectorANTS

These are represented mainly by the opiates, paregoric, morphine, heroin, and especially codein, all in small doses. These are used to depress the excessive cough reflex, especially if the secretion is scanty, and should not be employed when the mucus is excessive. They appear to diminish the secretion, presumably because the delay in its expulsion permits drying. Hydrocyanic acid was used in coughs to stimulate the respiratory center and perhaps for a local anodyne action. It is ineffective and obsolete. Small doses of chloroform are also employed.

SIMPLIFICATION OF EXpectorANTS

The great number of expectorants is not generally needed. The following suffice to meet the conditions in the most effective manner:

Against dry congestion: Syrup Ipecac, 1 c.c.; or Tartar Emetic, 5 mg.

Against thick secretion: Amnon. Chlorid, 0.3 Gm.; KI, 0.25 Gm.
Against excessive thin secretion: Terpene Hydrate, 0.15 Gm. in capsules.
Against irritation: Codein, 5 mg.; Alkaline gargles.

**EXPECTORANTS**

The syrups of tolu, of tar, and of wild cherry contain expectorant constituents, but their quantity is so small that they act merely as flavoring vehicles. The syrups of glycerrhiza and of acacia are also used.

**COUGH MIXTURES**

These polypharmaceutical preparations usually contain morphia and therefore give relief; but since they can not meet the special indications of the different stages, they should be avoided. The "Brown Mixture," whose activity depends on antimony and opium, is one of the best. This, and a few others, may be mentioned as illustrations.

**PREPARATIONS—COUGH MIXTURES**

(Syr. Scl. Co.—See Index).
*Syr. Pectoral, N.F.—Athana, Coltsfoot, Glycerrhiza, Anise, Mullein, and Orris. Used as Infusion 1:10 and Elixir.*

**CALCIUM SALTS**

**General Statement.**—The insoluble calcium phosphate and carbonate serve to give hardness to the bones and teeth. Their deficiency is one of the important phenomena of rickets and osteomalacia. Pathologic calcifications of arteries and other tissues are phenomena of degeneration; their mechanism is not understood.

The soluble Ca ions have equally important functions. They are present in all tissues, and appear to be essential to the proper permeability of the plasma membrane. Excess of Ca is depressant to most nervous and muscular functions, and is antagonistic to Mg and Na. These systemic actions are produced only on excised tissue or with intravenous injection, since the absorption of Ca is quite slow. It has been tried, with only partial success, in various spasmodic conditions.

Acute deficiency of Ca produces stimulation of these structures, most conspicuously of the central nervous system. This is seen in poisoning by oxalates, which precipitate Ca. It may also be produced by the intravenous injection of citrates or tartrates which decrease the ionization of Ca.

Calcium is also necessary for the coagulation of blood and for the typical clotting of milk. Calcium salts have therefore been administered in hemorrhagic conditions; but since these are not generally due to deficiency of Ca, it is questionable whether the additional Ca has any effect.

Calcium seems to decrease the permeability of blood and lymph vessels, and thereby to lessen exudation. It has been used with some success against serum rashes, etc. Calcium carbonate (chalk) is employed in diarrheas as antacid and protective; but it may also decrease the exudation directly. Lime-water (solution of calcium hydroxid) is added to milk to increase its alkality. Calcium oxide, quicklime, is a slowly acting caustic, and is used, as also the hydroxid or slaked lime, as disinfectant. Calcium sulphate, plaster of Paris, is important for its mechanical properties.
The calcium salts are also used for the actions of their anions (bromid, etc.). They are less rapidly absorbed, and perhaps less irritating than the corresponding Na salts.

**Distribution of Ca in Cells.**—Calcium is present in practically all cells and tissues. Only a few of the lower fungi are able to live without it. O. Loew, 1890, claimed that it occurred only in the nuclei and not in the cytoplasm of the cells. In support of this, Hoehammer, 1917, found it absent from the non-nucleated red blood cells (b叶), but present in the nucleated corpuscles of chickens. However, Macallum has adduced direct microchemic evidence that it is not in the nuclei proper, but in the nuclear membrane and cytoplasm.

**Calcium Income.**—The daily requirement for man has been estimated as 0.7 to 2.2 Gm. of CaO (5 parts of CaO = 3 parts of Ca). Ordinary diets contain 0.5 to 1.2 Gm. (according to Sherman and co-workers, 1919 and 1918). American diets yield 0.08 to 1.69; mean: 0.85 Gm.) It is therefore conceivable that the income may sometime be decreased by 1.5 per cent in the population. It is easily increased by drinking milk or by diluting the table-salt with an equal amount of chalk (McCollum, 1919). Only a part of the calcium is absorbed; Forster, 1889, estimates the absorption as about 60 per cent. It is stated that its utilization is better from meats than from vegetables. However, the calcium of carrots and spinach is said not to be as utilized as that of milk, and probably has no advantage over inorganic calcium salts (McClugage and Mendel, 1918). In fact, the inorganic calcium salts supply the needs as well as natural foods (Osborne and Mendel, 1918).

**Calcium in Milk.**—Adults require about 0.45 gram of calcium per day. This is fully supplied by a pint of milk, but would need pounds of meat or cereals. It is not generally realized that milk usually contains more calcium than does lime water (Sherman et al, 1918).

The calcium of milk seems to be more favorably retained than calcium lactates (Givens and Mendel, 1917).

**Calcium Excretion.**—This is automatically adjusted to the income, but the minimum quantity required to maintain equilibrium varies with the diet (Kochmann, 1916). Nelson and Williams, 1916, found the average daily excretion by urine and feces in man to total 0.4 to 1.2 Gm. of CaO (all ages, unrestricted diet). 0.15 to 0.5 Gm. per day are excreted by the urine, mainly as phosphates; the remainder leaves by the feces. It is believed (E. Voit, 1886) that a part of the fecal Ca is absorbed by the small intestines and re-excreted by the large. The administration of soluble Mg salts increases the urinary excretion of Ca, but not if phosphates are present in the alimentary tract (Hart and Steenbock, 1912). In human urine, either Ca or Mg may predominate, this being fairly constant for the individual, and largely independent of the food (Nelson and Burns, 1916).

**Hydropoemic injection of calcium, a large part is excreted promptly by the urine, a small proportion being temporarily retained. The intestines do not always participate in the excretion.** The output of Mg is also increased (Mendel and Benedict, 1906).

**Calcium Retention and Deficiency.**—The administration of Ca (chlorid or lacteal, several grams per day) increases the Ca stock of the tissues and blood, even in well-fed adults (Voorhoeve, 1911 and 1912).

Lactation depletes the Ca stock, in cows, even when Ca is added to the food (Forbes et al., 1912).

**Accidens en Ca Excretion.**—The Ca excretion is said to be increased in acidosis, and in epinephrin glycosuria (Underhill, 1916).

The oral administration of hydrochloric acid was said to increase the urinary excretion of Ca and Mg (Steibel, 1917). However, Givens, 1918, found that the Ca and Mg balance is not materially altered. Alkalies do not decrease the urinary Ca output in human diabetes (Givens and Mendel, 1917).

**Calcium Content of Blood.**—The corpuscles contain very little calcium; so that there is a marked difference between the calcium content of the whole blood and that of the serum. The calcium content of the whole blood therefore does not permit any conclusions as to calcium metabolism. The calcium content of the serum or plasma, on the other hand, is remarkably uniform (between 9 and 11 mg. of Ca per 100 c.c.); Halverson and Burch, 1917, even in most pathological conditions (Halverson et al., 1917). In rickets and especially in infantile tetany, there is a distinct, but still slight decrease (Howland and Marriott, 1917).
CALCIUM SALTS

In cows, Melges and Blatherwick, 1917, found the plasma calcium between 0.0066 and 0.0144 per cent.; practically unaffected by pregnancy, lactation, or considerable changes of diet (in very young calves, however, it is higher, up to 0.14 per cent.).

Explanation of Constancy.—Halverson et al., 1917, point out that the plasma is a practically saturated solution of calcium bicarbonate. The calcium content could therefore not be materially increased; whilst any loss of calcium would be made good by the solution of calcium from the bones.

Calcium Administration on Urine.—Calcium probably diminishes the permeability of the kidneys, and therefore diuresis. The effect is not great with ordinary doses, and probably varies with conditions, e.g., the ratio of Ca to other ions. The acidity of the urine is diminished since a part of the PO₂ is deflected to the intestines. This has been suggested as possibly beneficial in gout (v. Noorden, 1890), but the results are questionable.

The effect of Ca on diuresis is discussed by Porges and Pribram, 1908. Perfusion of the excised kidneys with Ca decreases the vein and ureter flow (Sollmann). The excretion of Cl is but little affected by Ca administration. Jacoby and Eiser, 1913, claim some increase of N, K, and W excretion. They state that it lessens greatly the excretion of sugar, acetone and N in phlorhizin dogs. It is said to prevent the uric acid increase after stophan administration (Abb. 1937). It prevents the glycosuria and fever of NaCl injections; but large doses of CaCl₂ may themselves produce glycosuria (Underhill and Kleiner, 1908). Wright and Koss, 1905, claimed that Ca cures orthostatic, but not renal albuminuria. This would need confirmation. Dürner, 1916, states that intravenous injection of calcium into rabbits converts a subacute uterine nephritis into the acute form. Calcium phosphate has been recommended in disease multibus, but has no effect even in the mildest cases (Bruning, 1898).

Calcium in Bone Diseases.—Rachitis and osteomalacia show deficient Ca content of the bone. Somewhat similar, but not strictly analogous changes, are produced by deficient Ca income in young animals. This suggested the treatment of these conditions by the administration of lime salts, particularly calcium phosphate. The results were disappointing; but it was found that the deficiency is not in the income, but in the assimilation of the Ca by the blood and by the bone-forming tissue.

Calcium-poor Diet.—If young animals are fed on such a diet, their bone formation is defective. The bones contain about the normal percentage of lime; but very little bone is laid down, and this is thin, pliable, deformed and fragile (E. Voit, 1885). It contains more water, Na and K, while the Mg is not materially increased. However, the percentages vary in different parts of the skeleton. The animals are underfed, with poor appeticte and defective nutrition (Weiser, 1914).

Mendel and Osborne, 1917, found that rats require considerable calcium and phosphate for growth.

In rabbits, the Ca content of the bones is increased by green food, diminished by exclusive oat diet (Laithian, 1912). The administration of sodium oxalate for a week diminishes the Ca content of the soft tissues before it affects the bones (Sarvonat and Roubier, 1911). If this diet is rich in magnesium, the bones may accumulate double the normal Mg content, but without improving the skeletal development.

Rachitis.—In this disease, the bone is even excessive, but is very poor in ash, as low as one-half the normal, and especially poor in calcium phosphate. The cause of this condition is controversy. It can not be due to deficiency of Ca in the food, for it occurs often in bottle-fed infants, who receive plenty of Ca (Stoelting, 1890). Zweifel, 1900, assumed defective absorption of Ca, but without good evidence. In fact, the absorption and excretion of Ca seem about normal (Rydel, 1853).

Howland and Marrott, 1917, found that the blood-plasma shows a distinct decrease from the average of 11 mg. of Ca per c.c. of normal infant blood, to 7 mg., in mild, and 4 mg., in severe cases of rickets. They believe that the retention of calcium is subnormal during the periods of exacerbation of the disease, and that a better calcium retention occurs during the periods of remission.

However, it is generally assumed that there is defective assimilation by the bones. The bone changes are probably a mere accidental phenomenon of the constitutional disturbance. Flawnicz, 1904, suggested a change in the absorption of Ca salts by the bone-matrix; but this is hypothetical. Sabban and Salvetti, 1913, investigated the precipitation of calcium carbonate in the presence of colloids.
The cases of rachitis being deficient assimilation and not deficient income of Ca, very little could be expected from the administration of Ca salts. This is also the verdict of clinical experience (M. Klott, 1915).

Osteomalacia. — In this disease, the bone contains but 20 to 40 per cent., instead of the normal 60 to 62 per cent. of inorganic salts, their place being taken by new formed osteoid tissue. The condition is also not ascribable to deficient Ca income, but to excessive destruction of bone tissue. Limbeck, 1894, found the excretion of Ca, especially by the intestines, to exceed the income. Neumann, 1906, also found the excretion high, especially in the early stages, when the Ca of the bones is still high. The latter's cases also show retention.

Infantile Scurvy. — There is a decided decrease of blood calcium, although not as much as in rickets. This is associated with slight acidosis. There is no tendency to tetany (N. F. Hess, 1910).

Menczewski, 1900, claims considerable loss of Ca in pernicious anemia.

Diabetes. — Kahn and Kahn, 1915 and 1916, find that diabetic patients have a negative calcium balance. They claim that the intravenous injection of calcium is diabetic patients, produces marked decrease of glucose excretion, gradual decline of the glycosuria, diminished urine output, and relief of symptoms; and that it appears to prevent the development of acidosis. They inject cautiously an m/8 solution of CaCl₂ in normal saline, from 15 c.c. upward.

Phosphorus Diabetes. — Jacoby and Rosenbloom, 1915, state that large doses of calcium diminish the excretion of sugar, nitrogen and acetone. The blood-sugar is also lowered, so that presumably the production of sugar is diminished.

Calcium Therapy in Phthisis. — This was recommended by Fourcroy, 1783. It has been tried repeatedly, on the assumption that phthisis is accompanied by excessive excretion of calcium. This has been affirmed by some competent observers, but does not appear to be an invariable phenomenon (Kahn, 1914). Mohler and Bergeim, 1917, found no characteristic changes.

The clinical reports are too discordant to justify faith in this treatment.

Intestinal Tuberculosis. — The intravenous injection of 5 c.c. of 5 per cent. calcium chloride, as described by Saxthorp, 1918. According to Fishberg, 1919, it relieves the diarrhoea and pain in minor grades. It is ineffective in the severe grades, and is at best only palliative.

Reproduction. — Emmerich and Loew, 1915, observed that administration of calcium to female mice, guinea pigs and rabbits was followed by increased number of pregnancies and higher average of the fets.

Degenerative Calcification. — This is a common pathologic process, especially in connective tissue.

The calcified areas are generally dead (except those that have the structure of bone). The lime deposits in the dead tissue have usually the same proportion of lime salts as bone, about 87 per cent. of phosphate, and to 15 per cent. of carbonate.

The mechanism of calcification is not understood. Klott, 1905, believed that it starts with fatty degeneration, the fats and proteins forming soaps, and these passing into Ca soaps, and finally into inorganic Ca compounds. Klott and Bothwell, 1915, describe fatty changes and deposition of calcium salts, especially in the capillary endothelium of the lungs of rabbits injected intravenously with olive oil or cholesteryl. However, this theory seems disproved by the experiments of Wells, 1906, and especially of Balfour, 1907.

Wells found that certain substances, including dead cartilage, when introduced into the tissue of rabbits, accumulated rather large quantities of calcium indicating a direct physiological affinity. He believes that the calcium exists in the blood, as a nearly saturated solution of an unstable double salt of calcium bicarbonate and calcium phosphate; and that is precipitated from this solution if the CO₂ tension is reduced.

Calcified Arteries. — MacCordick, 1913, finds the rigidity of calcified arteries different during life than after death, and therefore suggests that the Ca is in solution during life, and deposits in the plaques after death.

Intravenous Injection of Calcium Salts. — This lowers the blood pressure; paralyses the heart and respiration; arrests diuresis and peristalsis, etc. Hypodermic injections have similar, but much weaker and slower actions. Animals die of central paralysis a few days after the hypodermic injection of 0.3 to 0.4 Gm. CaCl₂ per kilogram. Oral administration does not produce these systemic effects.

Respiration of Mammals. — Schlick, 1911, described apparent stimulation in anesthetized animals. Hoffner, 1913, finds that this is indirect, due to failure of circulation from cardiac depression. The direct action is respiratory depression, which may be the cause of death.
Perfused Respiratory Center of Frog.—This was depressed by decrease of Ca, stimulated by absence or excess of Ca (Hooker, 1953).

Circulation.—Small doses, intravenously, sometimes increase the blood pressure and heart rate, while brief depression of the vagal center by Ca increases the heart rate and diminishes the blood pressure, by a mixed effect on the cardiac muscles and nerves (Cazzola, 1953). The small doses may considerably increase the output of the heart without changing the rate, i.e., by increasing the amplitude (Rothberger and Winterberg, 1912).

Calcium on Heart Muscle.—On the excited heart, Ca has a restraining action, antagonistic to Na; but complete absence of Ca rapidly abolishes rhythmic contracility. Absence of Ca also removes the rhythmic activity of other striped and unstriped muscle; and these reappear when Ca is added (Bulga, 1912). The effects are so rapid as to suggest that they must be exerted on the plasma membrane.

Other Earthy Metals.—Ba, Sr, Ca and radium emanations act identically on the isolated frog heart, the activity decreasing from barium in the upper order. Low concentrations increase the diastole, to diastolic standstill. Higher concentrations increase the systole to systolic standstill (Klonka, 1914).

Cardiac Vagus.—The presence of Ca is necessary for the inhibitory activity of the vagus (Schiff; Busquet and Pachon, 1909); but apparently not for muscarin (O. Loewi, 1913).

However, contradictory results are often obtained, the effects evidently being influenced by conditions. Thus, Brine, 1917 finds, contrary to the former workers, that calcium free solutions, or those poor in Calcium, do not interfere with the vagus excitability (inhibition in the perfused turtle heart).

A somewhat smaller concentration of Ca suffices in the presence of K (Hagan and Ormond, 1912). A moderate decrease of Ca increases the excitability of the vagus; excess of Ca diminishes the excitability (Cazzola, 1913). Similar phenomena are observed with the pelvic and chorda tympani nerves (O. Loewi, 1912). Increase of Ca also restores the irritability of the vagus when this has been depressed by Mg (Auer and Meltzer, 1909).

In complete heart-block injections of calcium (or barium) produce attacks of temporary arrhythmia and ventricular tachycardia, increasing to fibrillation. These attacks may be started by a group of powerful beats. The arrhythmia is larger in the same sense, but not as greatly. The blood pressure rises (Van Egmond, 1913).

Calcium Deficiency on Cardiac Drugs.—In perfused frog hearts, absence of calcium from the perfusing fluid does not appear to interfere with the typical action of epinephrin, aragonin, sarcopin, strophantin or veratrin.

Blood Vessels.—Hooker, 1911, found that Ca perfusion dilates the vessels of the frog. Pouchet, 1913, found Ca necessary for the vasoconstrictor action of epinephrin in perfused frogs; epinephrin in NaCl producing vasodilatation. Ca was not necessary to the vascular effects of curare, ergot, or barium. The conditions seem to be reversed in mammals, for Cow, 1921, found that the sensitiveness of arterial rings to epinephrin and pilocarpin was increased by absence of Ca; the reaction to barium was again unaffected.

Stripped and Smooth Muscle.—The rhythmic contractions, which are started in skelatal muscle when immersed in NaCl solution are abolished by Ca (Sidney Ringer, 1884). Calcium also has a curare action (Joseph and Meltzer, 1917). Excised bronchial muscle is constricted by Ca or Sr, though less than by Ba (Tredelenburg, 1912). Calcium arrests pituitary asthma (Kaysor, 1914).

Pupil.—Auer and Meltzer, 1909, observed that the intravenous injection of Ca produces a maximal miosis, in which the pupil is irresponsive to sympathetic stimulation. The simultaneous exhibition of other drugs shows interesting complex phenomena. The miotic action appears to be due mainly to direct stimulation of the sphincter muscle fibers, and probably also of their nerve-endings, supported by diminished irritability of the peripheral sympathetic mechanism.

Antagonism of Ca and Mg.—This was discussed on page 748. It should be remembered that the actions of Ca are conditioned on the ratio of other ions. Thus, the intravenous injection of Ca which is depressant to normal animals, causes recovery of an animal anesthetized with Mg. Strontium does not have this effect (Meltzer, 1909).

The Nature of Calcium Action and Antagonism.—This was discussed on page 748. Inactivation of Calcium.—The Ca in the body-fluids, and presumably in the cells, can be rendered inactive by the introduction of precipitant anions, such as the oxalates or fluorides; or by decreasing its ionization with citrates or tartrates (Sabbatani, 1901 and 1902). In the isolated heart, the toxicity is greatest for citrate, then oxalate, then tartrate (Salant and Hecht, 1914). In either case, the inactivation produces the op-
positive effects from Ca, viz., excessive stimulation, convulsions, hypersensitiveness of the autonomic nerves, and rhythmic contractions. Similar results are seen in intoxications by acids, As, Hg or chlorates, which probably all diminish the Ca content (Chaud and Froeschl, 1911). These effects may be promptly removed by the addition of Ca and less efficiently by Sr and Mg (Starkeinsein, 1914); but not by other cations, not even by those (Ba, etc.) which precipitate the oxalate. The stimulation is therefore not due to the oxalate, etc., as such, but to the inactivation of the Ca. This is confirmed by the observation that equimolecular solutions of the different inactivators have practically equal effects (Starkeinsein).

Salant and Hecht, 1914, describe some observations which they consider to contradict this explanation. They find in perfusion of the isolated heart that calcium citrate or tartrate solutions act practically the same as equimolecular calcium chloride. This, however, does not mean that the action, when already bound to calcium, does not disturb the ionization of the calcium in the tissues.

**Calcium Precipitants on Brain.—Direct application of calcium precipitants to the cerebral cortex, even when the white matter is left, increases the excitability of the gray matter to electric stimulation (Maxwell, 1900).*

* Use of Calcium in Convulsions.—The depressant action of calcium suggests its use in strychnin poisoning, but Fischer (1904) found it ineffective. Zandts (1905) obtained better results by dural injection; but the effective dose was so large as to be itself dangerous. Januske and Masslow, 1914, conclude that even large doses of calcium have no direct inhibitory effect on experimental convulsions, whether cerebral, medullary or spinal. The apparently successful results of Januske, 1913, and presumably those of Yogi, 1912, and other workers, are attributed to delayed absorption of the hypodermic injections of the convulsant, which results from previous calcium treatment.

**Parathyroid Tetany.—Netter, 1907, reported success from calcium-chlorid administra-
tion in tetany. This has been confirmed for gastric tetany by Klinicult, 1909, and for parathyroid tetany by W. G. MacCallum and Voegtlin, 1908; Carlson and Jacobson, 1910, and others. MacCallum and Voegtlin believed that the parathyroids control the retention of Ca; that their loss resulted in a diminished Ca content, espec-
ially the plasma, and that the administration of Ca replaced acts are seen in intoxica-
tions, even others could not find any diminution of the Ca (Cooke, 1910); and the Ca admin-
istration probably acts only by lessening the nervous irritability.

The administration of the parathyroid hyperplasia, which is produced in foetal by a diet of maize and wheat, is retarded by feeding calcium, accelerated by sulphuric acid or neutral sulphur.

**Infantile Tetany.—Goepert claims suppression of the frequent convulsions by calcium chloride, 8 to 14 Gm. daily, in doses of 1.5 to 2 Gm. The administration must be continuous, for spasms reappear if it is discontinued for twelve hours (M. Klotz, 1911).

The results would be explained by the observation of Howland and Marriott, 1917, that the Ca content of the plasma is always lowered in this disease; convulsions appear-
ging generally when the content is half the normal. The oral administration of Ca increases the percentage in the blood (from a mean of 4.45 mg. per 100 cc. of plasma to 8.15 mg.), and arrests the convulsions. Grunefelder, 1913, reports that larynge-
ospasm and tetany are controlled more promptly by calcium bromid (2 Gm. per day) than by NaBr.

In *guanidin tetany*, Watanabe, 1918, claims that the blood serum contains about the normal amount of calcium; but that the phosphate content is markedly increased.

**Control of Inflammations by Calcium.—Ca salts, even when adminis-
terated systematically, seem to lessen the inflammatory phenomena, espe-
ially the tendency to effusion. This is presumably due to decreased permeability of the vessel walls, analogous to the effects of Ca on other cells.

**Effect of Calcium on Effusions.—R. Chiriac and Januske, 1910 and 1914, found
that the hypodermic injection of Ca prevents the pleural effusion which ordinarily oc-
curs after fatal doses of NaI, diphteria toxin, thorinsamin, etc. It also prevented the inflammatory edema of the conjunctiva after oil of mustard or arsen; and the irritation of the skin by croton oil (Luithlen, 1913). It has been found similarly useful in various skin rash, and it is seen that these results were contradicted by Levit, 1911 and 1914, but con-
filed by Leo, 1912. The effect of a dose lasts about a day. Fleisher, Hoyt and L. Loeb, 1909, also found that CaCl2, intravenously, decreases the elimination of injected sodium chloride, not only by the kidneys, but to a lesser extent also by the intestines. It also causes some depression of intestinal absorption. On the other hand, it increases the tendency to peritoneal and pulmonary transudation. This is only partly due to
interference with the kidney function, for the ascitic tendency is exaggerated by Ca even after nephrectomy. Calcium has also been found unsuccessful in clinical serious effusions. Velden, 1913, suggests that it lessens the absorption of the ascites more than its formation.

Yanagawa, 1916, did not obtain any effect on the lymph line; but his observations were restricted to very acute changes.

**Mechanism of the Antidemic Action.**—Luff, 1909, attributed the effect of Ca to increased coagulability of the blood. However, Chiari and Januschké found it effective even when the blood was kept non-coagulable by hirudin. They suggest that the Ca has a precipitant effect on the cement substance of the endothelium but more probably, the permeability of all the cells is decreased. Deltjen (1904) has observed that small traces of calcium, strontium, bariun, and magnesius lessen the solvent action of distilled water on cells. Herbst found that sea-urchin ova swell when Ca is removed, and shrink when it is added. Osterheurt, 1911 and 1913, showed that CaCl₂ prevents the entrance of NaCl into spirogyra filaments, and that it renders the plasma membrane of help (laminaria) impermeable. Pfeffer, 1877, stated that calcium phosphate forms semipermeable membranes. These have been investigated in further detail by Menge, 1915. The changes in the appearance of fluorescein in the anterior chamber of the eye also indicate decreased permeability (G. Roseow, 1916).

The emulsion experiments of Clove, 1916, offer a possible explanation of the diminished permeability (see Emulsions, Index).

**Phagocytes** may also play a part. H. J. Hamburger, 1919, found that therapeutic quantities, hypodermically or by mouth, increase the ameboid movements of the leukocytes, and therefore chemotaxis and phagocytosis.

This holds true for the leukocytes of rabbits as well as horses (de Haan, 1918); for bacteria as well as carbon. It requires the presence of serum, and the favorable concentration has a narrow range, which varies with conditions and for different organisms (Redden, 1919).

On the other hand, Ikeda, 1916, reports the migration of leukocytes from inflamed frog's mesentery, as inhibited by calcium chlorid.

**Peripheral Aesthetics on Inflammation.**—Januschké, 1913, finds that the mustard chemon can also be checked by all drugs which paralyze the sensory trigeminal endings; and this independently of the central nervous system.

**Use of Calcium in Skin Rashes, Catarrh, etc.**—Wright, 1896, found that the administration of calcium chlorid tends to prevent the occurrence of skin rash. Netter, 1927, also found it useful in urticaria, acute edema, frost bite, and pruritus. Other similar conditions relieved by Ca are boils, erythema, lichen planus, hemoglobinuria, etc. (Luff, 1900); hay fever and iodid corzya (Chiari and Januschké, 1911, Emmich and Loew, 1915); asthma (Kayser, 1912, 1914). The beneficial results are clinically rather unreliable, but have been repeatedly confirmed, provided that the Ca is given in adequate doses for a sufficient time.

Strong solution of CaCl₂ (10 per cent.) applied to the scarified skin, raises an urticular wheal (Pilcher and Sollmann, 1916).

**Effects of Various Conditions on Skin Reactions.**—Luithlen, 1911 to 1913, studying the reaction of the skin of cats to croton oil, found that this may be modified by Ca and oxalates; by different diets (suggesting that excema may be a constitutional exaggeration of the reaction of the skin to normal irritation); and by the injection of serum, soluble starch and even mineral colloids, i.e., silica. Serum injections have been used clinically against certain skin diseases (A. Mayer and Linser); but are only efficient in those diseases which are based on excitation or transudation.

**Calcium on Intestines.**—Calcium carbonate, and to a smaller extent the phosphate, have long been used in diarrhoea. Their action is generally explained as antacid and protective, but it is possible that the depressant ion-action comes into play.

**Subile Calcarites.**—Chiari, 1916, calls attention to the fact that all the cathartic ions are antagonistic to Ca; and that this may explain their action, at least partly.

**Excised Intestine.**—Vanysek, 1914, states that calcium chloride stimulates the circular and relaxes the longitudinal muscle of cat's intestine.
Calcium in Hemorrhage.—Ca is necessary for the action of thrombo-
kinese on thrombogen (or for the conversion of prothrombin into throm-
bin—Howell, 1914) and hence for the coagulation of the blood. It has therefore been thought that the administration of Ca would be useful when it is desired to increase the coagulability of the blood, as in persistent hemorrhages, aneurism, hemophilia, purpura, etc. However, the normal content of Ca in the blood is more than is required for coagulation; further increase in Ca does not increase the coagulability. The addition of calcium to hemolytic blood in vitro delays rather than hastens its coagulation (Hess, 1915). Nor has it been shown that Ca is deficient in any of these conditions.

Estimations of the coagulation time after administration of Ca have given contradictory results, due partly to differences of technic, partly to the time when the observations were made. The experiments of Veldes, 1913, indicate that the coagulability is indeed increased for a short time. This increase is also produced by equal quantities of NaCl, and is probably due to a local action on the alimentary canal. It does not last beyond twenty or thirty minutes, and would therefore be useless. However, since the administration of Ca does no harm, its use may be permissible. Any benefits in purpura (Russel, 1907) could perhaps be explained by its action on the permeability of the vessels.

With hirudin plasma the coagulation is further delayed by the addition of calcium (Hess, 1915).

Clinical Data.—The use of Ca in hemophilia was started by Wright, 1893, who claimed a reduction of the coagulation time to 60 to 70 per cent. Colemann, 1907, found no effect on oral administration, but shortened coagulation time from hypodermal injection. Purely negative results were obtained by Robertson, Illmen and Dandrie, 1907; Addis, 1909; Rudolph, 1912; Dale and Laidlaw, 1912; and Hess, 1915. In obstructive jaundice, when blood coagulation is delayed by excess of bile in the blood, Lee and Vincent, 1913, report restoration of the coagulability by calcium lactate (17 Gm. per day).

The theories of hemophilia are reviewed by Hurwitz and Lucas, 1916. Kahn, 1916, reports one case where deficient calcium content of the blood

Other Substances Increasing the Coagulability of the Blood.—Gelatin, kaphalin and serum are discussed elsewhere (see Index). Veldes, 1911, also found increased coagulability after the digitalis group, suprarenal extract, and amylnitrite.

Coagulation of Milk.—Ca is necessary for the precipitation of the caseinogen as casein.

Rigor Mortis.—This is hastened by the systemic administration of Ca, delayed by Mg (Meltzer and Auer, 1907).

Oral Administration for Systemic Action.—Calcium carbonate and phosphate are absorbed almost as well as any of the calcium salts, since they are largely converted into soluble salts in the digestive tract (O. Loew, 1912). They should therefore serve quite as well for oral administration, as the water-soluble salts, viz. the chlorid, lactate or acetate; but as these happened to form the starting point of the modern calcium therapy, they are still generally prescribed. The chlorid is less costly, but its taste is rather more disagreeable than that of the lactate or acetate.

The single oral dose of the chlorid is 0.5 to 1 Gm., 8 to 15 gr., in solution, with meals. The daily dose against serum rash is 0.75 to 1 Gm., beginning on the day of the antitoxin injection, and continuing for three days after the last injection (Netter, 1909). Against hay fever, hemorrhage, etc., 1 to 3 Gm. are given daily, commencing as early as possible and continuing for several weeks. This continued use does not seem to cause harm (Emmerich and Loew, 1913, 1915). The lactate may be given in double this dosage.
HYPODermic Administration.—This has no material advantage. The lactate is preferred to the more irritant chlorid; at least, the chlorid should not be used in concentrations above 2 or 2 per cent. or there will be indurations. The concentration of the lactate should not exceed 5 per cent. since stronger solutions solidify (Hugenholtz, 1912). The hypoDermic Dose of the lactate is 0.5 to 2 Gm. in 20 to 50 c.c. of water. Intravenous injections have been employed in spasmodic conditions; 2 to 4 Gm. of the chlorid or lactate in a liter of normal saline, injected very slowly.

PREPARATIONS—CALCIUM

Calcium Carbonate Precipitatus (Calc. Carb. Precip.), U.S.P., B.P. (Precipitated Chalk). CaCO₃.—Fine white powder, without odor or taste. Practically insol. in water; decomposed by acids. Dose, 1 Gm., 15 gr., U.S.P., as powder. This will neutralize 0.75 Gm. absolute HCl. Larger doses are harmless. Dose, B.P., 1 to 4 Gm., 15 to 60 gr.

Creta Preparata (Cret. Prepar.), U.S.P., B.P.; Prepared Chalk (Drop Chalk).—Natural Calcium Carbonate freed from most of its impurities by crystallization. A white to grayish-white, very fine, amorphous powder, often formed into conical drops; odorless and tasteless. Almost insol. in water; insol. in alc. Dose, 1 Gm., 15 gr., U.S.P.; 1 to 4 Gm., 15 to 60 gr., B.P. Used extensively in tooth-powders.

Mist. Cret., U.S.P., B.P.; Chalk Mixture.—The average dose, 15 c.c., 4 drams, contains about 3 Gm. of Comp. Chalk Powder suspended in CIMANIN Water, U.S.P.; 3 per cent. of chalk, B.P. Dose, 15 c.c., 4 drams, U.S.P.; 1 to 30 c.c., 1/2 to 1 ounce, B.P.

Puls. Cret. Ca., U.S.P.; Compound Chalk Powder. A mixture of 30 per cent. of Cret. Prepar.; 20 per cent. of Arcasia; 30 per cent. of Sugar. Dose, 2 Gm., 20 gr., U.S.P.

Puls. Cret. Arom., B.P.—25 per cent. of Chalk; 20 per cent. of Sugar; with Aromatics. Dose, 0.5 to 2 Gm., 10 to 50 gr., B.P.

Calcium Chlorid (Calc. Chlor.), U.S.P., B.P.; Calcium Chlorid (not to be confused with Chlorinated Lime, miscalled "Chlorid of Lime"). CaCl₂.—White, transparent, hard fragments, or granular; odorless, of sharp saltness taste. Very deleterious, and should therefore not be dispensed in powders, but as solution. Freely sol. in water (1:10) also in alc. (1:10). Incompatible with carbonates, phosphates and sulphates. Dose, 0.5 Gm., 8 gr., U.S.P.; 0.5 to 1 Gm., 5 to 15 gr., B.P., diluted. It may be made non-hygroscopic by the addition of lactose. (Yearbook, American Pharmaceutical Association, v. 5, p. 298).

Calcium chloride occurs with varying quantities of water. The content of CaCl₂ is 100 per cent. In the anhydrous, about 75 per cent. in the fused, and 50 per cent. in the crystals. The U.S.P. specifies a minimum of 75 per cent. The B.P. is dried at 200°C.

Calcium Lactate (Calc. Lact.), U.S.P., B.P., Ca(H₂O)₆₆₋₆H₂O.—White, granular masses of powder, without odor or taste. Sol. in water (1:20), but very slightly sol. in alc. Dose, 0.5 Gm., 8 gr., U.S.P.; 0.5 to 2 Gm., 10 to 50 gr., B.P.

Syrup. Calc. Lactophosph., U.S.P., B.P.—2.5 per cent. of calcium carbonate dissolved in syrup with lactic and phosphoric acids, U.S.P.; 7.5 per cent. of Calc. Lact. with phosphoric acid, B.P.; orange-flower flavor. Dose, 10 c.c. 2/5 drams, U.S.P.; 2 to 4 c.c. 1/4 to 1 dram, B.P.

Calcium Phosphates, B.P., Ca₃(PO₄)₂.—White powder, insol. in water, sol. in acids. Dose, 0.5 to 1 Gm., 3 to 16 gr., B.P.

(See Index.)

STROMIUM

This cathion resembles calcium, and may take its place in some of its characteristic pharmacologic relations; but it is much weaker and also less toxic. Strontium possesses no therapeutic indication.

Like Ca, strontium hastens the coagulation of blood although it is much weaker (Howell, 1914). This action is not shared by Ba or Mg. In dilute solutions only very small amounts are absorbed from the stomach; none from the intestine, since it is converted into phosphates, in which form it is also generally deposited in the bones. The urine contains only traces of strontium, even if this is given subcutaneously; the excretion occurs mainly by the intestine (Wood, 1898). It increases the elimination of uric acid. Its administration to young animals is instrumental in the bone formation. The osteogenetic tissue is stimulated, but the bones are imperfectly cal-
cited, since the Ca is deficient and the Sr is deposited very imperfectly (Lehnerd, 1909 and 1913).  

Strontium Salts.—Strontium salts were formerly used mainly on the supposition that the actions would be more slowly absorbed, and would therefore have a more gradual and milder action. This theory is without foundation. Iodid, for instance, is absorbed with the same rapidity as from the potassium salt. (Krakulik and Pflüger, 1918); and the "toxic" effects of strontium salicylate are just as pronounced as with the sodium salt (Blankenhorn, 1916).

PREPARATIONS

Strontium Bromid, Iodid, and Salicylate are official. Their dose is that of the corresponding calcium salts.

Strontium Lactis.—Soluble in 4 parts water. Dose, 1 to 8 Gm. (1/4 to 2 drams).

OXALIC ACID AND OXALATES

Oxalic acid and the oxalates possess a strong acid action, resulting in local irritation and corrosion. In addition, they produce violent stimulation, and later paralysis, by depriving the tissues of their calcium through precipitation. These actions are completely antagonized by the addition of Ca. The oxalates have some toxicologic importance but no therapeutie interest. The small quantities which occur in many vegetables (rhubarb, etc.) are ineffective.

Lower Organisms.—Oxalates are toxic to all life except to a few lower fungi which do not contain calcium. They are toxic to most plants, but certain species contain soluble oxalates. In algae the main histologic changes are seen in the portions richest in calcium—nucleus and chlorophyll (O. Lowy, 1912). Oxalic acid is probably a constant product of metabolism, and possibly one of the functions of calcium is to render it harmless.

Actions on Peripheral Autonomic Nervous System.—The oxalates act like deprivation of Ca; i.e., they increase the sensitiveness to epinephrin and pilocarpin; but they diminish the excitability to electric vagus stimulation (Chiari and Frolich, 1911).

Skeletal Muscle.—If dilute solutions of oxalates are applied directly to skeletal muscle, they cause rhythmic contractions. Lessening the proportion of Ca by any other means has the same effect. Larger doses of oxalates depress the excitability and force of the skeletal and cardiac muscles.

Frog's Heart.—Injections of oxalate produce slowing and weakening; with strong concentrations prompt diastolic arrest, first of the ventricle, then of the auricles. The can be removed completely by rinsing with Ca solution (Janschke, 1909). Washing with NaCl alone gives much poorer recovery (Gros, 1913). Similar effects are seen with perfused mammalian hearts (Salant and Hecht, 1915).

Intact Frogs.—These show progressive and descending loss of reflexes; fibrillary twitchings; central paralysis; finally cardiac arrest. This is also promptly removed by Ca and Sr.

Intravenous Injections in Mammals.—The oxalates affect first the central nervous system in its whole extent, from mental functions to reflexes, producing at first stimulation, with convulsions, and then paralysis, the latter being the more conspicuous with large doses.

The medullary centers are especially affected. In consequence of the 

epileptiform 

produced in this manner they cause glycosuria, and possibly through the same cause indicanuria. The temperature rises. Death occurs from respiratory paralysis, excepting when the poison is injected directly into the circulation, in which case it may paralyze the cardiac muscle (slowed heart and fall of blood pressure, v. Wiesinghoef-Scheel, 1901; Starkenstein, 1914). In excited intestines, the calcium precipitants increase the tone and the pendulum movements (Starkenstein).

Oxalates, injected with Mg, increase the anesthetic effect, presumably by inactivating the antagonistic Ca (Gates and Meltzer, 1914).

Fate and Excretion.—Oxalates are very resistant to oxidation in the animal body. Indeed, there has been some question whether any is burned; but it seems certain that a limited amount is oxidized. The excretion (92 to 95 per cent. after hypodermic injec-
OXALATES

Tions) occurs almost completely by the kidneys. The fresh urine contains mainly oxaluric acid, CO₃H₂CONH₂ but on standing, this decomposes into urea and oxalic acid; and this forms calcium oxide. This is almost insoluble and occurs as envelope-shaped crystals, which are diagnostic of oxalate poisoning. The crystals may be excreted in such great amounts as to block the urinary tubes, and may thereby possibly lead to nephritis, or retention of urine and uremia. Calcium oxalate, in seed-shaped crystals, may be found in all the organs, but it may be absent from these in very acute poisoning (Münsen, 1885).

**Oxalate Poisoning.**—When taken by mouth, the oxalates are readily absorbed, and poisoning is not at all infrequent from confusion with other salts. The symptoms are: first, those of a local caustic, especially when the acid was used; then those of collapse, the latter possibly preceded by convulsions. The pulse is very small and weak.

**Death** by oxalic acid and oxalates usually occurs very rapidly, much more quickly than by other caustic substances. This is of diagnostic importance. (In one case death took place in ten minutes.) Sometimes fatal collapse may occur after hours of relatively slight symptoms (O. H. Brown and Scott, 1912). (A study of seventeen human cases of oxalic acid poisoning is reported by Wichern, 1922.) The fatal dose varies with the concentration. The smallest recorded amount is 5 Gm. Metabolism is markedly depressed in oxalate poisoning, especially the production of carbonic acid. The respiratory quotient falls (Corley, 1902). The urines in Wichern's cases were scantly, with traces of albumin, and rarely calcium oxalate crystals. Polyuria developed later. Hemorrhagic nephritis was not observed.

**Treatment of Oxalate Poisoning.**—The chemic antidote would be calcium in any shape, calcium chlorid and lactate, chalk, lime-water, etc. (Husemann). Liberal quantities of water should be given to prevent the deposition of crystals in the kidneys. Calcium lactate could also be given by vein; magnesium sulphate as cathartic; digitalis against collapse.

Experimentally, magnesium injection has proven of some value by quieting the stimulation (Gates and Melzer, 1917; Gates, 1918). **Cumulative Action.**—This is observed after continued feeding of rabbits with oxalates or citrates (Salant and Swanson, 1918).

**Rhubarb Leaf Poisoning.**—Serious and even fatal poisoning has been attributed to the eating of boiled rhubarb leaf "greens." The leaves contain about 10 grains of oxalate per pound, and this has been held responsible for the poisoning (J. A. M. A. 1917, 68: 1928, 1929, 72: 596). The connection appears rather doubtful. **Oxalate Content of Vegetables.**—Data are given by Arbens, 1917.

**PREPARATIONS—OXALATES**

**Acidum Oxalicum, C₂O₄H₂.**—Colorless crystals, easily sol. in water.

**Acid Potassimi Oxalatum, K₂C₂O₄.**—"Salt of Sorrel."

---

**FLUORID ION**

Sodium fluorid is a general protoplasmic poison. It has a strong local irritant action, a 2 per cent. solution being corrosive to mucous membranes. The systemic action resembles that of the oxalates and is probably produced in the same manner, by the formation of insoluble calcium salts.

In the frog, it produces fibrillary contraction of the muscles. These disappear on section of the nerve. Larger doses produce rigor. The systemic effects are dyspnea, loss of reflexes, stoppage of respiration, cardiac standstill. In mammals it causes salivation, gastroenteritis, dyspnea, muscular weakness and tremors, epileptic convulsions,
fall of arterial pressure, and stoppage of respiration and heart. Rigor sets in quickly (Tappeiner, 1885). The abdominal organs are congested. The intestinal epithelium is destroyed (even when the poison is introduced by other channels), while the cilia of the respiratory epithelium may still be moving (Siegfried, 1901). Small doses poison the blood vessels, first increasing their permeability (Asher, 1910).

Acute Fatal Dose.—For mammals, this averages about 0.5 Gm. per Kg. of body weight, by mouth; about 0.15 Gm. per Kg. hypodermically or by vein (Tappeiner, 1885).

Continued Administration.—When sodium fluorid is administered to rats over prolonged periods (Sollmann, 1921) in daily doses of 15 to 100 mg. per Kg. of body weight, it produces progressive impairment of growth and food consumption, but with little mortality; and without any histologic lesions.

The damage is proportional to the dose. It tends to outlast the administration of the drug; so that the growth of animals that have been poisoned with fluorid remains permanently below that of unpoisoned animals.

The diminished food consumption is not due to distaste of the fluorid food; for the animals do not prefer unpoisoned food (except with the highest concentrations).

The effects are not due to "general salt action" for corresponding doses of NaCl are not harmful.

Calcium fluorid in the form of "phosphate rock" produces the same effects as NaF and in nearly corresponding doses.

The deleterious effect of phosphate rock is not shared by other insoluble Ca salts (phosphate and carbonate) in equal concentration.

No deleterious effects on growth or food consumption occurred in nine weeks with daily doses of NaF of 8 mgm. per kilogram of body weight, or with smaller doses.

Similar effects from analogous doses have been observed by other writers on other animals, with similar doses. (Literature, Sollmann, 1921.)

Deposition in Bone and Normal Occurrence.—When fluorids are given in small amounts, greatly diluted, they are absorbed and deposited for the most part in the bones (Tappeiner and Brandl). The bones become unusually hard, white, and brittle, and contain small crystals, presumably CaF2. A small amount of the latter is normally contained in the bones and teeth (Gabriel, 1893); but the percentage (0.02 to 0.09) is so small that it can not be regarded as essential (Joebelner, 1901). Still smaller quantities are found in the epidermis, hair, thymus, testes, blood, milk, etc. (Gaurier and Clasmann, 1913, 1916).

Zalazek, 1910, found it present in the entire human body, but relatively richest in the liver, kidneys and bones. In the latter, half of the fluorin is in their fat.

Antiseptic Action.—The fluorids are quite markedly antiseptic. In the proportion of 1:2000 they prevent completely the development of bacteria, and are sometimes used for this purpose. They have no important therapeutic application, and small histologic importance.

Ammonium Bifluorid in Dentistry.—This was introduced by J. Head, 1913, for the treatment of pyorrhea alveolaris. He uses a 23 per cent. solution, injected once or twice weekly around the loose teeth. It is antiseptic and desintegrates the "tartrar.

Hydrofluoric Acid is a very violent volatile caustic. The burns suppurate, and heal very slowly.

Sodii Fluoridum (Sodium fluorid), NaF.—Soluble in 35 parts of water. Used externally as antiseptic. For dressings, 0.3 to 1:1,000; injections, 0.25 to 1:1,000; against fermentation in food, 10 to 15 mg. per liter. 0.25 Gm. is said to have produced dangerous symptoms in man.

BARIUM

Unlike the other elements of its group, Ca and Sr, this element is very toxic. Its effects resemble those of the digitals group; it produces a similar action on the cardiac muscle, a strong vasoconstriction by direct stimulation of the arterial muscle (occurring therefore after apocadine, Dixon, 1903); violent stimulation of peristalsis, even on intravenous injection; and a stimulation and later paralysis of the central nervous system. It also produces local irritation, and is inimical to the lower forms of life, such as yeast cells.
These actions are not utilized therapeutically (except in veterinary practice) on account of the toxicity. The excretion of barium occurs largely by the feces, as with Ca and Sr.

Its local action results in gastroenteritis and some degree of corrosion, and fairly large absorption. It may, therefore, produce its systemic actions even when given by the mouth. Poisoning is treated by sulphates and evacuation.

Excretion.——The main channel is by the intestine, only traces appearing in the urine when barium is given per os. After intravenous administration (G. M. Me Br., 1909), a small amount may be excreted in the bones. Barium lessens the elimination of uric acid (Abish, 1913).

Cardiac Action.——Ba, like digitalis, increases the excitability of the cardiac muscle, and the force of the contractions (Worthington and Boulet, 1917). The rate is slowed ven after atropin, so that this effect is muscular (Fillip). Intracardiac application causes systolic arrest; dilute solutions, or exocardiac application, produce diastolic arrest, just as does digitalis (Pousson, 1910; Werschin, 1911; Weyland, 1913). The effects in complete heart-block are similar to those of calcium (van Egmond, 1913).

Arterial Muscle.——The high rise of blood pressure under barium is due mainly to vasocostriction. The effect is directly on the arterial muscle, and involves all arteries, regardless of their innervation (Dixon and Halliburton, 1910; Cow, 1911). This might suggest its use in pulmonary hemorrhage; the lung vessels being strongly constricted (Barch and Pick, 1913; Berrizin, 1914). However, the increase of the general blood pressure more than offsets the local constriction, so that the bleeding becomes more profuse (E. Frey, 1909). The liver veins are constricted in the guinea pig, not in the dog (Berrizin, 1914).

Bronchial Muscle.——This is also constricted (Trendelenburg, 1912; Titose, 1915; acth and Pick, 1915-16).

Gall-bladder.——The isolated organ is constricted (Lieb and McWhorter, 1912).

Skeletal Muscle.——Barium has two distinct actions of frog’s gastrocnemius muscle (Soethoudt, 1910): (a) Fiber stimulation, persisting as long as the muscle remains in the solution. This requires the presence of Na ions, and is therefore abolished by isotonic sugar solution. (b) Contact irritability, seen only when the muscle is immersed or removed from the solution, being produced by the inward or outward passage of Ba ions. It is antagonized by certain Na salts.

Both irritations are antagonized by K, Ca and Mg ions.

Fetal Muscle.——Injection of BaCl2 produces only an increase of muscular tonus in the normal leg, but after denervation, it causes a strong contraction. The degenerating muscle has therefore become more susceptible to Ba. A similar result can be secured by preliminary injection of nicotine. Curare does not influence this contraction; indicating that Ba acts more peripherally than curare, nicotine or physostigmin.

Cerebral Stimulation.——Direct application of barium salts of the cerebral cortex simulates the white matter, and increases the irritability of the gray matter (Maxwell, 1902).

Therapeutic Uses.——Barium chlorid (0.03 Gm., 1/2 gr., well diluted) has been tried as a substitute for digitalis (Pesci, 1904). It is therapeutically inferior; by producing marked coronary vasocostriction. The maximal daily dose is 0.5 Gm., 1/4 gr.; this is dangerous (Reports Conc. Pharm. Chem., 1911-14). It has also been tried in various nervous disturbances; and externally, 10 per cent. solution, as a wash in cutaneous eye affections. In veterinary medicine, it has been used for acute tympanites of the sinuses, but even then it was found too dangerous.

Symptoms of Barium Poisoning.——These consist in vomiting, colic, violent diarrhea, convulsive tremors; slow heart pulse and high blood pressure; hemorrhages into the stomach, intestines and kidneys. Death occurs after a few hours or days. The total dose is probably 0.5 to 0.0 Gm. Barium carbonate is also toxic, but much slower in action. Crawford, 1908, attributed “Loco poisoning” to the Ba contained in the Western plants. This could not be confirmed (Alberg, Black and Marsh, 1912).

X-ray Diagnosis.——The insoluble BaSO4 is used in X-ray diagnosis. It is tasteless, incompressible, and does not delay the gastric movements, as does Radium. If pure, it need not be contaminated with soluble barium compounds (Geuenter and Bachem, 1911; Merck’s Report, 27:42).
BROMIDS

General Statement.—Fairly large doses depress the psychic functions and the reflexes; leading to a condition of mental dulness and apathy, which conducts to sleep, particularly in nervous insomnia. The bromids are also employed against other nervous hyperexcitabilities, hysteria, hyperemesis, cinchonism, etc. Their anticonvulsant action is utilized especially against epilepsy. They generally suppress or mitigate the convulsions, at least in the idiopathic form; but they seldom, if ever, cure. The effect occurs only slowly, and is correspondingly lasting. The administration must be fairly continuous. The action seems to be due to the Br ion as such. It is produced by all the bromids, and to a less degree by the organic bromin compounds. NaBr is generally preferred. The mechanism is not explained. The excretion of Br is analogous to that of Cl. A part is retained very persistently. The elimination is hastened by Cl administration; and conversely, the Br effect is increased by Cl-poor diet.

Continued administration of large doses often results in bromid acne, and other symptoms analogous to iodism. There may also be considerable psychic depression, malnutrition and lowered resistance. These may contraindicate the use in neurasthenic patients, etc. Acute bromid poisoning is rare, occurring only after enormous doses. Ordinary doses have no effect on the circulation.

Absorption.—The bromids are rapidly absorbed from mucous membranes. It was believed that calcium bromid is absorbed more slowly; but Hales and Fishman, 1908, found it excreted at about the same rate as NaBr. In ligated intestinal segments, the absorption of bromids is not delayed by the presence of chlorid; but bromid somewhat delays chlorid absorption. The lower segments of the small intestine are said to absorb bromid better than the upper (Bolgar, 1910).

Channels of Excretion.—The excretion occurs as bromid, mainly by the urine. Small quantities are also eliminated by the feces, sweat (Tachau, 1912) and other secretions; sometimes in the cerebro-spinal fluid (Hald, 1911).

Course of Urinary Excretion.—This starts promptly but proceeds slowly; it is one to one and one-half days only one-tenth may be excreted; and traces are found after twenty days. The rate is only half or less than with iodids (Hersefeld and Gormide, 1917). It depends somewhat on diuresis, but only imperfectly (Hales and Fishman, 1908). The quantity excreted is proportional to that administered, but always with considerable retention. With continued use, the percentage excreted increases until it equals the ingestion, constituting equilibrium or saturation for that dose. When the administration is stopped, the excretion diminishes; at first rapidly, then more slowly, so that traces may be present for a month or longer. The excretion follows the same laws in epilepsy as in normal individuals (v. Wyss, 1906).

Influence of Chlorids.—Chlorid administration hastens the elimination of both Br and I. Hersefeld and Gormide, 1912; Wyss, 1913; while Ch-poor foods slow the excretion (Honda, 1902; Sarvonat and Cremien, 1911). Conversely, the administration of bromids increases the elimination of Cl (Wolf and Opp, 1912; Wyss, 1913). Iodid also displaces Br and Cl (Boeniger, 1907). Claims that bromid administration may save animals from chlorid starvation, and replace the Cl of the serum completely. This is doubtful.

Bromids on Diuresis.—This is increased by salt action (Wolf and Opp, 1912).

Bromids in Uranium Edema.—Uranium animals become distinctly less edemic when bromids are administered. These cause a greater diuresis; the Cl excretion is as high as normal; and the urine contains a part of the Br. The body therefore loses both water and salt (Leva, 1912). This explains the effect.

Bromids on Metabolism.—The actions are not important. Chittenden, 1888, claimed slight increase of N and decrease of PO, excretion. Jappelli, 1912 and 1913, finds little effect on the total N or P; but diminution of the uric acid and increase of the purin bases. He considers that this is due to an inhibitory action on formic, analogous to the bromid effect on pepsin (Chittenden) and oxidase (Senter). The claim that bromid increases the elimination of phosphates needs confirmation.
Retention of Bromid.—The retained Br is distributed similarly to the normal Cl, which it partly replaces in the blood, gastric juice, etc. (Nencki and Szymonowski, 1883; Ellinger and Koteke, 1911). Apparently, the tissues and kidneys do not differentiate sharply between the two ions (E. Frey, 1910). The replacement of more than 40 per cent. of the Cl of the blood by Br is said to be generally fatal (Bernoüllü, 1912).

Distribution in Different Organs.—This has been studied especially by Wynn, 1906. He found the largest quantity in the blood. Even after long administration, the brain contained a relatively small proportion. In an epileptic patient, the percentage in the brain was 0.06; in the blood, 0.14. The quantity in the whole brain figured about 1 gm. Ellinger and Koteke, 1911, found the distribution proportional to the normal richness in Cl. The distribution after therapeutic administration is described by Carnot and Coiffe, 1914.

Condition in Blood.—The Br occurs almost exclusively in the serum (Wynn). However, Boenninger, 1906, states that the corpuscles are permeable to Br and Cl in both directions; that a Br solution may displace all but traces of Cl from the corpuscles; and that the Br in turn can be replaced by Cl.

Absence from Nervous Tissues.—Bald claimed the presence of Br in normal thyroid; but this was not confirmed by Roos, 1898. Pribram, 1906, also found absence of notable quantities in the thyroid and other human organs.

Relative Retention of Organic and Inorganic Br.—The organic Br compounds are apparently retained somewhat more efficiently than the inorganic. This has been cited as a proof of superiority; but it is doubtful whether the retained Br is the bearer of the therapeutic action (Magnus-Ablesen, 1911). Subrumin was retained relatively more in the adipose tissues, but not in the brain (Ellinger). Bromipirin was eliminated by the urine, partly in organic combination, but mainly as inorganic bromid (Bermann, 1910). He has also studied the fate of other organic Br compounds. The lipid-soluble bromural passes at first mainly into the nervous system; but it is rapidly decomposed into a water-soluble form, presumably bromid, which then follows the course of the ordinary bromids (Takeda, 1911).

Historical.—Bromids were first tried as substitutes for iodids. This was unsuccessful, but led to the observation of their sedative action. Their use in epilepsy is said to date from Locock, 1853; as hypnotic, from Behrend, 1864. The older literature is reviewed by Kroes, 1876.

Sedative Action in Man.—Doses of 1 to 2 Gm. of bromids have no noticeable action on normal individuals. Above 4 Gm., depression and decrease of reflexes become apparent. The effects are rather different from those of the ordinary hypnotics. They consist in a condition of insitude and lack of attention, which inclines toward sleep. Perception, observation, and motor reactions may be normal. With the smaller doses the subject awakens refreshed; but with larger doses, the psychic depression persists. Still larger doses (10 to 15 Gm.) cause, besides some nausea, considerable apathy and confusion of speech, but not sleep (Bino). These doses also lower the reflexes from the skin and mucous membranes; so that irritation of the fauces does not produce retching (Kroes, 1876). This was utilized, before the introduction of local anesthetics, for examinations of the throat, etc.

Use as Hypnotic.—Bromids do not enforce sleep, but act rather by permitting sleep through the elimination of excessive worry, etc. They are more efficient in quieting pathologic excitability; and of no value against pain. The dose should be 2 Gm. or more, one to two hours before retiring. The bromids may be usefully combined or alternated with the more powerful aliphatic hypnotics or morphin. The effect is simply additive (Kühneman, 1913); or perhaps slightly potentiated (Januschkke and Inaba, 1913).

Use in Other Conditions of Nervous Hyper-excitability.—The depressant effect of bromid is largely utilized in hysterical conditions; Basehow's disease; acute cerebral excitement and meningitis; in the nervous vomiting of pregnancy; in incontinence of urine; as anaphrodisiac in sexual hyperesthesia; and against
delirium tremens and convulsions—epileptic, chorea, and others. The dosage for the minor nervous conditions is 0.4 to 7 Gm. two or three times daily; against cinchonism, 3 parts of bromid to 1 of quinin; against seasickness, 4 to 5 Gm. daily for several days before the voyage; in pertussis, it is said to allay the paroxysms, but without shortening the course. Convulsions require at least 15 Gm.; if necessary by rectum. Large doses have been given in acute mania, but probably without much benefit.

**Use in Epilepsy.**—This is the principal employment of the bromids. They do not seem to be efficient in all cases, probably because epilepsy has different causes. The successful cases amount to something like 30 per cent. in idiopathic epilepsy.1 Large doses must be employed and continued for some time. In most cases, the attacks become milder and less frequent, or may be suppressed entirely; but they usually return soon after the remedy is removed. In a few cases, however, a permanent effect seems to have been obtained. It is possible that this cure was not due to the bromid, but was spontaneous.

**Dosage in Epilepsy.**—The effects are secured only when the organism is "saturated" with bromid. The required dose varies for different patients and must be ascertained by trial. The efficiency may be increased by Cl-poor food (Toulouse and Richet, 1900; Ulrich, 1912); or by the administration of calcium (Januschke, 1913). These modifications may succeed when the simple bromid treatment fails. The daily dose of bromid should be divided into three or four fractions, and freely diluted (never as tablets).

Poullon recommends the following routine, to be modified as needed: In the first week, 3 Gm. daily; second week, 4 Gm.; increasing by 1 Gm. each week, until 20 Gm. are reached in the eighth week. If well tolerated, and if the attacks persist, the weekly increase may be continued until 45 Gm. are reached in the thirteenth week. The dosage is then reduced in the same way until the attacks recur; when the treatment is again started in the same way. A few trials ascertain the doses required to reduce the attacks to a minimum. This dosage is then continued as long as needed; and renewed at intervals even after complete disappearance of the attacks, to anticipate recurrence. Bromid acme need not interfere with the treatment; but severe depression necessitates reduction, or even discontinuation.

**Other Drugs Used in Epilepsy.**—Besides the bromids, the following drugs have been used empirically: Luminol, Opium, Valerian, Belladonna, Zinc Oxid, Chloë, Adonis Vernallis, Solarum Carolinense, Salicylates and Antipyrin. It is very difficult to form an estimate of their value, since epilepsy is temporarily benefited by almost any placebo. These drugs can be recommended only when bromids have failed or are for any reason badly borne. No treatment will be successful except it be joined with a careful regulation of diet and general hygiene, excesses of all kinds being strictly proscribed.

The inhalation of Amyl Nitrite is sometimes useful during the attack.

**Central Actions of Bromids on Animals.**—These are analogous to man, and can be better utilized for studying the mechanism of Br action.

Albertoni, 1885, found that bromids lower the excitability of the motor center of dogs, so that a stimulation of the motor areas which, under the conditions of the experiment, gives rise to general epileptiform convulsions, will, after the administration of a bromid, be confined to the area directly stimulated. If a bromid is administered to animals under strychnin, the effect of stimulation does not have much tendency to spread, while the primary reflex, say the patellar, will still be exaggerated.

**Guinea Pigs.**—Large doses of NaBr (0.1 to 1 Gm. per pig of 200 to 250 Gm.) produce a deep sleep, lasting two or three days. This is preceded by a long latent period, even if the administration is hypodermic or by vein. The hypnotic effect is antagonized by picrotoxin or strychnin (Januschke and Inaba, 1913).

---

1 This gives the following complications: Total abolition, as long as drug is continued, 13 per cent. Diminished number and violence of attacks, 83 per cent. No influence, 13 per cent. Number of attacks, increased 134 per cent.
BROMIDS

Frogs.—These do not exhibit acute actions.

Rabbits.—These show both acute and chronic effects closely resembling those observed in man. The symptoms, rapidity and dosage are nearly the same, whether the administration is by mouth, hypodermic or vein (Bernoulli, 1912).

Nervous Symptoms.—0.3 to 5.2 gm. per kilogram, by vein, generally produce little immediate effect. After several hours to three days, the rabbit becomes apathetic and sluggish. The sensibility and reflexes are somewhat depressed and delayed. Muscular coordination is often disturbed and ataxic. Ascending muscular debility and paralyses are frequent.

Chronic Poisoning.—Also shows these paralyses, but no narcosis or other cerebral depressions (Januschke, 1913). Both forms prevent camphor and picrotoxin convulsions.

Local Symptoms.—The rabbits often show slowly developing irritant phenomena in the skin and mucous membranes, analogous to bromism: general dermatitis, loss of hair, conjunctival congestion, coryza, etc.

Outcome.—If the nervous symptoms are fully developed, spontaneous improvement is exceptional. The rabbits die in coma after several days.

Perfusion of Isolated Respiratory Center.—This is stimulated with insulin, bromid and nitrate ions (Macht and Hooker, 1918). The conditions and concentrations, however, are too artificial for practical application.

Efficiency against Experimental Convulsions.—Intravenous injection of sodium bromid suppresses the epileptic convulsions of camphor and the medullary convulsions of cocaine, but not the spinal convulsions of strychnin or picrotoxin (Januschke and Inaba, 1912). The Ehrlemyer mixture of NaBr, KBr and NH4Br, appears to differ in that it does not suppress cocaine convulsions with acute, but only with continued administration. This is perhaps explained by the observation that the injection of ammonium bromid is convulsive. CaBr2 is no more efficient than NaBr (Januschke and Masslow, 1914).

Mechanism of Bromid Action.—Wyss proposed the theory that bromids act merely by displacing Cl from the body. This explanation is inadequate. The older theories, that their action is due to the liberation of free Br, or to the formation of organic Br compounds, are also not established. It appears that the action is due directly to the Br ions.

Chloride-Deprivation Theory.—This was suggested by the increased elimination of Cl following Br administration. It was found that the efficiency of bromids was increased by CI-poor food; and conversely, that the administration of large doses of NaCl (20 Gm.) brought on epileptic attacks in patients who had been under the control of bromids (Wyss, 1912). These observations, however, do not prove the contention; for deprivation of Cl increases the retention of Br and administration of Cl increases the elimination of Br. The results would therefore equally support the theory of a direct Br action. On the other hand, a number of facts speak very strongly against the Chloride-deprivation theory: Simple dehydration may produce ataxia, but lacks the anti-convulsant action of bromids. The bromid action occurs even when Cl loss is fully compensated by the food. Recovery from Br may occur even when Cl is withheld. Injection of Cl causes some recovery from bromid poisoning; but citrates, sulphates and nitrates have a similar, though weaker saving action (Bernoulli, 1913). Januschke and Inaba, 1913, found that the bromid depression in animals could not be efficiently antagonized by the administration of NaCl, nor reinforced by CI-poor food.

The Effect of Bromid Action on the Tissues.—When injected into the tissues, bromid is produced in animals by all bromids; but not by organic Br compounds, nor by bromates (Januschke, 1912). Bernoulli 1912, finds that the excised brain and other tissues swell more in bromids than in equimolecular solutions of chlorids. He suggests that this may be the basis of bromid action; but this would require stronger evidence.

Actions on Circulation.—Bromid has no direct effect, except slight depression with single doses above 10 Gm. Sedative doses may indirectly slow the heart and lower the blood pressure somewhat, especially in cardiac neurones. Large doses of KBr may show the depressant potassium action.

In the cat, the intravenous injection of the NaBr, 3 c.c. of 1.5 per cent, per kilogram, had no effect (Lehndorff, 1914).

Perfused Hearts.—The substitution of bromids for chlorids in Ringer's fluid produces practically no effect in cold-blooded hearts, except a slight acceleration in starting.
In warm-blooded hearts, there was a slight decrease in rate and amplitude (Greene and Kruse, 1913).

Excised Uterus.—Replacement of Cl by Br or I produces a slight increase of tone, without affecting the rhythmic contractions, without injuring the muscle (Prochnow, 1911).

Isolated Intestine.—With this and other smooth muscle, the replacement of the chloride of Ringer's solution by bromid increased the tone, amplitude, rate and rhythmic excitability; especially in mammals (T. K. Kruse, 1917).

Secretions.—Bromid somewhat increases the secretion of mucus by salt action. It diminishes the milk. Variable results have been reported as to menstruation.

Gastric Irritation.—Large doses of bromid, especially in concentrated solutions, produce nausea, vomiting and gastralgia, by local salt action.

Acute Bromid Poisoning.—This is rare, but may occur from large doses, especially if the excretion is imperfect in nephritis. There is mild collapse, impaired speech, stupor, and paralytic phenomena. The treatment would be by NaCl infusion.

Bromid Rashes.—These occur frequently, especially in the face, when the administration of Br is prolonged. They resemble those of iodin. The mucous membranes may also be irritated. Similar effects occur in animals (Bernoulli, 1913). The rashes are best prevented or treated by cleanliness. They generally disappear promptly after discontinuation.

The bromid rashes resemble acne vulgaris (but without comedones). They sometimes become confluent, forming superficial carbuncles.

Children are especially susceptible and may show pustules and fleshy masses, distributed symmetrically over the face, trunk and limbs, often becoming confluent, and occasionally vegetating (W. MacCormac).

Explanation of the Skin-rashes.—An older explanation (Adamikiewicz) attributed the bromid and iodid acne to direct irritation by the liberation of free bromin or iod in the acid secretions of the sebaceous glands etc. This cannot be accepted (Usan, 1912) for these elements could not exist free at the reaction of the body (Sollmann).

Presumably the cause lies in a peculiar sensitisation of the skin; for bromid administrations sensitises to the "Lawson" test, although less actively than iodid (Cade and Paryzek, 1917; Kolmer, 1917).

Chronic Bromid Depression and Cachexia.—Long-continued use of the drug generally leads to psychic deterioration, weak memory, apathy, disturbed speech, ataxia, tremors, somnolence, sexual impotence; and to nutritional disturbances: anorexia, malnutrition, anemia, emaciation, diarrhea and lowered resistance. The symptoms disappear rapidly when the drug is stopped or the dose reduced, and especially if chlorid is given (Schabelitz, 1910); but the resistance remains low for some time.

Contraindications to Bromids.—Because of these depressant effects, large doses of bromids should be avoided in mental or physical debility, old age, melancholia, neurasthenia, etc.

Choice of Preparations.—The inorganic bromids are most efficient. NaBr is generally preferred because it is less irritant, and has a less disagreeable taste than KBr, or especially NH4Br and LiBr. NH4Br liberates bromin on exposure to air, which is a serious objection. A mixture (KBr:NaBr:NH4Br::1:2:1) has been advocated ("Erlenmeyer Mixture"); but it is difficult to see any advantage.

CaBr adds the depressant action of Ca and is said to be more efficient; but the continued administration of the large quantities of Ca may be detrimental. The same holds probably also for strontium bromid. HBO is too irritating.

Organic Br Compounds are said to be less likely to produce toxic Br effects; but this could be explained entirely by their own Br content. No
real advantage has been established for them, and they are probably much less efficient.

No effect can be expected from the bromin in salts which are used in small doses—

*e.g.,* bromid of quinin, of arsenic, etc. In these it can be useful only by influencing the solubility or dissociability of the compound.

**Sodium Bromid in Roentgenography.**—Weid, 1718, reports that the 25 per cent.
solution may be used in place of thorium citrate or potassium iodid solutions. The

shadows are fully as clear; bromid does not damage the kidneys; is less irritating to the pelvis and ureter, and is less expensive.

**PREPARATIONS—BROMIDS**

of HBr. Colorless, odorless liquid; strongly acid taste. *Dose,* 1 c.c., 15 minims, U.S.P.; 2 to 4 c.c. to 50 minims, B.P.; diluted.

*Ammon. Brom.* U.S.P., B.P.; NHBr.—Freely sol. in water (1:1.5); sol. in alc.

(1:12). Other characters, *dose,* etc., as Sol. Brom.

*Cale. Brom.* U.S.P.; CaBr₂—Granular; very deliquescent. Very sol. in water

(1:0.7); freely sol. in alc. (1:1.4). *Dose,* 1 Gm., 15 gr., U.S.P.

*Lith. Brom.* U.S.P.; LiBr—Granular; very deliquescent. Very sol. in water (1:0.6);

freely sol. in alc. *Dose,* 1 Gm., 15 gr., U.S.P.

*Pot. Brom. B.P.;* B.P.; KBr.—Freely sol. in water (1:1.5); slightly sol. in alc.

(1:29); freely sol. in glyc. (1:4.6). Other characters, *dose,* etc., as Sol. Brom.

*Natrium Bromidum* (Sol. Brom.), U.S.P., B.P.; NaBr—Colorless, cubical crystals or

white granular powder; odorless; saline taste. Freely sol. in water (1:1.1); sol. in alc.

(1:10). All bromids are *incompatible* with strychnin. *Dose,* 1 Gm., 15 gr., U.S.P.;

0.3 to 2 Gm., 5 to 30 gr. B.P.; in dilute solution.

*Solen. Brom.* U.S.P., B.P.; SrBr₂ + 6H₂O.—Very sol. in water (1:0.33); sol. in

alc. *Dose,* as for Sol. Brom.

**ORGANIC BROMIN COMPOUNDS**

The following are described in N.N.R.: *Adalin* = Brom-diethyl-acetyl carbamid.

*Bromural* = Monobrom-isovaleryl urca. *Bromalol* = Bornyl-bromvaletane. *Sahro-

min* = Calcium dibrom-benenate.

**IODIDS**

**General Statement.**—Our knowledge of the action of iodids is derived

mainly from clinical, rather than from experimental data. They increase

the secretion of mucus and urine; rather more powerfully, than other salts, but probably by the same mechanism. They are therefore used as

expectorants and diuretics, and to promote the elimination in chronic

mercury and lead poisoning. Their continuous use, especially in suscep-

tible individuals, produces inflammatory phenomena in the skin and

mucous membranes (iodism). Other iodic compounds act similarly.

Their principal use is in the various manifestations of tertiary syphilis.

They do not act on the spirochetes, but lead to the absorption of gumma-

tous exudations and perhaps connective tissue. This action is not ex-

plained, but is perhaps analogous to the iodism. The iodicids are similarly

useful in aortic aneurism, and in arteriosclerosis and angina pectoris.

They have no direct effect on the circulation. Their employment in

chronic rheumatism, fibrosis, asthma, neuralgias, etc., rests perhaps on a

similar basis.

The administration of iodicids and other iodic compounds increases the

formation of iodothyrin, and therefore affects metabolism. Their cautious

use is often beneficial in goiters, while excessive doses are dangerous.
Iodin in Food.—This is of wide occurrence, but the quantities are very minute (E. B. Forbes and Beege, 1916; Bohm, 1917).

Absorption, Fate and Excretion.—These are similar to the Cl, Br, SCN and NO₃ ions. They may mutually displace each other in their excretion. The elimination of iodid is more rapid than that of the related ions. A limited amount of iodin is stored as a special organic compound in the thyroid gland.

Absorption.—The inorganic iodids are rapidly absorbed from mucous membranes; so that, with oral administration, the absorption occurs principally from the stomach (Borutt, 1910). The rectum is said to absorb even better (A. Friedmann, 1910).

Rapidity of Absorption.—Administering KI to dogs with duodenal fistulas, iodid could be detected in the duodenum within five minutes; the absorption was completed in about three hours (L. Metzger, 1911).

Intestinal Loops.—Hasdlik, 1912, found the absorption of NaI solutions, placed in ligated loops, nearly equal from all parts of the small intestines; some, but less from the stomach and colon. The rapidity of absorption was not materially influenced by the extent of surface, or by the concentration of the solution. The absorption is very rapid at first; but becomes slower when one-half to three-fourths has been absorbed. The inhibition is due to a local change in the epithelium, which is also produced by the local application of dilute NaCl solution; but not by altering the habitual content of the tissues.

Absorption from the Skin.—The application of iodid ointment is irri-
tional; for although some absorption occurs, it is very imperfect.

The absorption varies with the iodid compound, the ointment base, and the texture of the skin. It is best for the scrotum. Hersfeld and Elin, 1912 (who also studied several compounds), state that petrolatum secures the best absorption; while Barro-

bach, 1909, found it better from lard than from petrolatum or lanolin.

Reactions Liberating Iodin.—When iodin is placed with an alkali, it forms combi-
nations containing iodide and iodate, or iodid and hypiodite. From these mixtures free iodin is liberated on aceticulation. Free iodin is also liberated from acid mixtures of iodids and nitrates, and from sulphoiodids and iodates. All these reactions, however, occur only in strongly acid media (pH = 4 or more), and therefore could not occur in the organism any place except in the stomach.

Moreover, no iodate is formed in the body when iodid, or even when iodin is given; for the free iodin is converted partly into iodid and partly into protein compounds (Solomann, 1917).

Channels of Excretion.—This occurs mainly by the urine; but partly also by the saliva, gastric juice, sweat (Tachau, 1911), and other secretions and body fluids and effusions.

Form of Iodin in Urine.—This exists mainly, if not solely, as iodid ions. A small part is probably excreted in organic combination (Crespolani, 1909), but the evidence for this is somewhat controversial (Schuerhoff, 1905; Harnack, 1910).

Rapidity of Primary Excretion.—The iodid appears in ten to twenty minutes, and reaches its maximum in two hours. About four-fifths is excreted within a few hours; but the remainder very slowly (Heubel, 1851). The excretion is twice as rapid as that of Br (Heimann, 1912). Considerable retention occurs (from one-sixth to one-half after a single dose). With doses of 0.5 to 1 Gm., the iodid reaction persists for forty hours; after larger doses or continued administration, traces persist over twenty days. The excretion can be hastened by the administration of chlorids and similar ions, but not by diuretics.

Influence of Catharism.—Sodium potassium and strontium iodids are absorbed and excreted precisely alike, both in regard to rate and total quantity (Krabulke and Ficher, 1912).

Influence of Roiled Ions.—This was discussed under Chlorids and Bromids. The administration of chlorids and related ions hastens the elimination of iodids (Hersfeld and Gormidor, 1912); while Cl-poor food increases the retention (Sarvanat and Cremin, 1911).
Iodides 815

Iodide Test of Renal Efficiency.—If a single test-dose of 1 Gm. of KI is taken after a meal, a healthy individual excretes on the average 80 per cent. of the iodid in the first twenty-four hours, and 15 to 20 per cent. between twenty-four and forty-eight hours, independent of the volume of urine. At the end of this time, the urine fails to respond to the ordinary iodid test.

A smaller excretion or more persistent reaction shows diminished permeability of the kidneys. With interstitial nephritis, for instance, the excretion may be only 17 per cent. and extend over five or six days. Tubular nephritis, acute or chronic, shows nearly normal excretion (Silvert and Kaminsky, 1914). Considerable delay occurs in experimental chronic passive renal congestion (Rowntree). The iodid delay would therefore seem characteristic of vascular rather than tubular disturbance, contrary to the view of Schlayter and Takayasu, 1914. The elimination of KI, after 1 Gm. by oral and rectal administration, has been studied in a variety of clinical conditions by Vowslin, 1915.

Differences with Age.—Amstad, 1914; finds the excretion in sucklings the same as in adults (64 to 72 per cent.); but older children appear to excrete less effectively; namely, 37 to 50 per cent. between three and five years; 41 to 48 per cent. between five and ten years. He offers no explanation for this curious observation.

Salivary Excretion.—This begins usually in six and one-half to eleven minutes. It is somewhat delayed when the stomach is filled, and much more in gastric diseases. This has been proposed as a diagnostic test (0.2 Gm. KI in gelatin capsules); but it is inconvenient and unreliable. The salivary excretion gives rise to a persistent disagreeable metallic taste; best corrected by gargling with bicarbonate.

Other Fluids.—The sweat contains only traces (Kellermann, 1905; Tschau, 1917). The Bile in man excretes about 1 per cent. of the administered iodid in twenty-four hours, the maximum being in three hours (Frickes, 1906). Its presence in effusions and cerebro-spinal fluid, five to fifteen hours after administration, has been confirmed by Achard and Ribot, 1909. Its passage into the cerebro-spinal fluid is not constant (Hald, 1911). Catton, 1916, also failed to find it in his patients after the daily administration of 6 Gm. for 12 weeks, and after 17 Gm. at a single dose.

Iodid also passes into the milk (Reipr and Scheffer, 1908).

Distribution of the Retained Iodid in Normal Tissues.—When an iodid has been administered, it is to be found, in inorganic form, in the liver, bone, hair, and nails, and in the thyroid. If any are present in the tissues, organically combined iodid must be considered. The proportion of organic iodid in the tissues is not constant; it varies with the diet. The proportion of organic iodid in the tissues is also variable, depending on the amount of protein in the diet. The proportion of organic iodid in the tissues is also variable, depending on the amount of protein in the diet. The proportion of organic iodid in the tissues is also variable, depending on the amount of protein in the diet.

Distribution of Iodin in Cell Constituents.—McLean, 1914, investigated the proportion of the retained iodid in the water-soluble, protein and lipid fractions of the liver, both after administration to an animal, and after direct addition to the excised liver tissue. With KI, the results were the same in either case: 66 per cent. in the water-soluble fraction, 34 per cent. in the lipid, and none in the protein. This held also for sodium administration. With iodid added to the liver without its administration, the protein fraction showed a larger (58 per cent.), and the water-soluble a smaller (42 per cent.) fraction.

Form of Iodin in Pathologic Tissues.—These generally contain more than normal. This is not explained by simple diffusion, since the tissues may contain more than the blood (O. Loeb, 1912).

The increased quantities have been found in tuberculous tissue (Loeb and Michaud, 1907) particularly in the necrotic areas (R. Well, 1910); carcinomatous tissue (Veldm, 1909; Takamusa); syphilitic tissue (Loeb, 1912); pus (Loeb, 1907); other necrotic tissue and implanted agar (Wells and Hedenburg, 1913); and organs rendered hypemic by Bier's stasis (Solomon, 1913). Tuberculous tissue is said to contain iodin even in animals to whom no iodin compound has been administered (A. Lewis and Krauss, 1914).

Organic Iodin Preparations.—Several different types of these have been introduced to avoid the undesirable actions of KI. This can be accomplished only very imperfectly. Their slight and doubtful advan-
tages do not compensate for the extra cost (McLean, 1912). They are all decomposed in the body, and develop the iodid action only when the iodid ion is regenerated from them (Edenmeyer and Stein, 1909). They do not therefore avoid iodism if active doses are given. The iodin-protein compounds are decomposed before they reach the blood, and behave practically like inorganic iodids. Iodized fats and fatty acids are absorbed largely unchanged and excreted more slowly, and therefore furnish a more steady supply of iodid. Their temporary distribution in the tissues is also different. They are held for a time in lipid-soluble form by the cells, and therefore enter more readily into nervous and other lipid tissue. However, this would probably not favor their penetration of syphilitic tissue. It is not clear that these features are especially advantageous (Dock, 1909); nor are these drugs entirely free from undesirable side actions (Notthaft, 1910; iodipin, Seifert, Nebenwirk, 1915, p. 214).

Iodin-Protein and Similar Compounds.—Iodo-albuminates, -peptonates, -tannates, -gelatin; iodon, iodosoloe, iodethylycglicin, are so rapidly decomposed that they behave as are excreted practically like inorganic iodids; and have no advantage (Filippi, 1912; McLean, 1914). Even the relatively firm iodalbarcid is completely decomposed before it reaches the blood (Fuerrth and Friedmann, 1908; McLean, 1915).

Iodized Fats and Fatty Acids.—Iodipin, sajodin, etc., are absorbed, decomposed and excreted more slowly (Winternitz, 1893; Bonitatibus, 1910; Bonanni, 1911; Abderhalden and Hirsch, 1911). This applies also to iodostarin (biniido-tartrinic acid) and iodipiod (ethylester of biniido-brassidinic acid) (Filippi, 1912; Hassel, 1914).

McLean found that they are retained mainly in the lipid-soluble fraction of the cell, and therefore enter the nervous system more freely than inorganic iodids. Their final excretion is in inorganic form (McLean, 1914, 1915).

M. Jacoby, 1916, claims that the storage of iodin in tissue fat does not occur when iodized fatty acids are administered as such, by mouth; but only when they are given in the form of their calcium salt. This needs confirmation.

Urine Flow.—Iodids have a saline diuretic action somewhat greater than that of chlorids (according to Cushny's theory, because they are not reabsorbed in the kidneys from the urinary tubules).

Other Secretions.—Iodids increase the secretion of bronchial mucus and render this less viscous. They are therefore used as liquefying expectorants. This may also contribute to their action in asthma. The secretion of saliva is not affected (V. E. Henderson, 1910). Their use is chronic mercury and lead poisoning is probably due to the conversion of the stored metals into more soluble compounds, but this is hypothetical.

Sexual Functions.—Iodids are said to increase menstruation; to decrease the secretion of milk; and cause atrophy of the mammary gland. Free iodin or loose iodal compounds (not KI) produce sterility in both sexes. The spermatoblasts show histologic changes, and the formed spermatoza are also affected (L. Adler, 1914).

Metabolism.—Iodids produce no demonstrated, definite, direct effects on normal metabolism. Their continued use, however, leads to malnutrition, as described under iodid cachexia. This may be due partly to their influence on the thyroid gland (as under Thyroid).

There may be some increase of urea, total nitrogen, uric acid, purin bases, and chlorid excretion (Chistoni, 1911).

Hypodermic injection of large doses may produce no effect or considerable increase or decrease of metabolism (Sgalitzer, 1908).

Normal Occurrence and Relation to Thyroid.—The thyroid gland contains a fairly high percentage of iodin as thyroxin. It can be increased by the administration of iodin or any of its compounds. There are quantitative differences, the I of bladderwrack being perhaps 100 times as
active as that of KI; probably because it is more easily assimilated by the colloid (Hunt and Sedell, 1910).

Rapidity of Fixation in Thyroid.—Injecting intravenously 50 mg. of KI into dogs, Marine and Rogoff, 1916, found the fixation completed in five minutes; i.e., as much had been fixed in the thyroids of the dogs killed after this interval, as in those killed after 30 hours. None was fixed by the liver or spleen.

The normal occurrence of iodin in animal and plant tissues was studied by Cameron, 1914; in foods, by Forbes and Beegle, 1919.

Use in Goiter.—The careful administration of iodids prevents simple goiters, and causes a regression of active thyroid hyperplasia into the relatively harmless colloid type of goiter.

Marine, 1911 and 1912, advocates the Syrup of Ferrous Iodid, in doses increasing gradually from 0.3 to 1.2 c.c., 5 to 20 drops, per day.

Prevention of Goiter.—The efficiency was tested by Marine and Kimball, 1917, and Kimball and Marine, 1918, on a large group of school girls in the Lake Erie goiter district. Sodium iodid was used, about 0.3 gm. per day (in 5 c.c. water) for 10 days twice per year, in May and November. None of the treated cases developed any thyroid enlargement; whereas this developed in 25 per cent. of the untreated. A third of the existing goiters shrunk or disappeared after the treatment. None developed any Basedow symptoms. Iodid rash occurred in only 1/4 per cent.

Toxic Effects in Goiter.—Goiterous, especially Basedow patients, often react badly to the large doses of iodid which are commonly used in other diseases; presumably by the overproduction of thyroxin in the hyperplastic gland. The patients become emaciated, even when the appetite remains good. There are nervous and psychic disturbances, sometimes fever. The symptoms are described in detail by Oswald, 1915. The effects do not cease promptly when the administration is suspended (Krehl, 1910).

Use in Circulatory Diseases.—Iodids are extensively employed in arteriosclerosis, coronary sclerosis, angina pectoris, aneurism (Bouillaud, 1858), etc. In the lighter grades of these conditions their continued administration seems to give gradual relief to the functional phenomena, especially the pain; but probably without effecting a cure. The effects are not due to any change in the blood pressure, but probably to structural alterations in the vessel walls, perhaps absorption of cellular exudates; analogous to the effect on syphilis. In many cases, a syphilitic factor is directly concerned.

Direct Action on Circulation.—Potain and others supposed that the iodids lower blood pressure by depressing the heart or blood vessels. This applies to fatal doses of KI, but is then a potassium effect. Ordinary doses have no effect on the blood pressure in normal men or animals (Stockman and Charteris, 1901). The slight circulatory changes in intravenous injection, described by Lehndorf, 1914, and Macht, 1914, seem practically insignificant. Salant and Livingston, 1916, observed no effects on the circulation of frogs or mammals, even with fairly high concentrations of NaI. (The intravenous injection of free iodin markedly depressed the circulation in cats, not in dogs.)

The blood pressure in arterial hypertonia is also unaffected acutely, and probably even with chronic administration (Hewlett, 1912). On the other hand, some clinicians claim a definite fall (f. i. Rutkewitch, 2 gm. daily). There is also a fall in lead poisoning probably indirect (Capps, 1912). Gutwirth, 1907, frequently observed increase of pulse rate with iodid administration. This may have been a thyroid effect.

Isolated Heart and Arteries.—Macht, 1914, investigated the effects of replacing part of the NaCl of Locke's solution by NaI or KCl. The results can not, of course, be transferred to intact animals, or man, since they involve different concentrations. He concludes that the iodid and Na ion stimulate the heart and constrict the vessels;
the cardiac stimulation being strong for iodid, weak for Na. The K ion depresses the heart and relaxes the vessels. Very weak solutions of metallic iodin are also stimulating; stronger concentrations are toxic. Salant and Livingston, 1916, found that the perfusion of dilute solutions of free iodin through the isolated frog heart produces cardiac irregularity and depressant after-effects. More concentrated solutions cause greater irregularity and diastolic arrest.

**Decreased Viscosity of the Blood.**—Iodids and sulphocyanides decrease the viscosity of colloids (Pauli, 1905; the other haloid ions have a similar but weaker effect; Gazzelli, 1913). O. Mueller and Inada, 1904, claimed diminished viscosity of the blood from therapeutic doses, and advanced this as an explanation of the circulatory effect. This could not be confirmed by Dernstt, 1908; Dernstt and Broeking, 1912; Lanu and Vergano, 1912, Tschekovskow, 1913, and Partumier, 1917. Chistoni, 1919, found more positive results. The changes are evidently inconstant, and perhaps accidental; they are so small that they would have no significance.

**Epinephrin Athoroma.**—Korayni, 1906, claimed that this could be prevented by iodin, but this has been disproven (Biland, 1906; L. Leob and Fleisher, 1907; Heissenger and Leob, 1907; Kleeberger, 1907).

**Trench Foot.**—Sweet, Norris and Wilmer, 1912 claim that potassium iodid, 4 gm. per day, gives decided relief to the pain within 24 hours. The observations, and the theory on which they are based would need confirmation.

**Iodids in Syphilis.**—The use of iodids in syphilis was introduced by Wallace, 1836. Large doses are used in the various tertiary and late secondary manifestations. They give marked relief, largely by leading to the absorption of gummatous formations. They are not curative, and do not affect the Wassermann reaction or spirochetes. The mechanism of their action is not explained, but is perhaps analogous to the irritable phenomena of iodism. It has been suggested that they cause the production of a proteolytic ferment. This is plausible, but requires further proof. Longcope, 1914, suggested that the breaking down of syphilitic tissue favors the access of mercury or arsenic to the spirochetes.

**Analogous Reactions in Tuberculosis and Other Conditions.**—Iodids produce a similar reaction as acts on the granulations of actinomyosis, sporotrichosis and blastomycosis. In tuberculosis, they soften the connective tissue and the tubercles, and cause a reaction similar to tuberculina. They have an analogous effect in leprosy and produce febrile reactions in a variety of infections. Experimental sporotrichosis of rats responds promptly to iodids, and is suggested for the investigation of iodid action (D. J. Davis, 1915).

Iodids are said to be contraindicated in tuberculosis. Sorel, 1909, found that they hasten death in experimental tuberculous infection of guinea pigs, but the direct toxicity of iodin is not greater for tuberculous guinea pigs than for the normal (Nicoiu and Nacota, 1916).

**Lucin Reaction.**—Administration of potassium iodid or other iodin compounds leads to a positive purpural or nodular lucin reaction, even in non-syphilis. Moreover, the intradermal injection of agar or starch alone produces similar reactions in iodized patients (Sherrick, 1913); Kolmer, Matsumani, and Broadwell, 1916; Stokob, 1917).

The minimal total dose of KI required to provoke the reactions is about 60 to 75 grains.

The dose of organic iodin compounds is not strictly proportioned to their iodin content (Paryzek, 1917). Bromid and nitrates also provoke the reaction, but not as powerfully (Cole and Paryzek, 1917; Kolmer et al., 1917).

**Older Theories of Mechanism of Antilithic Action.**—Numerous theories have been proposed without adequate evidence (Capps, 1912). The alterations produced by all action, and the effect on the thyroid, may play a part; but other salts and thyroid may lack the antilithic action. Bini, 1873 and 1894, suggested the liberation of free iodin but this is impossible; nor is free iodin especially toxic to spirochetes; the iodin is not toxic (Akatsu, 1917).

Heinz, 1869, describes increased leukocytosis and lymph flow, and assumes increased permeability of the blood vessels. Hirsch, 1914, however, did not find the phagocyte removal of tubercle bacilli hastened by daily KI administration.

In spite of these various theories, one must be struck by the fact that the results of iodid are altogether too specific to be explained by such general and indefinite explanations.
Ferment Theory.—The resorptive action of iodids on various pathologic tissues, and the similarity of its febrile and inflammatory reactions to anaphylaxis, suggest the possibility that it may cause or favor proteolysis under certain conditions. All the phenomena would thus be brought under the same heading; the lustre, tubercular and other pathologic tissues merely having an exaggerated susceptibility to the proteolytic and anaphylactic phenomena of iodism. These views, although plausible, have as yet no firm experimental foundation.

Several observers have described a rather doubtful acceleration of autolysis by the addition of iodid, in vitro; and a more definite acceleration after the administration of iodid (Stokey, 1907; Kepinow, 1911; Kashivabara, 1912; Morse, 1915).

Dick suggests that iodids lead to the production of a proteolytic ferment. Jilling and Peterson, 1914 and 1915, on the other hand, believe that they restrain the antityptic activity of the serum and tissues, by binding the unsaturated carbon atoms of the antityptic lipoids, thus permitting the autolytic digestion of the necrotic, lustre or tubercular material, etc. In support of this, they find that the antityptic power of serum or caseous tubercular material is actually diminished by incubation with iodin or iodids; that fall down of iodid, administered to man, greatly lowers the antienterist index of the serum, which, however, recovers with the outbreak of iodism; and that the administration renders caseous tuberculous material digestable, explaining the appearance of tubercle bacilli in the sputum. They assume that gummas would be similarly digested, thus also exposing the spirochetes to the germicidal action of mercury or arsenic. It will be seen that the theory, although attractive, still involves some unproven assumptions.

Use in Other Conditions.—Iodids are also employed to cause the absorption of non-lustreous hyperplastic tissue; to reduce chronic inflammatory swellings; against lymphatic swellings; in goit; chronic rheumatism; in neuralgia; in asthma, etc. The mechanism of their action is probably analogous to that in syphilis; in many cases there may also be an undiscovered lustre factor. The action on bronchial muscle is doubtful (Thorne, 1913).

Iodism.—The use of iodids is apt to produce irritative phenomena of the skin and mucous membranes, taking the form of various rashes, and of coryza, headache, conjunctivitis, laryngitis, bronchitis, etc.—i.e., the various manifestations of a "cold." Less common are stomatitis, parotitis, anorexia, etc. The skin affections generally occur somewhat later. They may consist in acne, furuncles, erythema, purpura, urticaria, vesication, etc., and these may be accompanied by fever. The lesions sometimes resemble gummas. The susceptibility to these irritations varies greatly. They may set in a few hours after a relatively small dose or only after the long-continued use of large doses; or again, the symptoms produced by small doses may disappear when the dosage is increased. They are more common when the excretion is interfered with by nephritis (v. Noorden, 1908). They disappear in a few days when the drug is discontinued. They may be produced by any iodin compound, e.g., iodiform; but probably only after the dissociation of the iodid ion. They were formerly attributed to the liberation of free iodin by carbonic acid, sebaceous secretion, etc. (Adamkiewicz).

There is no good evidence for this view (Unna, 1912). It is doubtless incorrect, for it is difficult to conceive how iodin could be liberated under the conditions of the body; and similar symptoms are produced by the related sulphhydracids, from which no irritant element could be liberated.

The catarrhal phenomena can be suppressed in one to three days by the administration of calcium lactate, 4 Gm. per day (Velden, 1913); but the continued use of calcium may have drawbacks which probably make it inadvisable. Iodin "Anaphylaxis."—Obermeyer and Pick, 1904, observed that the injection of serum that had been treated with iodin produces a universal precipitin in the serum of the injected animal; so that this precipitates with the serums of all species. Wolff-Eisner suggested that similar effects might be produced by the administration
of iodin compounds, i.e., that this resulted in iodized proteins, and in antibodies against these, which might produce anaphylaxis if iodin were again administered. This hypothesis seemed to find partial substantiation in the claim of Bruck, 1909, that the injection of the blood of patients with iodid idiosyncrasy rendered guinea pigs hypersusceptible to iodoform; and according to Klauser, 1910, also to potassium iodid. Cell, 1911, however, failed to confirm this; nor could he transfer passively a hypersusceptibility to copalba. The matter is evidently not so simple.

The work of Friedberger and Itu, 1912, has extended the sensitizing effect to guinea pigs serum iodized outside of the body, or by the intravenous injection of free iodin. They obtained the following results:

<table>

Iodid Cachexia.—The continued administration of iodid may also lead to anemia, emaciation, lowered tone, mental depression, nervousness, insomnia, and nervous tachycardia and tachyderma, etc. The phenomena result partially from the catarrhs, the thyroid action, etc.

Acute Effects of Intravenous Injection.—Large doses (0.8 Gm. NaI per kilogram) produce death in twelve to thirty-six hours, with symptoms of central paralysis. Autopsy shows pleural exudation; often with pulmonary edema and pericardial effusion (Boehm, 1876; Chiari and Janusche, 1910). Similar effects are produced with hyperdermic but not with oral administration (Spalitzer, 1909). The symptoms are comatose, and the statements regarding central actions are contradictory, and probably unworthy (Barbara, 1900; Jodlbauer, 1902; Heins, 1908). Intravenous injection is said to paralyze the vagus endings and to lower the excitability of the depressor. In frogs the iodids produce rigor and acidity of the muscles (Stockman and Charteris, 1901).

Respiratory Center.—The perfused respiratory center is stimulated by iodid bromid and nitrate ions (Macht and Hooker, 1918).

Choice, Administration and Dosage.—KI is generally preferred, although it has probably no real advantage over NaI. It is best administered freely diluted with water or milk, an hour after meals. The dosage for non-syphilitic conditions is from 0.3 to 2 Gm., three times daily. In lupus, this is often raised to 5 Gm. or more. It may be started with 5 drops of the saturated solution, increasing each dose by 1 drop (1 gr.) each day, reducing the dose if iodin becomes severe. In syphilis, one may begin with doses of 1.5 Gm., increasing by 0.3 Gm., every second day. Infants tolerate large doses (in meningitis, to 2.5 per day; A. Jacobi).

Intravenous Iodid Therapy.—In view of the rapid absorption of the iodids, intravenous administration cannot possibly have any advantage. Nevertheless, it has been used (7.5 gm of sodium iodid as 8 per cent. solution, daily; R. C. Howard, 1918).
Iodid Solutions in Roentgenography.—D. F. Cameron, 1918, found that solutions of potassium or preferably sodium iodid cast definite shadows, and are harmless to the tissues. He recommends 15 per cent. for the bladder; 25 to 30 per cent. for kidneys; and 50 per cent. for sinuses.

Incompatibilities.—Iodids should not be used with calomel or hydrogen peroxid, even in separate prescriptions. They precipitate heavy metals and some alkaloids (strychnin). They are incompatible with mineral acids and oxidizing agents. Salts or solutions which have become yellow by liberation of iodin should not be dispensed.

PREPARATIONS—IODID

Acid Hydriod. Dil., U.S.P., B.P.; 10 per cent. of HI. Colorless or pale yellow, colorless liquid; strongly acid taste. Should not be used if colored more than pale yellow. Prepared from iodin U.S.P. c. 0, 0.6 C.C. in 10 c.c. B.P.; diluted.

Syri. Acid Hydriod., U.S.P., B.P.—1 per cent. of HI. Dose, 4 c.c., 1 dram, U.S.P.; 2 to 4 c.c., ½ to 1 dram, B.P.

Ammon. Iod., U.S.P., N.F.—Minute, colorless, cubical crystals, or a white, granular powder; odorless; sharp, saline taste. Very hygroscopic. Incompatibilities, as Pot. Iod. Very sol. in water (1:10:0); freely sol. in alc. (1:3:7) or glycol. (1:7:6). Dose, 0.3 Gr., 5 gr., B.P.

(Syr. Ferr. Iod., U.S.P., B.P.—Each cubic centimeter is equivalent to 0.0235 Gr., 0.078 gr., of iodin; see Iron Preparations.)

Potassii Iodidum (Pot. Iod.), U.S.P., B.P., KI.—Colorless cubical crystals, or white granular powder, faint iodid odor, sharp saline taste. Incompatible with mineral acids, oxidizing agents, and many alkaloids. Very sol. in water (1:10:7); sol. in alc. (1:22); freely sol. in glycol. (1:22). Dose, 0.3 Gr., 5 gr., U.S.P.; 0.1 to 1.2 Gr. 5 to 20 gr., B.P. A 1:1 solution (1 minims = 1 grain) is convenient for dispensing. Dissolve 1.3 in 2½ Gr. of water, and make up to 1 fl. 5.

Ung. Pot. Iod., B.P.—10 per cent. of KI (Irrational).

*Potassii Iodidum, U.S.P., B.P.; NaI.—Properties and dose similar to KI. Very sol. in water (1:10:53); freely sol. in alc. (1:12) and in glycol. (1:12).

Strent. Iod., U.S.P., SrI + OEtO.—Very sol. in water (1:10:2); sol. in alc. Dose, 0.3 Gr., 5 gr.

SULPHOCYANIDS (THIOCYANATES; RHODANATES)

These produce actions resembling the iodids; but their use has not become popular. They are not dissociated into cyanids, and are relatively non-toxic. Their normal occurrence in the saliva is interesting, but without much practical significance.

Iodid Effects.—NaSCN influences the aggregation of colloid in the same way as the iodid ion, being even somewhat more solvent. This analogy suggested a therapeutic trial. In the limited number of cases in which it has been tested, it was found to affect neurones, arterioles, and syphilis in a manner analogous to the iodids, being even somewhat stronger (Paulii, 1905 and 1910). It also hastened the elimination of metals—perhaps by rendering the metal-protein compounds more soluble. It resembles the iodids further in producing coryza, acne, and other symptoms of iodin. Coppee, 1917, observed no results in tuberculosis. Nerking, 1913, reports many disagreeable effects, especially in gastric hyperacidity. A conspicuous difference from iodids lies in the fact that it does not act on the thyroid gland. It was used as the sodium sulphocyanid in the maximal dose of 1 Gr. (15 gr.) per day. This salt is quite soluble in water. The potassium salt could probably be used in the same dose.

Toxic Actions.—The earlier authors (Cl. Bernard, etc.) considered the sulphocyanids as relatively non-toxic; and as mentioned, they have been used therapeutically in granuloses. F. Franz, 1912, confirms that no cyanid is split off in the animal organism. Intravenously, very large doses, 0.03 Gr. per kilogram, produce no toxic symptoms. Even 0.36 Gr. per Kg. Intravenously, produces practically no effect on the circulation or respiration or bile and urine flow (Ges. Leib. und Kuhn, 1917). The effects resulted in man from the continuous administration of ½ to 2½ Grains per day. The minimal
fetal dose by vein for rabbits is placed by Cooper, 1915, as 0.4 to 0.6 Gm. per kilogram. By mouth there were only the local salt actions. Lodhola, 1905, described toxic effects from KSCN, which must have been due either to the potassium or to impurities.

**Stated Muscle.**—Immersion of a frog's gastrocnemius in a 2 per cent. solution of sodium sulphocyanid (in Ringer's solution) produces a strong primary contraction, followed by gradual increase of tonus, slow waves of contraction and intermittent twitchings (Worthington, 1921; Langley, 1916). One per cent. in Ringer's solution are found in the human parotid and submaxil- lary saliva, but not in all individuals; also in the saliva of many animals, not in dogs and horses. It is absent in new-born infants (Rittershain); also in suppurative middle-ear disease (Juergens, 1907). It is found in other mucous (nasal, conjunctival, gastric). It is excreted quantitatively in the urine and feces (Pollak, 1903; A. Meyer, 1904), generally in the proportion of 1:2 (Gies and Kahn, 1913). In dogs in which it is absent from the saliva, it occurs in the blood, liver, intestines and urine (Kahn, 1913). In normal dogs, it is present in the urine to the extent of 0.001 per cent.; in the blood, 0.003 per cent.; in the bile, from nothing to 0.001 per cent. (Gies, Lieb and Kahn, 1914). Its quantity depends on the available supply of CN radical. It is formed when BCN is administered, constituting a chemical disintoxicating mechanism. Its quantity is increased by tobacco smoke, which contains BCN. It is also increased by feeding amino-acids (alanin) and acetonylitrile; not by sulphur, sulphid, thiouracil or taurin. It is probably produced from the protein in the liver (Kahn), the saliva being merely an excretory channel (Socha, 1907).

Dezani, 1918, confirms that the excretion in dog's urine varies with the nitrogen intake, so that it is apparently derived, at least in part, from the food. Its content in the saliva has no relation to tooth decay (Lathrop and Gies, 1911). The quantities present in the mouth could not have an antiseptic effect (Gies and Kahn, 1912 and 1918); although sulphoncyanid is toxic to higher plants; and in great concentration to bacteria. Sulphoncyanid acid (0.4 to 0.4 per cent.) inhibits the gastric digestion of fibrin (Cavazzani, 1915). A comprehensive review of the literature is given by Kahn, 1912.

---

**NITRATES**

Potassium nitrate, Saltpeter, was formerly used as a cardiac depressant in fevers, etc.; it is now recognized that ordinary doses do not possess this action. Its effects are simply those of a neutral salt; somewhat more irritant to the gastro-intestinal tract, and somewhat more diuretic than NaCl. It has practically fallen into disuse. Accidental poisoning from large doses is not uncommon. It presents the phenomena of gastro-enteritis, similar to those of all other soluble indifferent salts. This may be serious, especially if it is swallowed undiluted.

**Fate and Excretion.**—Nitrates are readily absorbed. Their excretion is similar to that of the halogen ions, and shows the usual mutual relation (Collmann). Practically the entire quantity is excreted unchanged (Aberolden and Hirsch, 1913); but a small proportion may be reduced to nitrites. This reduction takes place so slowly, in the case of the inorganic nitrates, that no nitrite action can ordinarily be seen, but very large doses may cause methemoglobin formation (Binn and Gerlinger, 1901). Metabolic studies have given contradictory results (Graves and Wietz, 1913). Normal urine contains 0.1 to 0.4 per cent. of KNO3. This is considerably more than is ingested with the food, so that a part must be formed as an end-product of metabolism (H. H. Mitchell, Shonley and Grindley, 1916). Nitrites provoke the lactic reaction (Colds and Paryzek, 1927).

**Excised Ureter.**—Non-toxic concentrations are slightly stimulating (Macht, 1921).

**Toxic Symptoms.**—These consist in great abdominal pain, vomiting, frequently bloody stools; irregular pulse, convulsions, and collapse; suppression of urine, or that passed is albuminous and often bloody. The
gastroenteritis may be so violent as to lead to an early fatal ending. Of the salts so far studied, the potassium nitrate is by far the most violent; 30 Gm. (1.5) may be fatal if taken in concentrated form.

Smaller doses, long continued, cause a hemorrhagic tendency, edema, and fatty heart (Fackelmann, 1886).

The treatment would consist first in dilution, since they act mainly by virtue of their concentration. Large quantities of water should be drunk and the stomach washed. Demulcents—milk, egg white, acacia—are also useful. The symptoms should be met as they arise.

PREPARATIONS—NITRATES

Potassii Nitras (Pot. Nit.), U.S.P., B.P. (Niter, Saltheter), KNO₃—Colorless, transparent prisms, or white, crystalline powder; saline, cooling taste. Freely sol. in water (1:2.8); very slightly sol. in alc. Dose, 0.5 Gm., 8 gr., U.S.P.; 0.5 to 1.2 Gm., ½ to 30 gr., B.P.; diluted.

Sodii Nitras (Chili Saltheter), NaN₃—Freely sol. in water (1:1); sol. in alc. (1:100). Dose, as Pot. Nit.

POTASSIUM CHLORATE

General Statement.—A saturated (1:10) solution is used as an antiseptic and astringent mouth wash in stomatitis, especially mucosal and ulcerative; and as a gargar in pharyngitis and tonsillitis. It often seems to be effective, but its action is unexplained. It was introduced with the idea that it would act as an oxidizer, and thus be antiseptic. However, it does not part with its oxygen in the body, being excreted practically unchanged.

It should not be employed internally, since this has repeatedly led to serious toxic effects (A. Jacob, 1879), especially by the production of methemoglobin and destruction of the corpuscles, thrombosis, etc. Patients should be cautioned against swallowing the gargarles. The popular tablets are to be condemned.

Excretion.—Chlorates are excreted mainly by the urine, but partly also by the saliva. The urinary excretion begins promptly and is completed within forty-eight hours, about 90 per cent. of the chlorate being recovered (Rosenblum). A great deal of this is reduced to chlorid after the urine is voided. It is doubtful whether this reduction occurs ordinarily in the body. Bromates are partly reduced in the tissues, and sodates intensively, when given by mouth, but not when administered hypodermically or by vein (Crespolani, 1900).

The distribution of fatal doses has been studied by Rosenblum, 1912.

Blood Changes.—When the chlorates are added to blood, either inside or outside the body, they effect the formation of methemoglobin. The chlorate ion is not used up in this process, so that it may convert an indeterminate amount of hemoglobin. They differ in this respect from the nitrites (see index), and their action is in consequence more violent and more prolonged. They may in this way produce an actual asphyxia.

In a severe case of human poisoning the blood, examined 15 hours after taking the chlorate, contained both methemoglobin and hematin. Hemolytic icterus developed later. Similar conditions were found in poisoned animals (Feigl, 1916).

In addition to this formation of methemoglobin, the chlorate break up the blood corpuscles (Huber, 1912). This may produce emulsion; the proteins, etc., which are liberated by the destruction of the corpuscles are irritant to the kidneys and produce interstitial nephritis, with the usual phenomena—proteins in the urine, casts, sometimes hemoglobin compounds. Possibly the chlorate ion itself irritates the kidneys.

Fat embolism of the lungs and other organs are also of frequent occurrence, at least in animals. They originate from the bone-marrow. The blood contains numerous normoblasts. Fragmentation of the heart muscle is a frequent cause of death (Winiogradow, 1907).
Methemoglobin Formation by Chlorates.—The blood of different animals shows a different degree of susceptibility for the methemoglobin formation. These differences are common with all poisons acting on the blood, especially as between carnivorous and herbivorous animals. The cause is not understood, but is perhaps connected with differences in the alkalinity of the body. The conversion occurs fairly readily into \textit{vires} in man, dog, and cat, while rabbits and guinea pigs are almost immune. But in the test-tube chlorates convert rabbit's blood, although more slowly than dog's. The action is much slower outside of the body, often requiring several hours. The concentrations that are injurious for the blood have been determined by E. Caesar, 1918.

Iodates and Bromates have a similar action on hemoglobin (Heinz, 1868).

Potassium Chlorate Poisoning.—This is fairly common, either by an overdose, since the laity does not generally regard it as a toxic substance; or by the swallowing of some of the solution given for gargling.

Fatal Dose and Course.—The susceptibility varies greatly and this is one of the principal dangers. The variation may be due to differences of absorption and excetration, embolism, etc. In general, 10 Gm. may be considered as toxic, 25 to 50 Gm. as fatal (Lewin). The mortality is about 70 per cent. The symptoms may start at once or be delayed to six hours; death may occur in six hours to seven days.

Symptoms of Poisoning.—These consist in gastritis (nausea, vomiting, gastralgia); methemoglobinemia (cyanosis, collapse and terminal convulsions); and nephritis (lumbar pain, anuria, albumin, casts, blood, etc.). The postmortem findings correspond with the symptoms.

Treatment.—This consists in gastric lavage, hot drinks, and symptomatic measures.

PREPARATIONS—CHLORATE

*Potassium Chlorate (Pot. Chlorat), U.S.P., B.P., \text{KClO}_3.* Colorless crystals or white granular powder; odorless, cooling, characteristic taste. Sol. in water (1:1:1); nearly insol. in alc: sol. in glycer. \text{Explosive} when triturated with organic matter (not when in watery solution). \text{Dose}, 0.25 Gm., 4 gr., U.S.P.: 0.3 to 1 Gm., 5 to 15 gr., B.P.

Trock. Pot. Chlorat., U.S.P., 0.15 Gm., 0.5 gr.; B.P., 0.2 Gm., 3 gr.

Sod. Chlorate, \text{NaClO}_3.—Freely sol. in water (1:1); sol. in alc. (1:100). \text{Dose}, 10 Pot. Chlorat.

BROMATES

These act similarly to chlorates, but are considerably more toxic, mainly by central paralysis (Santesson and Wickberg, 1913). They form methemoglobin in vivo, but not as actively as chlorates (v. Mehring, 1885; Cushny, 1908).

IODATES

Macciotta, 1916, found \text{KIO}_3 to be tolerated without disturbance, with oral administration of 0.25 Gm. per Kg. The urine contained no trace of iodate, but only iodid. Hypodermically, the above dose was fatal.

METHEMOGLOBIN FORMATION\footnote{For Bibliography, see Benedicenti, \textit{Archiv f"ur Physiologie}, 1897, p. 810.}

Methemoglobin contains the same amount of oxygen as oxyhemoglobin, but in different combination, so that it is held more firmly (except against certain reducing agents (Haldane). The two hemoglobin compounds therefore differ essentially in certain of their properties:

1. The spectrum (see Fig. 20). The color of methemoglobin has more of a brownish tinge.
METHEMOGLOBIN FORMATION

2. In the readiness with which they give up oxygen. While the oxyhemoglobin is a very unstable compound, giving up its oxygen and taking it again, with great readiness, methemoglobin is a comparatively stable and unchangeable compound.

3. In their behavior to certain reagents. For instance, HCN does not form any characteristic compound with oxyhemoglobin, but with the methemoglobin it gives cyanmethemoglobin. Similar compounds are formed with HNO₂, sulphocyanids, and many other salts, and also with alkalies.

FIG. 39.—Spectroscopic bands of blood pigments.

Methemoglobin may be formed from oxyhemoglobin in quite a number of ways:

1. By oxidizing agents: Potassium chloride, ferricyanid, permanganate, H₂O₂, etc. 
2. By reducing agents: The nitrites, hydroxyamin, formalin, iodin, chrysarobin, etc. 
3. By certain tumors. (Phenyldihydrin also gives reduced hemoglobin, and destroys some of the hemoglobin absolutely, producing a new compound which, under certain conditions, yields a green pigment, hemoverdin.)
4. In the early stages of putrefaction, and by the action of light.
5. By salts and glycerin.
6. By acids (this has been denied).

The physiologic significance of this methemoglobin formation rests on the stability of the compound and its consequent inability to carry out the functions of oxyhemoglobin. This produces asphyxia of the tissues. Pure methemoglobin solutions may be injected into the blood, without causing any symptoms. Even the urine remains free from albumin or methemoglobin. The compound is in part secreted by the bile, in part deposited in the hematopoietic organs.

Nor is the temporary conversion of a considerable proportion of the oxyhemoglobin into its isomer of great significance; for methemoglobin is not absolutely stable, and as soon as the oxygen starvation of the tissues is carried to a certain degree, they seize upon the methemoglobin and decompose it. The conversion of a third of the hemoglobin into methemoglobin causes only very slight symptoms; and life is still possible when three-fifths of the hemoglobin has been replaced. Life becomes extinct when the hemoglobin has sunk to one-third. The condition can therefore become dangerous only if the methemoglobin-former continues its action. This does not occur in therapeutic doses of any of these drugs, but may contribute to the fatal ending in cases of poisoning. The symptoms are those of asphyxia. There is a peculiar blue tint about the lips and finger-nails, etc. The methemoglobin gradually returns to oxy- or reduced hemoglobin after death, so that an examination after several days may fail to reveal its presence.

Most of these drugs transform the hemoglobin inside of the corpuscles, without injuring the vitality of the latter; but some cause, in addition, a breaking up of the corpuscles, and this greatly increases the danger. Aside from the asphyxia which must be proportioned to it, the proteins and other substances liberated cause injury to the kidney—albuminuria, glycosuria, methemoglobinuria, etc. It is also claimed that it causes the sudden formation of fibrin ferment, which may then cause extensive intra-vascular clotting. The debris is credited with causing emboli. But these views are not admitted by all investigators. A small destruction, such as may be caused by the subcutaneous injection of glycerc, certainly has no permanent injurious effect.

826

THE REACTION OF THE BODY (REMOTE EFFECTS OF ACIDS AND ALKALIES)\textsuperscript{1}

General Statements.—The $\text{H}^+(\text{aq})$ ions of acids and $\text{OH}^-(\text{aq})$ ions of bases part readily with their electric charges, and therefore alter the state of colloids. In this way, and also by direct chemic changes, they produce extensive alterations in the functions of cells, which would be rapidly fatal if they exceed a certain degree.

Actual Potential and Total Acidity and Alkalinity.\textsuperscript{2} These effects are produced only by the dissociated ions, which represent the actual acidity and alkalinity. The activity of an acid or base depends therefore not only on its total concentration, but also on its dissociation. The mineral acids, $\text{H}_2\text{SO}_4$, $\text{HCl}$, which dissociate freely, are much "stronger" than equimolecular solutions of the organic acids or acid salts, which dissociate only slightly. Under like circumstances, the same actions and as practically inert in this respect. They may, however, be drawn upon to neutralize added acid or alkali, in proportion as the free ions become combined, and in this respect are equivalent to the dissociated ions. They may therefore be considered as potential acidity or alkalinity. This relation was formerly not understood, and this has given rise to much confusion. The ordinary methods of titration measure only the total acidity or alkalinity (actual + potential). In complex fluids, like the blood or urine, this bears no relation to the true actual acidity. The actual reaction is measured by the electric potential; or by the use of a series of indicators which are only affected by certain concentrations of free $\text{H}^+(\text{aq})$ or $\text{OH}^-(\text{aq})$ ions (Goerensian); or by determining the velocity of certain reactions (inversion of cane-sugar, saponification, etc.), which depend on the $\text{H}^+(\text{aq})$ or $\text{OH}^-(\text{aq})$ concentration.

Hydrogen-ion Concentration.—The actual reaction is also termed the true reaction or H-ion concentration. It is generally expressed as reciprocal logarithms (as the "hydrogen exponent," $\log_{\text{H}}\, f$), a solution containing 1 molecule of dissociated $\text{H}^+(\text{aq})$ in 10,000,000 L. (1:10\text{\textsuperscript{7}}) is said to have the $\text{H}^+(\text{aq})$ concentration of 7.0 (also written $\text{pH} = 7$). This constitutes neutrality, since water dissociates at 25\textdegree C so as to contain $\text{H}^+(\text{aq})$ and $\text{OH}^-(\text{aq})$ ions, each in the proportion of 10\textsuperscript{-7}. An increase of $\text{H}^+$ ions means, of course, a relative diminution of OH ions and vice versa.

This system of notation, although convenient, is at first somewhat confusing. It must be remembered that $\text{pH} = 0$ (really 10\textsuperscript{-1}) means a higher acidity than $\text{pH} = 7$ (really 10\textsuperscript{0}). The acidity is therefore inverse to the number. Also, since logarithms are used, $\text{pH} = 3$ means an acidity 1,000 times as great as $\text{pH} = 6$; not twice as great.

\footnote{1 The local actions of concentrated acids and alkalies are discussed under "Local Irritants," see Index.}

\footnote{\textsuperscript{2} Advanced students are advised to consult the book of Michasila, "Die Wasseroberflächen-Konzentration," 1915, for a fuller presentation of the subject and detailed data.}
THE REACTION OF THE BODY

The following may perhaps serve to render the subject clearer:

\[ \begin{align*}
    \text{H}_2 & = \frac{N}{10} \text{ acid} \\
    \text{H}_6 & = \frac{N}{1,000,000} \text{ acid} \\
    \text{H}_7 & = \text{Neutrality} \\
    \text{H}_8 & = \frac{N}{1,000,000} \text{ alkali} \\
    \text{H}_{14} & = \frac{N}{10} \text{ alkali}
\end{align*} \]

The older notation is simpler, but less convenient; i.e., \( \text{H}^+ = 2 \times 10^{-7} \) denotes twice as great acidity as \( 1 \times 10^{-7} \), 0.5 \( \times 10^{-7} \), one-half as great; etc.

**Actual Reaction of the Body-fluids.**—The normal reaction of the tissues and fluids within the body proper is very near neutrality, inclining a trifle to alkalinity \( (pH \approx 7.1 \text{ to } 7.8) \). The gastric and intestinal juices and urine are the only fluids in higher animals which depart from this rule. The neutrality of the blood is maintained even in acidosis—although the cells where the pathologic acid is formed, probably develop an increased acidity, which is supposedly responsible for the symptoms. Normal living cells have an alkaline or neutral reaction, judging by intravital stains (A. P. Mathews).

**Reaction of Normal Blood.**—The \( \text{H}^+ \) of fresh debribinated blood is very weakly alkaline, almost neutral. It is stated, for instance, as \( 0.3 \) to \( 0.7 \times 10^{-7} \) (Friendenthal, 1904); \( pH = 7.45 \) for arterial, \( 7.3 \) for venous (Hasselbach, 1912); \( 7.6 \) to \( 7.8 \) for human serum, \( 7.2 \) to \( 7.5 \) for oxalated blood (Levy, Rowntree, and Narvott, 1915), at air temperature; at \( 37^\circ \) the alkalinity would be about 0.1 higher. Similarly, excessive ventilation of the lungs with air or oxygen lowers the \( \text{H} \) concentration of the blood, whereas excessive ventilation with \( \text{CO}_2 \) increases it (Milyon, 1914). The \( \text{CO}_2 \) tension has some influence, so that venous blood is a little less alkaline than arterial.

**Pathologic Blood.**—Levy et al., found the reaction of the serum in sixty miscellaneous medical cases to be normal \( (pH 7.0 \text{ to } 7.8) \); the whole blood was also nearly unchanged \( (pH 7.1 \text{ to } 7.3) \). Even when symptoms of acidosis are present, the alkalinity is but little decreased \( (pH \text{ of serum } 7.2 \text{ to } 7.5; \text{ Levy et al.}) \). Under alkali therapy, this is restored toward normal.

In diabetic coma, Benedict, 1906, records an extreme change to \( 1.5 \times 10^{-7} \). Masel, 1913, and Van Sylke, 1915, found practically no change, except just before death (7.71, Masel); van Sylke, however, observed that the addition of \( \text{HCl} \) to acidosis blood raises its \( \text{H} \) concentration much more than when added to normal blood. The essential blood change of acidosis is therefore the diminution of the reserve alkali.

In normal animals, feeding with acids or alkalis has practically no effect on the \( \text{H} \) concentration of the blood. Intravenous injection of acid into dogs or rabbits produces air hunger when \( pH 7.65 \) is reached; death occurs with \( pH 6.0 \) (Levy et al.; 9 \( \times 10^{-7} \), Salie, 1908). At the other extreme, concentrations above \( pH 7 \) are probably also fatal (Rowntree).

**Other Body Fluids.**—With few exceptions these have about the same reactions as the serum (Friendenthal, 1901, Michaelis, 1914). On standing outside of the body, they may become acid (Handlik, 1914).

The hydrogen ion concentration of the cells must generally be somewhat higher than that of the blood, since they supply the acid that is excreted by the urine and lungs.

**Effusions:**—Handlik, 1914, found the \( \text{H} \) of edema and pleuritic fluids about \( 7.4 \); ascitic fluid, \( 7.42 \).

**Lobar Pneumonia.**—The circulation in the pneumatic lung is so greatly restricted (Kline and Witternitz, 1914), that a rather high \( 
\text{H} \) ion concentration may accumulate. That of the press-juice at autopsy has been obtained as \( 0.0 \) and even \( 5.4 \) (F. Lord, 1919). However, postmortem changes might have occurred. Lord considers the acidity a possible factor in recovery, since pneumococci are injured by \( pH 7.8 \), and killed quite rapidly by \( 6 \) to \( 5 \).
Bile.—When flowing directly from the liver, bile is nearly neutral (6.07 to 6.2 X 10^-7). The bile from the gall bladder is more variable (6.08 to 7.18) and may become slightly acid on prolonged sojourn. (Okada, 1915; Quagliariello, 1916).

Digestive Fluids.—The following pH figures are taken mainly from Michaelis, 1914: Saliva, 6.09; gastric juice, 1.72; intestinal juice, 8.00.

Actual Reaction of the Digestive Tract.—This may differ materially from the reaction of the digestive fluids, since these tend to be neutralized by each other, as well as by the buffer-action of proteins. Bacterial activity may also introduce modifications.

Stomach.—The resting empty stomach may be nearly neutral. During the first one and one-half to three hours after a meal, the acidity rises rapidly to pH = 2 or even 1; depending on the individual. It then remains stationary until nearly all the food has left the stomach (McClendon, 1925).

The reaction of the duodenal contents is the resultant of the neutralization of the acid chyme by the slightly alkaline intestinal and pancreatic juice and bile.

The actual pH of the duodenal contents, however, is much more acid. Myers and McClendon, 1920, found the usual reaction in man to be between 3.2 and 5.2.

Small Intestine.—Long and Fenger, 1917, found the reaction of the intestinal contents slightly acid throughout the small intestine; the acidity decreasing somewhat with the distance from the pylorus. In the human jejunum, it ranged from pH = 3.8 to 7.8, mean 5.8; in the upper third of the small intestine in hogs, it ranged from 6.6 to 7.4, mean 6.7; in the middle third, 6.5 to 7.6, mean 6.9; in the lower third, 6.4 to 8.1, mean 7.

Similar figures were obtained in calves, lambs and dogs. They have been confirmed by McClendon et al., 1920.

Milk.—This is about 7.

Cerebrospinal Fluid.—Hanulik, 1914, found this to range between 6.08 and 7.3.

Hurwitz and Traxler, 1916, found the alkalinity constantly somewhat higher than the blood (average pH, fluid, 8.11; blood, 7.66; difference, 0.45). This normal reaction was not changed in any stage of syphilis.

Placental Cells.—These may reach an acidity as high as pH = 3, as shown by their color indicators. (Haas, 1915).

Reaction of Urine.—This usually inclines toward actual acidity, the normal range in man being pH = 5.12 to 7.46; the average about 6.03. (The acidity is greater after fasting and perspiration, Haas, 1914.) It exceeds 5.0 in less than 1 per cent. and 5.5 in less than 10 per cent. In most diseases, the acidity averages distinctly higher; in cardiac disease, about 4.91. The highest acidity so far reported is 4.7 (L. J. Henderson and pupils, 1914). The reaction is determined mainly by the ratio of phosphates.

According to Cushny’s theory, the acidification of the urine occurs in the tubules by the active re-absorption of alkaline ions; the cations being more easily absorbed than the phosphate anions. Carbonates, being readily absorbed, do not contribute much to the process.

On the other hand, Trevan, 1916, claims that the acidity of the urine, from perfused frog kidneys, does not depend on the absorption of alkali, but on the tubular excretion of NaH2PO4 being faster than that of Na2HPO4.

Administration of Acids and Alkalies on Urine.—Acid sodium phosphate raises the acidity, especially if the urine was previously alkaline; but the acidity does not surpass the normal limit (pH raised from 6.7 to 5.3, Henderson and Palmer, 1913; from 7.2 to 4.85, Hanulik and Collins, 1913). Alkalies increase the alkalinity somewhat beyond the normal range (20 to 40 Gm. NaHCO3 per day, pH = 8.7 Henderson and Palmer: 4 Gm., change from 6.2 to 7.4, Hanulik and Collins). Sodium citrate also makes the urine somewhat alkaline (7.2 to 7.4, Hanulik and Collins).

Regulating Mechanisms.—Metabolism leads to the production of acids (carbonic, lactic, sulphuric, phosphoric, etc.) which would tend to increase the acidity of the body.

The carbonates derived from the combustion of vegetable salts would tend to render it alkaline.

However, the maintenance of the normal, nearly neutral reaction is so highly important that it is regulated with the greatest nicety by the use of several mechanisms. The carbonates and alkaline phosphates of the blood and tissues constitute a stock of potential alkali; and the carbonic acid and acid phosphates of potential acid. These are sufficient to neutralize at once all ordinary attempts to change the actual reaction. The
amphoteric character of the proteins permits them to neutralize a limited quantity of either acid or alkali. The administration of acid or alkalis by mouth therefore does not change the actual reaction of the blood and tissues, but only the potential acidity or alkalinity, i.e., the alkali reserve. The ammonium formation, and the excretion by the urine and lungs, finally restore the equilibrium of potential alkali.

Neutralization in the Alimentary Canal.—Neither acids nor alkalis are absorbed unchanged from the alimentary canal. The alkalis (including the carbonates) are neutralized by the HCl of the gastric juice. Or if given in larger amounts, they enter into loose alkali-protein combinations before they reach the blood. The acids undergo a similar change, or if they are not entirely absorbed before entering the intestine, they are there neutralized by the carbonates. The immediate effects, then, would consist only in altering the reaction of the alimentary canal.

(Concentrated acids and alkalis produce corrosions by direct chemic actions. These local effects were considered under Irritants.)

Neutralization in the Blood.—It is difficult to alter the reaction of blood even in vitro. Friedenthal, 1903, showed that serum requires, to secure a given change of reaction, thirty to forty times as much NaOH and 327 times as much HCl, as would be needed in water. This stability is due to the presence of the salts of weakly dissociating acids, which limit the liberation of \( H^+ \) ions to practical neutrality. This property is especially marked with phosphates and carbonates, which are important "buffer" constituents of the serum. The proteins act similarly.

If \( H^+ \) ions are added to such a system, they will be expended in liberating the weak acid from its salt; and since the weak acid is not ionized in the presence of its salts, the actual reaction will be practically unaltered. If OH\(^-\) ions are added, they will be expended in neutralizing the free weak acid; and thus will also leave the actual reaction unaltered. A notable change in the true reaction can occur only after enough acid or alkali has been added to neutralize or liberate all of the weak acid—i.e., there will be no material change of reaction until not only the free, but also the potential acidity or alkalinity has been overcome. This would require quantities of strong acids or bases much greater than it would ordinarily be possible to introduce into the living body.

So far as this neutrality regulation is concerned, the blood may be considered as a solution of \( H_2CO_3 \), \( NaHCO_3 \), and \( NaHPO_4 \). All these dissociate so weakly that in solutions of \( NaHCO_3 \), \( NaHPO_4 \), the concentration of blood, their \( H^+ \) and OH\(^-\) concentration, separately or together would be practically that of neutrality; i.e., in the close neighborhood of 10\(^{-7}\).

If an acid (HCl) were added to the mixture, it would react with the salts, producing:

\[
\begin{align*}
HC_2H_3O_2 + NaHCO_3 & = NaCl + H_2CO_3 \\
HC_2H_3O_2 + NaHPO_4 & = NaCl + NaHPO_4
\end{align*}
\]

This would increase the ratio of \( H_2CO_3 \) and \( NaHPO_4 \); but these dissociate so weakly that they practically leave the actual reaction unaffected. The \( H^+ \) concentration would therefore not be increased until all the NaHCO\(_3\) and NaHPO\(_4\) are used up.

If an alkali (NaOH) were added to the mixture, it would react as follows:

\[
\begin{align*}
NaOH + H_2CO_3 & = NaHCO_3 + H_2O \\
NaOH + NaHPO_4 & = NaPO_4 + NaHPO_4
\end{align*}
\]

This would reduce the ratio of the free acids, \( H_2CO_3 \) and \( NaHPO_4 \); but since these acids were practically neutral, this does not affect the actual reaction materially, until all the carbonic acid and acid phosphate are used up.

1. Michaelis and Garmendia, 1915, state the normal ratio of the phosphates in blood plasma as \( NaHPO_4 \sim \frac{3}{1} \) (molecules).
The theory of "buffer salts" has been elaborated especially by Stévens and L. J. Henderson. Tables are also contained in the book of Michaels. W. M. Clarke and Lubis, 1916, have determined the hydrogen electrode potentials of phosphate and borate mixtures.

Blood Corpuscles.—These also contribute to the protective buffer action, since they contain bicarbonate and phosphates.

Restoration of the Potential $H^{+}$ and $OH^{-}$ Ions.—The regulating mechanism of the blood is important for protecting the body against sudden changes, for meeting temporary emergencies. However, this impairs the stock of potential $OH^{-}$ ions, and therefore would not furnish a permanent protection. Other mechanisms are called into play to restore the normal ratio of these potential ions; mainly by regulating the excretion of CO$_2$ through the lungs; by varying the reaction of the urine; and by the more or less complete conversion of NH$_3$ into urea.

Regulation by Excretion of CO$_2$.—Addition of acid to the blood liberates CO$_2$ from the bicarbonate. This increases the CO$_2$ tension, and thus its excretion by the lungs. The increased CO$_2$ tension stimulates the respiratory center, and thus hastens the elimination. This restores the normal ratio of H$_2$CO$_3$ + NaHCO$_3$. Conversely, the addition of alkali diminishes the tension of CO$_2$ and thus its excretion.

Regulation by Combustion of Organic Acids.—The organic acids arising in metabolism are normally oxidized to CO$_2$ and H$_2$O, and excreted by the lungs and urine. This mechanism is disturbed in disease, starvation, etc., and then gives rise to acidosis.

Conversely, the injection of alkali materially increases the excretion of unoxidized lactic acid by the urine (Macleod and Knapp, 1918).

Regulation by the Urine.—The urine, like the blood contains a mixture of acid and neutral phosphates (Orth found a mean of 60 per cent. as $MgH_2PO_4$ and 40 per cent. as $MgHPO_4$). When acid is introduced, the ratio of acid phosphate is increased; alkalis increase the proportion of alkaline phosphate. This elimination of the excessive acid or alkali ions rapidly restores the potential acidity or alkalinity of the tissues. The flow of urine is also increased, so that acids and alkalis act as effective diuretics. The administration of acids first increases the $PO_4$ excretion; later, this decreases with the available supply of these ions (Fitz, Altschul and Henderson, 1907). The influence of nephritis was studied by Palmer and Henderson, 1915.

Under normal conditions, the human kidneys free the body from 50 to 70 c.c. of normal acid per day. In diabetic coma, this quantity may be increased ten times (Henderson and Palmer).

Acid on Alkali Excretion.—Secchi, 1904, reports that the administration of HCl to man or dogs on a meat diet increases the elimination of ammonium persistently; that of $K$ and Na temporarily. The Ca and Mg are not materially affected in the urine, but increased in the feces, especially Ca. The calcium of the tissues may thus be diminished.

Stehle, 1917, confirmed the increased excretion of Ca and Mg, with dogs. Givens and Mendel found the urinary excretion of Ca increased more than the Mg. However, the alterations of the total balance of N, Ca, Mg or P were not material (in dogs).

With rabbits on a cabbage diet (rich in Ca) administration of acid markedly increases the elimination of Ca and Mg, less that of $K$ and Na. The Ca excretion is mainly by the urine. The tissue Ca is greatly decreased (Stehle, 1914).

Feeding with HCl may cause arterial changes (Adler, 1914).

Mineral Metabolism in Experimental Acidosis of Rabbits.—Goto, 1918, administered 25 to 75 c.c. of N/4 HCl daily for 1 to 4 weeks. Most of the animals that received more than 25 or 30 c.c. per day died within 1 to 2 weeks. The major alkaline reserve were utilized in the following order: first the plasma bicarbonate; then the alkaline carbonate and phosphate of the muscles; and the calcium carbonate of the bones.
The plasma bicarbonate was reduced. The urinary phosphates are first increased, then diminished. The fecal phosphate also decreased. There was also marked loss of phosphate and potassium from the muscles. The sodium was not diminished. The skeleton lost to per cent. of its weight, mainly as calcium carbonate, thus increasing the ratio of calcium phosphate.

Urinary Reaction Regulation in Man.—The administration of HCl increases the titratable acid and the ammonia, leaving the factor titratable + ammonia practically unchanged. Administration of acid sodium phosphate also increases the titratable acid, but not the ammonia; so that the acid + ammonia factor rises. This is probably explained by a smaller increase of the hydrogen ion concentration, making less demand on the ammonia elimination. Administration of phosphate mixture of pH = 7.4 increases the titratable acid but slightly, and diminishes the ammonia, so that the acid + ammonia factor rises (Marriott and Howland, 1918).

Hesselbach, 1916, also made out a definite relation between ammonium excretion and the reaction of the urine, varying in acidosis conditions.

Regulation by Ammonia.—NH₃ is a normal precursor of urea. Its conversion is not quite complete and somewhat elastic: If the acidity tends to rise, a larger part of the ammonium is left unconverted, and is used to neutralize the excessive acid. If the alkalai tends to rise, more of the ammonium is converted, leaving its union to neutralize the alkali. The ratio of unconverted ammonia (reflected in the ratio of NH₃ to total N of the urine) is therefore an index of the acid or alkali tendency of the body. It rises if acids are introduced or formed in the organism (acidosis); and is lowered when alkalies are administered. Ammonium is also produced by de-amination of proteins. Ammonia Regulation in Man.—In man, also, there is a close relation between the ammonia and excretion of acid by the urine (Hasselbach, 1916).

Acidosis in Infancy.—Infants and young children develop acidosis readily, presumably because they have a relatively low alkali reserve. They also form acetone substances easily.

Gastric Secretion.—During stimulation of gastric secretion by food or water, the absorption of the acid chyme from the intestines leads to increased ammonium output in the urine (Ivy, 1925).

The increase of the ammonium quotient in the urine is not, however, an infallible proof of acidosis. It requires confirmation by other tests. Nor, on the other hand, is increased ammonia excretion a constant feature of clinical or experimental acidosis. It occurs especially in the ketonuric types, but is absent in certain nephritic acidoses.

Efficiency of the Regulating Mechanism in Different Animals.—The protection against acids is conspicuously more perfect in carnivora, both as concerns the NH₃ and the elimination (Spino, 1909)—probably because these are accustomed to ingest a certain degree of fat with their food. It is impossible to lower the alkalinity of the blood of a dog, to such a degree as to produce symptoms, by introducing acid into the alimentary canal, unless corrosion be produced. But if an acid or acid salt be injected into a vein, it will cause very pronounced symptoms. In herbivorous animals, these may also be produced if large quantities are given by the mouth. They will result in death even before the reaction of the blood has become neutral. So that it is not strictly correct to speak of an "acid action," but rather of the effects of diminished alkalinity (Kettner, 1902).

Influence of Diet on Ammonium Conversion.—The ammonium regulation is not entirely absent in herbivora. Cows and calves use it quite efficiently when acid is fed (Hart and Nelson, 1913). Eppinger, 1906, claimed it to be influenced by diet: viz., that a vegetable diet renders dogs susceptible to acid poisoning; and that a meat diet, or injection of amino-acids, evokes the ammonium mechanism even in rabbits, and thus protects them against acid. However, later observers were unable to confirm him (Pohl and Mungan, 1906, G. Bostock, 1913).

Acid-base Content on the Diet.—This has not been worked out in detail. Proteins and fats tend to predominance of acid; and salts of vegetable acids tend to alkali. Meat or grain diet is therefore acid producing; fruits, carrots, etc. tend to alkaline.

Effect of Nephritic Poisons.—Acid producing diets render rabbits more susceptible to mild nephritic poisons; for instance to oils (Salant and Bengis, 1917).

Alkalosis.—Vegetarian diet would tend to increase the alkalinity of the body. This is prevented by the retention of carbonic acid; by the
conversion of NaH₂PO₄ into Na₂HPO₄; by more complete oxidation of ammonium; by neutralization of proteins, and by increase of unoxidized organic acid, especially lactic acid.

Lactic Acid Excretion in Alkalosis.—Injection of sodium carbonate or oral administration of the bicarbonate produces a distinct increase of the urinary lactate. However, the excreted acid would neutralize only about 3/4 of the alkali (MacLeod and Knapp, 1918).

Nature of Acidosis.—Acidosis or acid-intoxication means a depletion of the alkali-reserve of the body; but not necessarily a change in the actual relation is proportional to when acids or acid salts are introduced in excessive quantity, or when the organism fails to dispose promptly of the acids that are formed in metabolism. So long as there is an adequate store of potential alkali, the actual reaction of the blood is not materially changed, although it contains less carbonate. The acidity and the ammonium of the urine will also tend to increase. If the acidosis is due to faulty metabolism, oxalyluric acid and acetone substances will appear in the urine.

True and Compensated Acidosis.—Rowntree, 1916, proposes the term "Compensated Acidosis" for diminution of reserve alkali (decreased alveolar CO₂ without material change in the actual reaction of the blood; and "True Acidosis" when the alkalinity falls below pH = 7.4. This occurs only when the respiration fails to remove the excess of CO₂, i.e., till as death approaches. A true acidity of the blood (pH above 7.0) is not seen clinically.

Symptoms of Acidosis.—The chief clinical sign of moderate acidosis is the hyperpnea, required to eliminate the liberated CO₂. When the actual reaction of the blood becomes noticeably changed, the vasomotor and other medullary centers are also stimulated; especially if the cause is acute, as with intravenous injection of acid. With further rise of the H-ion concentration, the nervous centers become depressed, as also the cardiac muscle. The effects agree with those of excessive CO₂ tension, asphyxia and oxygen deprivation, and diabetic coma, which are really forms of acidosis. The final symptoms consist of coma, convulsions, depressed respiration and fall of blood pressure, etc. Death takes place by respiratory paralysis, generally before the blood becomes actually acid. The symptoms are at once removed—even in the last stages—by injection of Na₂CO₃ (F. Walter, 1877).

Toxicity of Acids.—This varies greatly according to conditions. In cattle, for instance, Berg, 1915, sometimes found considerable tolerance (0.87 gm. of HCl, as 40 per cent., vein, per kilogram).

Respiratory Center.—This is inhibited by decreasing the H ion concentration of the blood, and stimulated by increased H ion concentration (Douglas and Haber, 1901; Winterstein, 1915). For instance, the intravenous injection of 0.5 c.c. of normal lactic or other acid per kg. of dog produces a marked increase of the rate and amplitude of respiration (S. J. Cohen, 1918). The effects on the respiratory center do not appear until the H ion concentration lies beyond pH 7.3 and 7.6. Evidently, the center is much less sensitive to diminution than to increase of H ions. The effects occur also on perfusion of the medullary centers (Hooker and Wilson, 1917); and by direct application of acids to the medulla of frogs.

Role of H-ion concentration and Carbon Dioxide.—In general, the respiratory stimulus is proportional to the H ion concentration (Winterberg; F. B. Robertson, 1916. However, carbonic acid stimulates more than would correspond to its acidity (Rozewski, 1914.). This holds also for the perfused center (Hooker and Wilson). R. F. Scott, 1918, finds that excess of CO₂ stimulates respiration even if the blood is made distinctly more alkaline (pH = 7.65), as by sodium carbonate injection. The greater efficiency of carbonic acid is probably due to more rapid penetration into the cells.
THE REACTION OF THE BODY

pneum following on excessive respiration is due to deficient CO₂ tension and lowered H⁺ ion concentration. **Chyme-Stoker respiration** is attributed to accumulation and oxidation of acids (V. Henderson, 1910).

**Globin.**—Increased acidity diminishes the affinity of hemoglobin for oxygen (Boothby, 1916). In the actual H concentration is not much altered, but the diminution of reserve serves every increase of CO₂ much more effectively; for instance, the respiration is a decompenated patients by 2 to 3 per cent. of CO₂ in the air, while normal is require 4.5 to 5.5 per cent. Alkalai treatment restores the response to normal.

**the Dyspnea.**—This is often but not always associated with acidosis. In the it is not relieved by alkalai. Such cases probably involve direct changes in the sol of the respiratory center (Christian, 1910).

**Vasomotor Center.**—The stimulation (reflected in the rise of blood has been studied by Mathison, 1911. Ficher and Sollmann, 1915, found and temporary stimulation, independent of blood-pressure changes.

**Rate in Man.**—This shows a close parallelism with the H⁺ ion concentra-

cardiac blood, and therefore with the oxygen consumption (Boothby, 1915, id method of Keough and Lindhard).

**Vessels.**—These are temporarily dilated by weak acids including CO₂ and Lemberger, 1917). Alkalai do not constrict. This has been generally con-

in the lying mesentery, the minimal effective concentrations are: for dilation, constriction, H⁺ 9 to 11. Excited arterial rings do not respond satisfactorily. They are constricted by H⁺ (I. Adler, 1916).

**Heart.**—The automatic contractions of the heart are only within certain ranges of concentrations, which differ for the various portions of the heart (Dale and Thacker, 1916). He shows the highest H⁺ concentration (H⁺) = 4 to 9.5; the vent-

**Heart.**—H⁺ ion changes within the physiologic range elicits effects. **Increased alkalinity** (H⁺ 7.0 to 7.8) increases tissues, especially on the circulation, by increasing the amplitude of the beats, and diminishing the tonus (Andrus, 1917).

**Mammalian Heart.**—The effects of oxidizing substances, acids and alkalai, bed by Loewenhart and Eyster, 1915. Yanagawa, 1916, finds the coronary restricted by increase of alkalinity, dilated by acidity.

**Functions.**—**Excised Ureter.**—The movements are depressed by acid, stimu-

latability (G. B. Roth, 1917).

**Concentration of Perfusion Solutions.**—The H⁺ of Locke's solution is about 7.5, a low buffer value. That of Tyrode's solution is 8 to 8.1 (G. B. Roth, 1917).

**of Skeletal Muscle.**—Fatigue or paralysis is produced by perfusion with acid lactric acid, acid potassium phosphate or CO₂ (Ranke, 1863; Burridge, 1910). Cular work is accompanied by the production of these acid products, parts the occurrence of ordinary fatigue.

**Irritation.**—Acids produce prompt stimulation of sensory nerves. They used to test reflex excitability, as for instance in Turck's method. With this, the reaction time is influenced not only by the H⁺ ion concentration but also on the acid to penetrate cells (Crudder, 1918).

**Flow.**—Yanagawa 1916, found the thoracic lymph flow unaffected by the injection of acids, to the point of toxicity. Alkalai acted only like neutral.

**Flow.**—In excess of kidneys of rabbits, perfused with sodium chloride solutions, flow varies inversely to the H⁺ ion concentration (Isaacs, 1917). In life, the conditions are much more complex.

**Ischemia.**—Living tissues resist the entrance of all acids, except sallicylic. Dead area to all (Harvey, 1914).

**Ischemia.**—Living tissues resist the entrance of all acids, except sallicylic. Dead area to all (Harvey, 1914).

**Ischaemia.**—Living tissues resist the entrance of all acids, except sallicylic. Dead area to all (Harvey, 1914).
Metabolism.—Acid intoxication lowers gas metabolism and heat production (Choo-stek, 1853).

The administration of non-toxic doses of acids and bases (to dogs) does not materially alter the balance of N, Ca, Mg or P (Givens and Mendel, 1917).

The effects of lesser changes in the reaction of body tissues must be rather limited, since these are so promptly brought back to normal. While it can not be doubted that such changes must have an influence upon metabolism, the nature of this can not be stated, because it is complicated by the actions of these substances on the alimentary canal.

The latter is different in the case of acids and alkalis. Some of the other actions also require separate consideration. Organic Acids and their salts are rapidly burned to carbonate after their absorption; so that they act as acids only in the alimentary canal but as alkalis after they are absorbed (Buchoff, 1888).

Dicarbonates and bicarbonates of the alkali metals diminish the toxicity of acids for the fish Fundulus. CaCl₂ is considerably more efficient (J. Loeb and Wastesneys, 1911). The effects of electrolytes on the penetration of acid into Fundulus ova are discussed by J. Loeb, 1912.

Effects of Increased Alkalinity.—Slight increase stimulates many physiologic processes; a few are depressed.

The injection of lethal doses of alkali produces tremors, rigidity; finally vomiting, convulsions, relaxation of sphincters; sometimes edema and ascites (Rowntree, 1918). An excessive intravenous injection of bicarbonate, in a human subject, was followed by tetany, with recovery (Harrop, 1919).

Vichow, 1854, showed increased motion of spermatozoa; Gaule, 1878, increased cardiac activity; Bethe, 1909, diminished rhythmic movements of medium. Packard, 1906, found that sodium bicarbonate increases the resistance of fundulus to lack of oxygen.

Occurrence of Clinical Acidosis.—Acidosis is not a primary disease of a clinical entity. Accumulation of acid, or rather, diminution of the bases of the body, may occur in many pathologic conditions, i.e., wherever the elimination of acid fails to keep step with its production. This may happen through faulty absorption or unusual loss of alkali; or diminished excretion of acid, as in some nephrites; or by increased production of acid, especially in disturbances of metabolism associated with deficient oxidation. The most striking examples of this form occur in diabetes; but minor degrees are present in fasting, especially with low carbohydrate and high fat income; in poisoning by P, As and other metals; in narcosis, etc. Except in diabetic and uremic coma, the acid does not usually rise sufficiently high to produce symptoms other than dyspnea.

Pathologic Conditions Associated with Acidosis.—Among the most important are (Rowntree, 1916; Frothingham, 1918): Diabetes, starvation or other conditions in which the combustion of fats is disproportionate to that of carbohydrates; fevers, pregnancy, eclampsia, nephritis, renal insufficiency, cardiorenal and cardiac diseases; post-operative and post-anesthetic conditions, especially shock; decerebration operations of animals (Macleod, 1918); cholera and other severe diarrheas.

Minor or occasional acidosis has been described in cardiac diseases; in cachexia, anemia, cancer, Addison's disease, hepatic cirrhosis, etc. In normal pregnancy there is only a negligible and compensated acidosis.

Acidosis is ordinarily absent in Graves' disease; epilepsy, lung abscess, syphilis, subacute nephritis; chronic cardiac lesions.

Chemic Criteria of Acidosis.—The hydrogen-ion concentration of the blood has only a limited value, since it is not materially altered until the bicarbonate-poisoning of the blood has fallen greatly, i.e., only in the most severe cases. The determination of minor degrees of acidosis depends on the direct or indirect estimation of the bicarbonate of the blood; or of the elimination of a sodium or acetate substances by the urine. The urine furnishes only qualitative data at best, since it can indicate only the excretion, and not the retention of acid. In nephritic acidosis it would be entirely deceptive (Peabody, 1915; Van Slyke, 1916).

Indeed, the different acidosis tests often do not go parallel in different diseases (Frothingham, 1916). For instance, acetone substances are prominent in diabetes,
rivation conditions, and especially in children; they are generally absent in the acidosis nephritis, of diarrhea, and of diarrhea. The ammonia excretion varies as do the tone substances.

**Most Useful Tests of Acidosis.**—These are the determination of:

1. The trace of alkali in the blood by the 
   a. CO₂ content (Van kel), or
   b. the Mitchell factor; or
   c. the alkali tolerance test (Sellards).

2. The alveolar CO₂ (Plesch-Levy).

**Estimation of the Bicarbonate Content of the Blood.**—This furnishes a quantitative of the potential alkali store, and its diminution is therefore the earliest sign of dose and the most accurate gauge of its severity and progress. The bicarbonate can determined directly by measuring the CO₂ liberated by acetylation of the plasma. Normally, this is 52 to 75 per cent. volume.

It is not easily altered beyond this limits. If it is a reduced fixed acids must be sent, constituting acidosis in the sense of Van Slyke. A level of 30 volume per cent. CO₂ indicates dangerous acidosis, 20 per cent. is fatal. Hydrogen ion + bicarbonate equilibrium. Hydrogen ion concentration and bicar- rate are normally practically constant. Either may, however, be changed independently of the other, giving the following conditions (adapted from T. Henderson and ggard, 1916).

**Bicarbonate law, c.f. (hydrogen ion concentration) normal.** This is acidosis through production of fixed acids, compensated by increased elimination of CO₂ through the molar response of the respiratory center.

**Bicarbonate law, c.f. high:** Uncompensated acidosis by production of fixed acids and tary uncompensated acidosis with exhaustion of reserve alkali.

**Bicarbonate normal, c.f. high:** Inefficient response of the respiratory center leading to accumulation of CO₂ (for instance in morphin poisoning).

**Bicarbonate high, c.f. low:** Excess of alkali reserve or "alkalosis." (alkali injection).

**Determination of "Buffer-Value" of Blood.**—R. L. Levy and Rowntree, 1916, ress this in c.c. of 2 HCl or NaOH that can be added to blood without changing "H ("simple buffer value"), or without changing it beyond the normal ("reserve function value"). The simple buffer value is clinically the more important. The sum of the acid and alkali values gives the "total buffer value." The simple buffer value ranges 0.18 for normal blood; serum averages 0.11 for acids, 0.05 to 0.5 for alkalies.

**Determination of Alkali Reserve of Plasma.**—This is stated by Marriott, 1916, c.f., i.e. the H-ion concentration after removal of the CO₂ (by aeration). It appears to be a very delicate index of acidosis.

The normal value of R₇H, vis. 8.5, corresponds to an alveolar CO₂ tension of 38 to mm. Moderate acidosis ranges between 8.6 and 8.9 (50 to 75 mm. CO₂); dangerous loss = 7.7 (50 mm. CO₂); coma = 7.3 (11 mm. CO₂). An R₇H 7.0 can be controlled the oral administration of alkali; R₇H 7.7 requires alkali intravenously.

**Alkali Administration on Alkali Reserve.**—With normal man, the oral administration sodium bicarbonate, 20 Gm. every hours for 8 doses, increases the reserve alkali the plasma by 74 per cent. The effect was well marked within 40 minutes after each dose, and was still fairly marked 10 hours after the last dose (Gottier and Lindeman, 27).

**Alveolar Carbon Dioxide.**—Indirectly, the carbonate content of the blood may be by the alveolar CO₂ tension, and by the "alkali-tolerance test." The volume of CO₂ in the alveolar air is generally about one-tenth of that which can be rated from the plasma. This relation holds for normal individuals and for diabetic acidosis, where it has been utilized by Beddard, Pembrey, and Spriggs, 1915; and Poulsen, 5. It does not apply, however, to conditions in which the respiration or circulation seriously disturbed (Van Slyke); as in pulmonary insufficiency and cardiac dyspnea term, 1917). It is also not very delicate in nephritic acidosis (Peabody).

**Alkali Tolerance Test.**—When the bicarbonate of the blood is lowered, larger dosage of alkali is required to change the reaction of the urine to alkaline than is the case normally. This increased tolerance for alkali a delicate and reliable index of decreased potential alkalinity of the dy, and therefore of even slight degrees of acidosis, including renal idiosyncrasy; and an equally reliable criterion of the progress of the acidosis d of the need of alkali therapy (Sellards, 1912; Palmer and Henderson,
1913; Peabody, 1915; Frothingham, 1916). However, it is useless or misleading if there is marked renal insufficiency.

The test is carried out by giving orally, between meals, 3 Gm. of sodium bicarbonate (in water) every two hours, until the urine becomes alkaline to litmus. Normally, this occurs with the first or second or at most with the third dose (the pH of the urine being reduced to an average of 7.6, sometimes to 8.3, within an hour, Palmer and Henderson).

**Renal Acidosis.**—Light grades of chronic nephritis, with normal phenol-s-phthalein output, usually show little or no acidosis. In severe grades, the kidneys fail to excrete acid properly, and thus an acidosis (diminished potential alkalinity) develops, which is fairly proportional to the degree of phenol-s-phthalein retention.

The alkali-retention test shows this much earlier than the alveolar CO₂; the latter generally diminishing only when the phenol-s-phthalein output falls below 10 per cent. in two hours. The actual reaction of the blood is not materially altered except in the extreme stages; so that even in uremia, the symptoms are not commonly attributable to acidosis (Peabody, 1915). The acidosis of infancy is frequently connected with diminished output of urine (Howland and Marriott, 1915).

M. Fischer, 1915, refers to acidosis both the edema and the CI retention. His theories have been discussed in another place.

The toxicity of uranium is associated with acidosis, and can be diminished by administering alkali. This also protects the urinary kidneys against anesthetics (Mar-Nider, 1916).

**Phosphates and Acidosis.**—Nephritis is often accompanied by phosphate retention, and this diminishes the acid excretion of the kidneys. This would not be evident efficiently by alkali administration. Calcium salts may be useful by eliminating phosphates through the intestines (Marriott and Howland, 1916).

**Low Blood Pressure.**—Reduction of the blood pressure below a certain critical level exhausts the alkali reserve, presumably by deficient oxidation, and thus produces acidosis. This occurs especially when the blood corpuscles have been diminished by hemorrhage. If the pressure is restored, for instance by the injection of gumsalts, the acidosis is diminished.

In man, the plasma-bicarbonate CO₂ does not begin to fall below the normal (30 cc. per 100 c.c.) until the systolic blood pressure is below 80 mm. At 70 to 80 mm., the CO₂ averages 43 cc.; at 60 to 70 mm., 35 cc.; below 60 mm., it falls to 27 cc. (Cannon, 1910).

Cannon attributes the acidosis of low blood pressure to deficient blood flow (Groll, 1910) and consequent tissue asphyxia, resulting in production of fixed acid (Araki, 1853). **Anesthetics During the Acidosis of Low Blood-pressure.**—Animals in this condition are hypersensitive to chloroform, ether and asphyxiant concentration of nitrous and Nitrous oxide with plenty of oxygen is said to be safe.

**Rebreathing in Shock.**—This was advocated by W. T. Porter to increase the apatatory action of thorax; and by Y. Henderson, to prevent acidosis and increase the alkaline reserve. Neither the theories nor the published data are convincing.

**Acid-base Regulation During Anesthesia.**—Surgical anesthesia tends to diminish the alkali reserve; probably mainly by the partial asphyxia. Reimann, 1890, found compensated acidosis in 30 to 85 per cent. of routine operative anesthesia; and 15 to 20 per cent. of uncompensated acidosis.

**Asiatic Cholera.**—This disease results in a considerable loss of reserve alkali, with the production of acidosis. It is benefited by the early administration of sodium bicarbonate, 0.5 Gm., increasing the dose with the severity of the symptoms (Sellards, 1914).

**Diabetic Coma.**—Diabetic coma is essentially a manifestation of acidosis (Stadelmann, 1883). There is not only a close resemblance in the symptoms; but the increased elimination of beta-oxybutyric acid discovered by Stadelmann (1883), and ammonium (Boussignaut, 1853), and the degenerate diminution of carbonates in the blood (to 10 per cent.; Minkowski, 1888; Kraus, 1880) furnish direct evidence of increased acid production. Accordingly, the administration or injection of alkalis has proved fairly successful in preventing and meeting this condition (Magan-
Levy, 1899). It usually relieves the dyspnea, produces diuresis, and often more or less mental improvement.

The success is not so striking as in experimental acid-intoxication; mainly because the acid, in diabetic acidosis, is primarily within the cells, and therefore is not so readily reached by the alkali. The details of this treatment will be discussed under Sodium bicarbonate.

The alkali could also be furnished by the administration of the salts of organic acids (Polin, 1906; Lichtwitz, 1911), or by Ca or Mg; but probably not in sufficient quantity. Eppinger, 1906, suggested increasing the formation of ammonia by the administration of amino-acids; but his results have been challenged by Pohl and Muenzer, and by A. Loewy, 1906.

Ehrmann, Eser and Loewy, 1912, claim that the injection of neutral oxybutyric salts also produces coma, so that the diabetic coma would not be a pure acidosis.

Acetone Type of Acidosis.—The acidosis of starvation conditions, notably diabetes, fever, especially in children (Howland and Marriott), severe dysentery and some hepatic derangements (phosphorus poisoning) are associated with the appearance in the blood and urine of beta-hydroxybutyric acid, aceto-acetic acid and acetone (the so-called acetone substances, ketone substances or acidosis substances). These do not occur in some other acidoses; for instance, they are absent in nephritis, in the summer diarrhea of infants (Howland, 1910), etc.

They are essentially due to the abnormal metabolism of fats; i.e., they arise whenever the combustion of fats is out of proportion to the combustion of glucose.

The appearance of acetone substances in the urine signifies the production of abnormal acids; but is not a quantitative index; for considerable quantities of oxybutyric acid may be present in the blood when the urine shows only traces of acetone substances (Prothomoumax, 1916; R. Fitz, 1917). On the other hand, acetone substances may be excreted in the urine when the alkali reserve has not yet been noticeably depleted; i.e., when there is no acidosis.

Their appearance is generally associated with increased ammonium excretion.

Toxicity of Acetone Substances.—Hurtley and Trevan, 1915, find that the neutral salts of aceto-acetic acid produce respiratory changes.

Source of Acetone Substances.—These arise in the catabolism of fat; but may also be formed from leucin and tyrosin, and therefore from protein; but not from carbohydrates.

(The agents that may give rise to the ketone substances are called ketogenic; those that tend to prevent it are osathetogenic).

Origin from Fat.—The acetone substances are formed in the course of the combustion of the fatty acids with an even number of carbons (the combustion of the odd-carbon acids results in glucose; A. I. Ringer, 1913).

Marriott, 1914, believes that oxybutyric acid is normally formed by the successive steps of fatty acids— butyric acid (?)—aceto-acetic acid (readily burned). It may also be derived from the amino-acids (leucin and tyrosin) of protein, but not from carbohydrates. Normally, the oxybutyric acid is completely burned. This seems to require the simultaneous combustion of a certain quantity of glucose (at least one molecule of glucose to three molecules of the higher fatty acids). It is conditioned on the olefhydrol group of the glucose, analogous to glyceronic acid formation. Ringer, 1914, assumes the formation of a glucosidal compound, which facilitates oxidation.

When the ratio of the glucose is insufficient, the oxybutyric acid is not completely burned; a part is excreted unchanged, and a part as aceto-acetic acid and acetone (G. Lust, 1900).

\text{Acetone} & \\
\end{align*}
\]

Quantity of Oxybutyric Acid in Blood and Tissues.—Since this acid is an intermediary product of normal metabolism, traces are normally present in the blood and tissues, especially in the liver; but much less than in acidosis. For instance, in normal subjects,
100 c.c. of blood contains less than 1.5 mg. of aceto-acetic acid, and less than 4 pm.
of oxybutyric acid. In acidosis, the proportion may rise to 28 mg. of acetoone and 47
mg. of oxybutyric acid (Marriott, 1914). The quantity in the liver and other organs
also is greatly increased in phlorhizin acidosis, and especially in diabetic coma (Sassa,
1916).

Conditions Leading to Oxybutyric Acidosis.—These arise whenever the
rate of carbohydrate metabolism is inadequate, relative to the fat catalo-
gism. The most important are starvation; diabetes; and hepatic anomalies
(Woodyatt, 1916).

Fasting.—This may result in acidosis, or not; according to whether the subject has
fat to burn or must live on his protein. In very severe diabetes, increased protein intake
may increase acidity (in ketonic amino-acids); but in phlorhizin acidosis, when
the organism can still burn sugar, the feeding of protein diminishes the acidosis (Benedict
and Osterberg, 1914).

Diabetic Acidosis.—This corresponds exactly to the starvation acidosis; the impaired
utilization of sugar furnishing the condition for the faulty fat metabolism.

Hepatic Anomalies.—The acidosis substances are mainly regulated by the liver. It
is therefore natural that hepatic derangements should give rise to acidosis. Matthews,
1915, indeed, refers all acetone-conditions to enforced over-activity of the liver, since
he finds them constantly associated with fatty infiltration of the liver cells.

Lactic Acidosis.—Lactic acid appears in the blood after violent exercise, strychnine
spasms, and phosphorus poisoning. It has also been found in the urine after coca
convulsions (Underhill). The lactic acid is derived from glucose, for it does not occur
in glycogen-free animals (Lusk, 1916).

Lactic Acid Excretion in Alkalosis.—Macleod, 1918, finds that the injection or ad-
ministration of alkalies increases the elimination of lactate, sufficient to neutralize
about 1/20 of the excess of alkali.

Creatin Elimination.—This appears to be connected with acidosis. In rabbits,
Underhill, 1916, finds that acid-producing foods (oats and corn) cause the appearance
of creatin in the urine, and this is removed by base-producing foods (carrots).

Creatin Excretion in Starvation.—This also appears to depend largely on the acidosis.
It may be abolished by alkali administration in the early stages of starvation; much
more difficulty later. However, carbohydrate deficiency may cause creatinuria even
in the absence of acidosis (Underhill, 1916).

---

DILUTE HYDROCHLORIC AND OTHER ACIDS

General Statement.—These are used mainly for their local action on
digestion in gastric hypoacidity, etc. The sparingly soluble acid salts
(acid potassium tartrate) extend their action into the intestines, and pro-
duce catharsis. After absorption, the mineral acids and their acid salts
increase the acidity of the urine, and are employed, usually with hexa-
methylenamin, against ammoniacal fermentation of the urine. They
are further used as antidote to alkali poisoning; as local astringents
against excessive perspiration; and as local hemostatics.

Action on Digestion.—The reaction of the gastric and intestinal con-
tents modifies the activity of the motor and secretory functions, and of
the digestive ferments. These effects may give rise to digestive disturb-
ances, or be utilized for the correction of digestive disorders. The results
depend on the condition of the alimentary canal, and therefore on the time
of administration, as well as on the dose and concentration of the acid.

Action in the Mouth.—Acids have a characteristic "sour" taste, and are slightly astringent in the mouth. This taste determines their use as
flavors. They soften the enamel of the teeth, and should therefore be
taken through a glass tube. They also reflexly increase the flow of saliva,
but this is of little practical importance.
Use in Fevers.—The addition of acid makes it easier to take larger quantities of cold water than could conveniently be taken without. They are therefore of therapeutic value in fevers, when one wishes to obtain at the same time the refrigerant action of cold and the diuretic effect of large quantities of fluid. It was believed that the alkalinity of the tissues is raised in febrile conditions, and that this is counteracted by acids. The modern ideas render this doubtful.

Action in the Stomach.—The presence of acid is important for the digestion of proteins and connective tissue; for the control of the pyloric sphincter; and for its antiseptic properties.

Gastric Acidity.—Pure human gastric juice, pathologic as well as normal, is secreted with about 0.4 to 0.6 per cent. of free HCl (Koeder, 1905; Rehruss and Hawk, 1914; Carlson, 1915) the same as in dogs or cats. This corresponds to $\text{HCl} = 0.05$ to 1 (Menten, 1915).

The acidity, however, is not normally maintained in the stomach, the acid being rapidly neutralized by the saliva, the mucus and the reflux of duodenal contents, to 0.15 to 0.2 per cent. HCl (Bolodyreff). The breaking down of this mechanism appears to be the basis of "hyperacidity," in which the acid remains at the same concentration (0.3 per cent. HCl) at which it was secreted (Carlson, 1915). The curve of the acidity during normal digestion has been studied in man by McClenod, 1915. He also determined the hydrogen-ion concentration of human duodenal contents, $\text{pH}^+ = 2.10^{-7}$.

 Liberation of HCl.—The mechanism by which HCl is liberated is not fully established. Koegpe, 1906, supposed that it is formed in the stomach from NaCl; assuming that the epithelium is permeable to Na and not to Cl ions, the sodium would diffuse out of the stomach, and H ions would diffuse into it. The theory requires further proof. Hammert, 1915, confirms Fitzgerald that the acid exists in the bodies and canaliculi of the parietal cells.

Pyloric Control.—Free acid in the stomach increases the pyloric peristalsis; it closes the cardiac and opens the pyloric sphincter. However, the presence of free acid in the duodenum closes the pyloric sphincter until the acid is neutralized by the intestinal juices. Moderate gastric acidity therefore hastens the discharge of food from the stomach, but excessive acidity prolongs the sojourn because it cannot be promptly neutralized in the duodenum (Cannon, 1911).

The controlling influence of acids on the emptying of the stomach appears to be exerted mainly from the duodenal side: clinically, the time of discharge is often normal in achyia; and gastric stasis often exists in hyperchlorhydria. In fasting anesthetized dogs, we have diagnosed from the stomach the rapidity of any degree of acidity in the duodenum; the acids causing a delay, proportional to their concentration. Duodenal regurgitation begins with 0.2 per cent. HCl (W. E. Morse, 1919).

Foods also act on the acid regulation of the pylorus: proteins by binding the acid, prolong the sojourn; so do fats, by binding the duodenal alkali. Carbohydrates are indifferent.

Relation of Gastric Pain to Acidity.—The pain of gastric ulcer has been attributed to direct irritation by the free acid. However, it appears to be indirect, due sometimes to the increase of gastric peristalsis and tone, and pyloric spasm; or more often to hyperesthesia to these motor activities.

In human subjects with normal stomachs, Lowenthal, 1893, found no sensation from 0.5 to 0.7 per cent. HCl. With 0.5 per cent. there was sometimes a warm sensation, but no pain. Other observers report absence of any sensation with 0.5 per cent. J. E. Schmidt, 1906, found no symptoms with 0.5 to 2 per cent. With 1 per cent. Boring reports a sensation similar to hunger-pains.

The results on patients with gastric ulcer are more variable. Pain is sometimes not always present, after 0.5 to 0.7 per cent. HCl. Ginsberg et al., 1916, find that the pain is always accompanied by strong contractions, indicating that it is due to tension. This was relaxed by alkalis or amyl nitrite; strengthened by pituitary.

L. L. Hardt, 1918, found that ulcer pains occurred in the absence of free acid, and sometimes even be relieved by 0.3 per cent. HCl.
Digestive Action.—*Pepsin* acts only in the presence of free acid. While any acid may answer for this purpose, hydrochloric seems to be the best, and is most efficient in the concentration existing in the gastric secretion; it also aids in the solution of the connective tissue of meats; and it determines the antisepic qualities of gastric juice.

The ingestion of dilute acid also increases the secretion of gastric juice. This effect is partly reflex, for it is observed in Pavlov's separated stomach (Bickel, 1905) but only when it is given with food (Heinsheim, 1906).

Salivary Digestion in the Stomach.—Very slight acidity accelerates the action of all juices, but somewhat stronger concentrations depress it. However, the bulk of the food remains for an hour or more in the cardiac pouch, with only the surface layer impregnated by acid (Heyde and Gruetznner). Salivary digestion proceeds practically undisturbed during this time (Cannon, 1911).

Pancreatic Juice.—The flow is increased by acids.

This action is perhaps partly reflex, but it has been shown (Bayliss and Starling, 1902) that the presence of acid in the jejunum leads to the production of a chemic substance, "secretin," the intravenous injection of which stimulates the pancreas to increased secretion.

Bile.—The secretion of bile, and the contractions of the gall-bladder are increased by the introduction of acid into the duodenum (Okada, 1915).

(Kless and Kaeppel, 1914, claimed that the evacuation of the gall-bladder is hastened by injection of acid or soap into the duodenum.)

Use in Indigestion.—Acids are administered in dyspepsias in which the secretion of acid is deficient; in putrefactive fermentation; and in infantile diarrheas due to this cause. All mineral acids act alike. Dilute Hydrochloric Acid (1 c.c., diluted, just before or after meals) is generally preferred. It is often combined with bitter stomachics.

It has been objected that doses much greater than the ordinary would be required to restore the normal acidity. However, when taken after meals the acid would be confined to the surface of the food-mass and would therefore suffer little dilution.

The increased flow of pancreatic juice and of bile is probably too small to be of any value.

Acids are contraindicated in catarrhal conditions, in which there is a hypersecretion of mucus. Even in normal individuals the prolonged administration of large quantities of acids is apt to prove too irritating, and interferes with digestion. This is the explanation of the popular use of vinegar to reduce obesity. A direct limitation of diet would seem a more rational means for this purpose.

Lactic Acid Organisms.—These were introduced with the object of supplying the antisepic action of acids to the intestines, in infantile diarrheas, etc.; but they have not fulfilled these expectations very satisfactorily. They are discussed in N.N.R.

Combined Acid.—In order to avoid the irritant effects of free acid, loose acid compounds have been administered to liberate their acid gradually; such are Acidal (beet hydrochloric), and Oxynin (acid protein). However, they are not perfect. Long and Hull, 1915, showed that the quantity of acid bound by proteins is quite definite and does not depend simply on the H-ions, but it is so small that it barely suffices for the digestion of the combined protein. Betain hydrochloric is more active, but still below therapeutic efficiency (Long, 1915).
Action on Urine.—The administration of acids increases the acidity of the urine. This leads to increased irritability of the mucous membranes of the urinary passages, so that inorganic acids are to be avoided in all inflammatory conditions of these organs. They must also be avoided where there is a tendency to the formation of uric acid or oxalate calculi. On the other hand, they are indicated with phosphatic calculi. They are used especially to enhance the action of hexamethyleneamin (see Index). It may be repeated that they increase the ammonia of the urine at the expense of the urea.

Acid Irrigation of Phosphatic Renal Calculi.—These dissolve, although very slowly, in 0.06 per cent. HCl. Since this strength would be harmless, Geisinger et al., 1918, suggest its use by continued irrigation, for stone in the renal pelvis or ureter.

Effects upon Metabolism.—Outside of the change in the ratio of ammonia and urea, these are quite small, as far as our present means allow us to judge. The excretion of nitrogen seems to be pretty constantly slightly increased.

Applied directly to excised organs—muscle, nerve, etc.—the result is an increase and subsequent diminution of function.

Stryptic Action.—The local application of dilute acid is fairly efficient (Hanulik, 1918).

Organic Acids.—The local actions are along the same lines as those of the inorganic acids, but present important differences in detail. They are little used in digestive disorders. Their systemic actions are quite different, since they are for the most part burned in the body. They are therefore more conveniently discussed in connection with their salts.

PREPARATIONS—DILUTE MINERAL ACIDS

These have a uniform strength of 10 per cent. They are colorless, odorless liquids, of strongly acid taste; miscible with water, alcohol or glycerin. They are incompatible with alkalies and the salts of weak acids (carbonates, salicylates, sulphides, sulphites, etc.). Dose, 1 c.c., 15 minims, U.S.P.; 0.3 to 1.2 c.c., 5 to 20 minims, B.P.; in one-half tumbler of water after meals.

Acetum Hydrochloricum Dilutum (Acid. Hydrochl. Dil.), U.S.P., B.P.—Incompatible also with salts of Ag and Pb.

Acetum Nitricum Dilutum (Acid. Nit. Dil.), B.P.

Acid. Sulph. Dil., U.S.P., B.P.

Acidum Sulphuricum Aromaticum (Acid. Sulph. Arom.), U.S.P., B.P.—An alcoholic dilution of sulphuric acid, flavored with ginger and cinnamon. Contains free sulphuric acid and ethylsulphuric acid equivalent to about 20 per cent. of H₂SO₄, U.S.P.; about 14 per cent., B.P. A clear, reddish-brown liquid; pleasant aromatic odor; intensely acid. Dose, 1 c.c., 15 minims, U.S.P.; 0.3 to 1.2 c.c., 5 to 20 minims, B.P., diluted. It is doubtful whether it possesses any advantage over other acids. Ethyl-sulphuric acid acts simply as a mineral acid (Uyed, 1910).

Inf. Res. Acid., B.P.—1.15 per cent. Acid. Sulph. Dil., 2.5 per cent. dried rose petals. Dose, 15 to 30 c.c., 1/2 to 1 ounce, B.P.

SODIUM BICARBONATE AND OTHER MILD ALKALIES

General Statement.—Sodium and potassium bicarbonates are used as liquefying expectorants, and to dissolve mucus in other catarrhal conditions. Sodium bicarbonate is particularly useful for neutralizing hyper-
acidity in digestive disturbances. Magnesium oxid, or magnesium or calcium carbonate, act more persistently, but less promptly and efficiently. Excessive doses of alkalies disturb digestion and produce diarrhea.

The systemic effects are utilized for combating acidosis. Smaller doses, especially in the form of potassium bicarbonate or citrate, are used in rheumatism and gout. Their action, if they have any, is not understood.

The administration of alkalies increases the flow of urine and reduces its acidity or renders it alkaline. This is useful for decreasing the irritation in cystitis, and to prevent the formation of urate calculi.

Sodium carbonate is too irritant for internal use.

Effect on Mucus.—Mucin is more soluble in alkaline media, so that the alkalies dissolve any accumulations of mucus or render them more fluid. At the same time they increase mucous secretion through a mild irritation.

Use in Catarrhal.—Mild alkalies, especially bicarbonate and borate, are used as washes or gargles (1 to 4 per cent.) in all kinds of catarhal conditions; as expectorants; in cystitis, dysentery, etc.

Removal of False Membranes.—The false membranes of diphtheria, croup, etc., are also composed largely of mucus, and may be broken down by alkalies. These may be applied by inhaling the vapors produced by slaking lime in the sick-room.

Use on the Skin.—Alkalies are also employed to soften the crusts in eczema; as a soothing lotion in dermatitis and burns; to relieve itching, etc.

Action on Normal Digestion.—Strong alkalies, including sodium carbonate, produce local irritation and gastritis. The weaker alkalies, such as the bicarbonates, would also tend to interfere with normal digestion. They tend to inhibit the secretion of digestive juices; the activity of pepsin; the gastric peristalsis and the opening of the pyloric sphincter (Cleland, 1911); the protective action of the mucus and the antiseptic action of the gastric acid. They might be conceived to aid the digestion of fats; but the intestines are normally sufficiently alkaline.

In fact, however, these detrimental actions are very slight, and the utilization of the food is practically perfect (unless excessive doses are taken), because moderate quantities are rapidly neutralized and absorbed.

Secretion of Gastric Juice.—It was formerly claimed that this is stimulated; but practically all of the later experiments indicate that it is rather diminished both in quantity and acidity (Pawlow, 1897; Bickel, 1905; Heinsheimer, 1906; Rosenblatt, 1907; Wilbrand, 1914; Chiarl, 1915).

King and Hanford, 1917, found in a dog with a Pavlov stomach, that one per cent. sodium bicarbonate excites some flow of gastric juice, but rather less than distilled water. The total acidity of the "alkali juice" was a little lower than the "water juice." The peptic activity was about the same.

Pancreatic Secretion.—This is diminished by the oral administration of bicarbonate (Wilbrand, 1914).

Ferments.—Diastases are hindered by free alkali, being very sensitive. Pepsin is also inhibited or destroyed (Hamburger, 1915; see under Sodium Chlorid). Trypsin can act in a weakly alkaline medium.

Use of Alkalies in Digestive Disturbances.—While alkalies are either indifferent or disturbing to normal digestion, they are very useful to restore the normal conditions in digestive diseases.

The literature on alkalies to 1890 is covered in the work of Stadelmann.
MILD ALKALIES

Gastric Catarrh and Dilatation.—The alkalies dissolve the excessive mucus which lessens the permeability of the walls of these organs, preventing at once the pouring out of digestive juices and the absorption of the digestive products. This mucus forms a similar impermeable coating about the masses of food. Further, the mere presence of a large amount of indigestible material—and tenacious mucus must be regarded as such—is in itself irritating. Lavage with 1 per cent. bicarbonate is the most efficient treatment of these conditions; but the alkali may also be given with an emetic or cathartic.

Intestinal Catarrh and Catarrhal Jaundice.—The alkalies are similarly useful. (They do not increase the secretion of bile; Rutherford, 1879.) In intestinal affections, the slowly soluble alkalies, magnesium oxide or magnesium or calcium carbonate, may be preferred, so that they will not be neutralized before reaching the intestines. A saline cathartic enhances their usefulness. This combination exists in several mineral waters (e.g., Carlsbad). For infants, lime-water is generally preferred to the other alkalies.

Gastric Ulcer.—Alkalies are useful by diminishing the quantity and acidity, and therefore the irritation, of the gastric juice. They also permit the destruction of the pepsin through sodium chlorid. Bismuth subcarbonate is preferable, because its action is more prolonged, and because it adds a mechanical protection.

An efficient routine for continuous alkali treatment for gastric ulcer is described by Sippy, 1915: Soft food is given every hour. Midway between the feedings, the patient receives an alkali, alternating between (1) magnesia and sodium bicarbonate, each 0.65 Gm., 10 grs., and (2) bismuth subcarbonate, 0.65 Gm., 10 grs., with sodium bicarbonate, 2 Gm., 30 grs. The progress is controlled by the reaction of the stomach contents, which should not be allowed to become acid.

Gastric Hyperacidity; Functional Dyspepsias, Heart-burn; Gastric Flatulence, Etc.—In these conditions, the soluble alkalies (sodium bicarbonate or aromatic ammonia) are commonly used and effective. They neutralize the excessive acid, relax the spasmodic pylorus (Enriquez, Binet and Gaston Durand, 1914), and thus empty the stomach and lessen the pain and irritation. The CO₂, which is liberated stimulates the gastric movements (Schierbeck, 1861), and promotes the expulsion of the gas. It acts perhaps also as a mild local anesthetic. The bicarbonate is usefully combined with an aromatic carminative (peppermint) and cathartic (rhubarb).

Time of Administration.—This has given rise to much theoretical and unproductive discussion. The alkalies should evidently be given when the digestive conditions call for them. This is better recognized by the symptoms than by rules. The soluble alkalies (bicarbonate, 1 Gm.; aromatic ammonia, 2 c.c.; for infants, lime-water) should be administered whenever they are indicated by gastric distress, and repeated as often as needed; also at bedtime and on arising. For intestinal effect, they should be given on an empty stomach.

Obesity.—Alkalies are sometimes used. Their effects are probably due to disturbance of digestion.

Use in Arterial Hypertension.—Full doses of alkalies temporarily lower the arterial pressure, probably as a result of the nausia. The benefit is doubtful. Schefler, 1908, advocated sodium silicate, but bicarbonate accomplishes the same result.

Alkalosis and Scurvy.—Hess and Unger, 1919, describe the occurrence of minor scurvy on alkalinized milk, in guinea pigs; and also in infants fed on malt soup formulas.
which contain potassium carbonate. The condition yields promptly when antiscorbutics are added; so that the carbonate might act by destroying the hypothetical antiscorbutic vitamin of milk.

Use of Alkalies in Acidosis.—Their rationale has been discussed. The alkali must be administered in large quantity. This can best be accomplished by sodium bicarbonate. This has the advantage over the carbonate, and especially the hydroxid, in that its actual alkalinity (OH ions), and therefore its local action and toxicity are much lower; while its potential alkalinity, and therefore its neutralizing power is not very much inferior.

In view of the lower toxicity, considerable larger amounts of alkali can be introduced safely, and with more rapid effect.

The carbonate can take up more carbonic acid than bicarbonate, but this advantage is illusory; for the ratio of carbon dioxide and carbonate is immediately adjusted in the lungs to the normal equilibrium (Sellards).

Neutralizing Power of Alkalies.—To neutralize 100 parts of 10 per cent. HCl requires the following quantities of the official sodium salts: acetate = 67.3; citrate = 50.6; bicarbonate = 23.5; carbonate = 17.4; calcium carbonate = 13.6; sodium hydroxide = 12.2; magnesium oxide = 5.5.

To neutralize a given quantity of acid therefore requires nearly 60 per cent. more of NaHCO₃ than of Na₂CO₃ (absolute). On the other hand, a given quantity of NaHCO₃ gives about 27 per cent. more of CO₂ than the same quantity of Na₂CO₃ or, in other words, it requires about 27 per cent. more of Na₂CO₃ to obtain a given quantity of CO₂ than would be required of NaHCO₃.

Administration and Dosage in Acidosis.—The use of the bicarbonate should not be delayed until coma has set in, for it may then be too late. It should be begun as soon as the acidosis is recognized. The initial daily dose by mouth may be 30 to 45 Gm., or 1 to 1 ½ ounces, in divided doses and freely diluted, best between meals. This may be raised to 100 Gm. or more.

It should be continued at least until the \( \text{pH} \) of the plasma is normal; and if possible, until the reserve-alkalinity of the plasma has been restored.

These large doses generally produce a cathartic effect. This purging may not be entirely useless. At all events, plain purges have been found useful in such cases, and so has pilocarpin, originally used on the theory that it helps the elimination of the "toxins."

After coma has set in, the oral administration may be continued, and "drop enemas" of a 4 per cent. solution may also be given. However, these can not be relied upon to secure sufficient absorption; and sterilized bicarbonate solution should be injected slowly by vein.

The heat of sterilization drives off some of the CO₂, and thus converts part of the bicarbonate into the carbonate. This is highly corrosive to the subcutaneous tissue. The ordinary solutions must therefore never be injected hypodermically, nor even allowed to escape into the skin from the intravenous injections; for serious sloughing may result.

Intravenous Dosage of Sodium Bicarbonate.—It may be injected as 5 per cent. solution. As a prophylactic, 3 to 5 gms. may be administered every 2 to 3 hours until the reaction of the urine changes. In developed acidosis, much more must be given; generally 200 c.c. of the 5 per cent. injected slowly (in half an hour), is a safe maximum (Sellards).

Hypodermic Injection of Pure Bicarbonate Solution.—If the solution is freed from Na₂CO₃ by saturating it with CO₂ until it is colorless to phenolphthalein, it does not cause nausea and only very slight irritation. Magnus-Levy, 1913, and Campbell, 1914, advocate the hypodermic use of a liter of a 2 per cent. solution of this kind to follow up the intravenous injection; or if the latter presents special difficulties (sometimes the flow becomes arrested).

* After combustion.
Alkalies and Acids on Sugar Metabolism.—Aside from the neutralization of acidity, alkalies are probably further useful in diabetes by promoting the utilization (combustion) of sugar. Acidosis, on the other hand, tends to produce hyperglycemia. There is thus a vicious circle of hyperglycemia and acidosis, which may be broken by the alkali. However, the experimental data are somewhat contradictory, probably depending on accessory conditions that are not understood.

Alkali on Glucose Metabolism.—Pavy and Godden, 1912, observed that the injection of alkali prevents ether and chloroform acidosis. Elias, 1913, found that feeding alkali removed hunger glycosuria and diminished pancreatic diabetes.

Underhill, 1916, found that alkali also lowers epinephrin glycosuria. In a case of severe human diabetes, large doses of alkali markedly decreased the sugar excretion and raised the carbohydrate tolerance.

Fulk and Macleod also confirmed the tendency of alkalies to diminish the sugar of the blood. This is not due to a change in the glycogen formation, so that the sugar must be more rapidly destroyed. This is reflected by an increased lactic acid content of the blood, lactic acid being a product of glucose combustion (Macleod and Hoover, 1917). The injection of acids conversely diminishes the lactic acid.

The injection of dextrose, in large amounts, in itself increases the hydrogen-ion concentration of the blood (Macleod and Fulk, 1917), perhaps by leading to incomplete combustion of lactic acid. If dextrose was injected with sufficient alkali, the liver removed the sugar more actively from the blood (Macleod, 1917).

On the other hand, Beard, 1918, found no constant influence of sodium bicarbonate administration on the carbohydrate tolerance in diabetes.

In normal rabbits, the blood sugar is not lowered by the injection of sodium bicarbonate (McDannell and Underhill, 1917).

In normal dogs, alkali injection does not increase the respiratory quotient, but tends to inhibit glyconeogenesis (Kramer and Marker, 1916), and increases the deposition of injected dextrose in the liver (Macleod, 1915).

Murlin and Kramer, 1916, confirmed that the injection of alkali suppresses the glycogenolysis of disorganized animals, or at least lowers the D + N ratio. The respiratory quotient rises, and the blood-sugar and the glycogen are not increased, so that there must be an increased combustion of sugar.

The retained glucose is not deposited as glycogen, nor excreted by the saliva, stomach or intestines (Kramer, Marker and Murlin, 1916). When the pancreas has not been completely removed, there is distinct improvement in sugar combustion. After complete excision, however, the combustion is not improved, and nevertheless the sugar is retained.

Prophylaxis of Anesthetic Acidosis.—W. H. Morris, 1917, recommends the administration of 15 to 30 gm. of sodium bicarbonate in the 36 hours preceding the anesthesia—sufficient to render the urine alkaline.

MacNider, 1918, confirmed that intravenous injection of sodium carbonate protects naturally nephropathic animals against anesthetic acidosis and renal injury. Intravenous saline does not confer this protection.

Acids on Glucoseuria.—Elias, 1913, showed that the injection of acid produces hyperglycemia. However, the acid was too strong (54 normal HCl) to make the results available for human diabetes. Watanabe, 1917, concluded that acid administration to rabbits does not have any definite effect on the blood sugar. Jensen, 1917, found no effect on the sugar tolerance of a dog that had been highly sensitized by partial excision of the pancreas; but in another animal, that had been rendered glycosuric by the operation, the administration of acid produced a distinct rise in the sugar excretion.

Intravenous Bicarbonate in Shock.—This often gives better results than plain saline infusion; the rise of blood pressure being more sustained and the respiration deeper (Seelig, Tierney and Rodenbaugh, 1913). The bicarbonate, 0.5 per cent., may be added to the normal saline (Dawson, 1902); or 1.5 to 5 per cent. bicarbonate may be used as such. The 1.5 per cent. is isotonic with blood. These solutions should not be boiled.

Sodium Carbonate on Epinephrin Output.—Intravenous injection of concentrated solution increases the epinephrin output temporarily, presumably by the hypertonic stimulation of the bulbo-spinal centers (G. N. Stewart and Rogoff, 1919).
ALKALI INJECTION IN NEPHRITIS.—M. H. Fisher, who conceives nephritis and edema as acidosis (page 255), has advocated this treatment. The clinical results in the hands of others have often been unfavorable and sometimes dangerous (Wyss, Weiland: Newburgh, 1915). Bogue, Underhill and Mendel, 1915; found that the restoration of the blood volume after injection of saline solution was not hastened by the addition of 0.4 per cent. of sodium carbonate, either in normal or in nephritic animals.

Renal injury (spontaneous glomerular nephritis of dogs) renders the acid-base equilibrum unstable, so that it is easily upset by anesthesia, especially by chloroform. This results in more severe nephritis, anuria or failure to respond to diuretics (MacNider, 1927).

bicarbonate edema.—Large doses of sodium bicarbonate (about 20 Gm. per day) may lead to the retention of water and eventually to edema, in proportion to the dose (Hayem, 1890). This may occur in diabetic as well as in normal individuals (Widal, 1911; Levison, 1915; Beard and Rountree, 1917). It is probably analogous to salt edema.

alaikales and salicylates.—The administration of sodium bicarbonate with inorganic salicylates, tends to prevent the precipitation of the irritant salicylic acid in the stomach. It has been affirmed that it would also prevent the albuminuria and acetone that sometimes follow salicyl administration (Olunga, 1911); but it is ineffective for this purpose (Hanlik).

alaikales and cinchophen.—These are often prescribed together, with the view of preventing the precipitation of the increased uric acid in the urine.

Metabolism.—The direct effects of alkalies are not important. Perhaps the only certain action is the increase of urea at the expense of ammonia. The indirect effects of digestive disturbance may be more serious.

It is known that alkalies favor oxidation; and it has been found that they lead to an increased oxygen consumption and CO₂ excretion (Lehmann, 1884). This effect is not, however, very large—probably because the alterations in the reaction of the body are never very great. Experiments made to determine the effect on nitrogen metabolism have given somewhat variable results, and these were certainly not greater than might be expected from the pure salt action, or from the interference with digestion which would result from large doses. (Doses as large as 15 Gm. sodium carbonate, 20 Gm. of sodium bicarbonate, or 40 Gm. sodium citrate do not influence the total nitrogen excretion.) MacLeod and Haskins, 1906, found increased elimination of endogenous uric acid and purines. AB, 1913, attributes this to the intestinal derangement. The effect upon carbon metabolism is equally small and uncertain.

Increase of alkalinity is said to heighten the bacterial power of the serum and tissues; but further evidence is needed.

Use in Rheumatism, Gout, Etc.—The alkalies, especially potassium bicarbonate, acetate, and citrate, have considerable reputation in acute and chronic rheumatism, gout, etc. It is difficult to estimate their efficiency. There is no good foundation for the assumption that they increase the oxidation of uric acid or its solubility in the tissues. Explanations of their actions are purely speculative.

Actions on Urine.—Alkalies increase the flow and alkalinity of the urine. These effects are utilized especially in catarhhs of the urinary passages, and to prevent the formation of urate calculi. To secure this alkalinity requires about 7 Gm. of sodium bicarbonate or 15 Gm. of sodium acetate or citrate, per day. The organic salts are preferred, to avoid disturbance of digestion.

Sodium bicarbonate slows the excretion of intravenously injected lactose, and decreases the chlorid output (Hertz and Goldberg, 1914).

Use in Vesical and Urethral Catarh.—Alkaline urine is less irritating to the inflamed mucous membranes, and helps to dissolve the mucus and pus. The dilution of the urine, and the flushing of the urinary passages by the diuretics are similarly useful.
MILD ALKALIES

Use Against Urate Calculi.—Alkalies and diuretics can not dissolve these calculi; but they prevent the precipitation of uric acid and urates, which can occur to a serious extent only in acid urines. The alkalies (potassium or sodium citrate or acetate) must be given in sufficient quantity to keep the urine alkaline to litmus. In a few instances, it has been observed that alkalies caused the breaking up of large stones into small fragments. This can not be attributed to solution of the uric acid. The explanation is that probably the calculi were composed originally of small fragments glued together by mucus, and that the alkalies caused the solution of the latter.

The alkalies can exert no effect on the condition of the uric acid in the tissues, since the reaction of these is not altered. This will be discussed further in the next section.

Cystinuria.—Alkali has a solvating action on cystin; its administration in sufficient quantity to keep the urine alkaline prevents the deposition of cystin crystals (Smillie, 1913).

PREPARATIONS—BICARBONATES

*Potassa Bicarbonata; (Pot. Bicarb.), U.S.P., B.P.; KHCO₃.—Colorless crystals; odorless; saline and slightly alkaline taste; permanent in the air. Freely sol. in water (1:20); practically insol. in alc. Diss., 1 Gm., 15 gr.; U.S.P.: 0.3 to 2 Gm., ½ to 30 gr., B.P.

*Sodi Bicarbonata, U.S.P., B.P. (Baking Soda); NaHCO₃.—White powder; odorless; cooling, mildly alkaline taste. It is permanent in dry air, but slowly decomposes in moist air. Sol. in water (1:12) at 15°C., practically without decomposition. When heated, it loses CO₂ and is converted into normal carbonate. Practically insol. in alc. Incompatible with acids and acid salts; and with the salts of most alkaloids, metals and earths; not with magnesium salts in moderately dilute solutions. Diss., 1 Gm., 15 gr., U.S.P.: 0.3 to 2 Gm., ½ to 30 gr., B.P.

URATE SOLVENTS

URIC ACID AND ITS SALTS

Acid urates occur in solution in the blood and tissues; and as the peculiar sodium bieurate deposits in gouty tophi, etc. In the urine, acid urates also occur in solution. When the urine is scanty or acid they may be deposited as free uric acid or "quadrirrate," i.e., a mixture or compound of free uric acid and acid urate. These deposits may concrete into urinary calculi.

Uric Acid, C₅H₄N₄O₄, is a weak dibasic acid, which, under proper conditions, can form three series of salts, namely:

Neutral Urates.—C₅H₄N₄O₄-N₂H, also named dibasic, normal or secondary urates. These are formed only by strong alkalies, and can not occur under natural conditions, being decomposed by CO₂ and even water. They need not be considered further.

Acid Urates.—C₅H₄N₄O₄-N₂, also named monobasic or primary urate or bieurates. They are neutral to litmus.

Quadrirrates.—C₅H₄N₄O₄-Na⁺ + C₅H₄N₄O₄; also named hemibasic urate or tetrurate. It is a mixture or solution of uric acid and acid urate. The quadrirrate forms the sedimentum latericum in cooling acid urines. On standing, it separates uric acid crystals. Water dissolves out the acid urate, and leaves the uric acid.

There has been much discussion as to the nature of the combination. Kohler, 1911, considers it a simple mixture. Krieger and Schmutzer, 1912, regard it as a "solid solution" of uric acid in acid urate; which can be formed at body temperature, but which is unstable on cooling and thus separates the uric acid.
Other Urates Deposits in Urine.—These may consist of uric acid in acid urine; of acid urates in acid or neutral urines; and ammonium urate in neutral or ammonial urine. The acid urate is generally amorphous; but may be crystalline in neutral urine.

Urate Tophi.—These consist always of acid urates (Ritter, 1897); so do the urate deposits in animals, even when free uric acid is injected (Lochern, 1907).

Actions of Urates.—The importance of these lies in the fact that they may be formed or retained in excessive amounts in pathologic conditions, when they first produce inflammatory necrosis of cells, and are then deposited in insoluble granular form. This, becoming crystalline, acts as a powerful mechanical irritant, producing the phenomena of gout. These can be simulated in animals by the injection of suspensions of acid sodium urate, and in birds by the subcutaneous injection of chromates, or even by ligations of the ureters. The cause of the abnormal appearance of the uratic deposits in gout, etc., is not understood. It seems to be connected with changes in protein metabolism, perhaps also with intestinal putrefaction.

Solubility and Precipitation.—Free uric acid is very little soluble. The acid urates also have a limited solubility. The solution may be favored or hindered by a variety of conditions, some little understood. It would be desirable to increase their solubility, &c., to prevent urate deposits in the tissues and urine; if possible, to dissolve these deposits when formed, and perhaps to favor the elimination of the urates in gout, etc. Many attempts in these directions have failed, because they were based on imperfect understanding of the chemical data. Alkalies dissolve a limited amount of free uric acid, by converting it into the more soluble acid urates. This is the only direction in which some success has been found, and this is confined to the urine.

The study of the solubilities is greatly complicated by the small quantities going into solution, the polyvalence, formation of colloidal solutions, supersaturation, the influence of small quantities of impurities, decompositions, etc. (His and Paul, 1900).

Uric Acid.—Pure water dissolves at 18°C. only 25 mg. of uric acid per liter = 1:25,000 (His and Paul). At 40° the solubility is probably doubled. Alkalies, even the boric anion or phosphate, transform part of the uric acid into acid urate, and therefore increase its solubility. Free acids diminish the solubility, since they decrease the ionization; undissociated uric acid being less soluble (His and Paul). Addition of free uric acid to urine may precipitate a part of the uric acid originally in solution (Voll), presumably by acting as a crystallizing nucleus. The solubility in serum is much greater (500 mg. per liter) than in water (Bechhold and Ziegler, 1909). This is probably due to the colloids; and it is probable that the colloid constituents of the urine also contribute to the solubility of the uric acid and urates (Lichtwitz, 1910). Ruedell, 1890, claimed that urate has an important solvent action; but Ritter, 1897, finds this very limited.

Acid Urates.—The solubility of the different urates in water is about as follows (Allan and Bensch, 1848, etc.): Li, 1:750; K, 1:800; Na, 1:200; NH₄, 1:600; earth, 1:400 to 6,000. Excess of the alkali or other salts decreases the solubility, by "saturating out," in proportion to their concentration (Roberts; Ritter). The salts of the plasma, &c., reduce the solubility to one-tenth of that in water (His and Paul).

Solid sodium urate occurs in two forms: when freshly precipitated, it is pale yellowish; after standing, it becomes green, the colloidal form is more easily soluble (Bensch). Gudzont, 1908 and 1909, claims two forms, the ordinary more soluble lactam, which is gradually converted into the less (two-thirds) soluble lactin.

\[
\begin{align*}
\text{HN} - \text{C} = \text{O} & \quad N = \text{C} - \text{OH} \\
O - \text{C} & \quad \text{C} - \text{NH} \\
\text{C} = \text{O} & \quad \text{OH} - \text{C} - \text{NH} \\
\text{HN} - \text{C} - \text{NH} & \quad \text{N} - \text{C} - \text{NH} \\
\text{Lactam form} & \quad \text{Lactin form}
\end{align*}
\]

There is some reason to believe that uric acid exists in the blood in two forms (S. Benedict, 1916).

Influence of Phosphates on Acid Urines.—The acid Na₂HPO₄ liberates and precipitates uric acid; this is counteracted by the presence of the alkaline Na₂H₂PO₄; but even of the latter precipitates the acid urate by "salting out" (Ritter).
Alkalies on Urate Deposits in Tissues.—The solvent action of the alkalies extends only to free uric acid. When all the uric acid exists as acid urate, as it does within the body, the addition of alkali can have no further solvent action. On the contrary, excess of alkali or other salts tends rather to decrease the solubility of the urates. It is evident therefore that no direct solvent action can occur on the urate tophi (Ritter). This inefficiency has been confirmed by clinical experience. If alkalies have any effect, which is doubtful, it would be due solely to their diuretic action.

Loghem, 1907, even claimed that hydrochloric acid is more useful for preventing the formation of urate deposits in animals, presumably by lessening the “salting out.” Ritter had a similar idea. This has not been confirmed (Staal, 1908).

Uric Acid Retention in Disease.—The older notions were based on faulty analytic methods. According to the more reliable determinations of Folin and Denis, 1913 and 1915, and Pratt, 1913 and 1915, normal human blood contains 1 to 2.5 mg. of uric acid per 100 c.c. The proportion is notably increased (3.5 to 4.7 mg.) in gout (average 1.7 mg.); in lead poisoning, leukemia, and some cases of arthritis and nephritis. Injected uric acid remains in the blood of gouty patients longer than with the non-gouty (McCleare and Pratt, 1917).

Relation of Uric Acid to Gout.—The occurrence of urate tophi is a striking proof of disturbed uric acid conditions in this disease, but need have no causal connection. As has been said, the uric acid of the blood is very generally increased, but this may be even higher in other diseases and non-gouty arthritis. In gout, however, this is not accompanied by retention of non-protein nitrogen (Folin and Denis, 1913). It was formerly believed that definite changes in the uric acid content of the blood occurred during the acute gouty attacks. The modern results indicate that this is not correct; but that the urate concentration is the same during as between attacks; and that the attacks occur also when the urate concentration has been lowered by cinchophen (Daniels and McCrudden, 1915).

The urate deposits are not due to simple over-saturation; for the solvent power of serum for uric acid is much higher than the concentration in gout.

Increased Elimination by Drugs.—This has been discussed under Cinchophen. The elimination is also increased by diuresis, but without any constant ratio (J. H. Robertson, 1914).

Alkalies on Urates in Urine.—The conditions for the solvent efficiency of alkalies are much better in the case of acid urine. This contains not only acid urates, but also free uric acid, often in saturated solution. When the urine cools, becomes more acid, or under other conditions, the solution may become supersaturated. The uric acid will then precipitate alone, or in combination with part of the acid urate (quadrurate). This can be prevented either by making the urine more dilute (diuresis), or by making it less acid. Alkalies act in both directions (Buchheim, 1853). The greatest solvent action can be obtained by administering adequate doses of sodium citrate or bicarbonate, together with plenty of water (Haskins, 1916). Too high a concentration of alkalies, as of other salts, would render the acid urate less soluble; but in practice, the administration of alkalies does not raise the total concentration of the urine, especially if water is taken freely. Alkaline urines would also dissolve actually precipitated uric acid; for the urine, after the administration of alkalies, is able to dissolve more uric acid than before (Haskins, 1916). With the practical limits of the alkalinity of the urine, however, this solution is so slight that it has little effect on formed calculi. The injection of alkaline solutions into the bladder has not been more successful (Buchheim).

Solvent Power of Urine for Uric Acid.—Haskins, 1916, finds that this varies with its reaction and concentration. Urines of acidity pH = 6.2 and over can not dissolve any added uric acid; those that are less acid or alkaline take up more and more, according to
their alkalinity. Concentrated urines dissolve more (though not in strict proportion) than do dilute urines of the same reaction.

* **Destruction of Uric Acid.**—Basham, 1870, claimed that alkalies increase the destruction of uric acid; but further experience showed this to be uncertain and really negative (Severin, 1868; lithium, Bosse and Buchheim, 1869). The destruction by more concentrated alkalies has been studied by Stevens and May, 1911.

**Difference in Bases.**—The acid urates of different bases differ somewhat in solubility. The solubility of sodium urate, \(\text{NaUO}_4\), is about one-fourth that of potassium urate, one-seventh that of lithium urate, etc. It might seem therefore that the solubility could be improved by the administration of K or Li salts. This is true of pure solutions (or when sodium urate or urate stones or tophi are treated with lithium carbonate); but it can not occur in the presence of an excess of Na; for according to ordinary chemical laws, when several bases compete for an acid, it is the least soluble salt which is always formed (e.g., \(\text{BaSO}_4\) in a mixture of \(\text{H}_2\text{SO}_4\), NaOH and \(\text{Ba(OH)}_2\)). Since there is always an excess of Na ions in the blood and urine, the Li and K would have no chance to exert their solvent action. The very slight superiority of lithium could exist only with very large doses, and these are unsafe (Haskins, 1916).

**Organic Bases.**—The same reasoning applies to these (ethyleneamines, piperazin and piperidin). These also would be unable to compete against the Na. Moreover, they are excreted imperfectly, so that their alkaline efficiency in the urine is probably inferior to that of the ordinary alkalies. However, in some unexplained manner, large doses of piperazin (2 Gm.) do confer a somewhat greater solvent action than exists in normal urines of the same reaction. The difference is not sufficiently great to be significant (Haskins, 1916).

* **Piperazin.**—This is diethyl-diamin, \(\text{HN}+\text{CH}_2-\text{CH}_2\text{NH}\). It produces no symptoms and is practically non-toxic. The solvent power for uric acid, in pure solution, is said to be higher than that of \(\text{LiCO}_3\) (Mayert and Schmidt, 1892; Pluge, 1897; Stevens and May, 1911), but still insufficient to make much impression on a urate stone (Penzoldt). In the presence of Na salts, and therefore in the blood and urine, it is not superior to the alkalies (Mendelsohn, 1893; Meisel, 1893); and since a part is oxidized, and therefore only a fraction appears in the urine, its effect on the alkalinity, and therefore on the solvent power, is less than that of NaHCO3. The clinical results have been inconsistent and indefinite.

These limitations apply also to the derivatives of piperazin (dimeethyl-piperazin = Lyceol, Wittzack, 1864; ethylen-ethylenidamin = Lysoin, Ladenburg, 1864). Eczema has been reported from lysoin (Ortner). Piperidin, \(\text{CH}_2(\text{CH}_2)\text{NH}\), was introduced by Tunicliffe and Rosenheim.

**Organic Bases on Elimination and Destruction of Uric Acid.**—The attempt to attribute the supposed clinical effects to these mechanisms is also without foundation (Waucomont, 1911), although piperidin does somewhat increase the elimination of uric acid, probably by increasing its formation through intestinal irritation (Ald, 1912).

**Hexamethylenamin on Uric Acid.**—This and the related compounds (Cinarin, etc.) have a solvent and destructive action on uric acid, even in acid urines (Stevens and May 1911; Haskins, 1913). This is due to their formaldehyde. They were therefore advocated as urate solvents (Bardet and Laquiers). The action, however, is imperceptible with the ordinary doses (Nicolai; Haskins, 1912; review, Hanzlík, 1916). Doses of 4 Gm. make the urine distinctly more soluble; but an equal effect can be secured by rendering the urine alkaline to \(\text{pH} 7.4\) to \(7.4\), through the administration of bicarbonate, etc. (Haskins).

1 The literature on organic urate solvents is reviewed by Hanzlík.
ORGANIC ACIDS AND THEIR SALTS

Local Action of Organic Acids.—Free citric and tartaric acid are relatively mild acids, used mainly for flavoring and for producing effervescence with carbonates. Acetic acid is somewhat more active. Lactic acid is employed as a mild caustic for the solution of false membranes, and in laryngeal tuberculosis. Formic acid is used as a counterirritant. The fatty acids are discussed under the Oils.

Fate and Systemic Actions.—The organic acids are mostly oxidized in the tissues to CO₂ and H₂O. Their salts therefore are converted into the bicarbonates, potassium acetate into KHCO₃(K₂C₂H₃O₂ + 4O = KHCO₃ + CO₂ + H₂O); sodium citrate, into NaHCO₃ etc. and thus exert an alkaline action after absorption; although before combustion they may be neutral or acid. Their systemic action is thus identical with the administration of alkalies, but the local action is absent. This is sometimes of material advantage, as in rendering the urine alkaline with potassium acetate or citrate. They are also diuretic, and are often used in catarrhal cystitis.

Before the oxidation is completed, they may exert ion actions. These are small for acetates and formates. Oxalates, citrates and tartrates inactivate calcium. The tartrates are but poorly absorbed, and hence act as saline cathartics. Citrates share this to a less degree.

ACETATES

Potassium and sodium acetates are used mainly as alkaline diuretics.

PREPARATIONS—ACETATES

Acidiun Ascorbicum Glacie (Acid. Acet. Glac.), U.S.P., B.P.; Glacial Acetic Acid—90 per cent. of C₂H₄O₂. Congeals about 14.7°C.

*Acid. Acet., U.S.P., B.P.—36 per cent., U.S.P.; 33 per cent., B.P.

*Acid. Acet. Dil.—6 per cent., U.S.P.; 5 per cent., B.P. Clear, colorless liquid, characteristic vinegar-like odor, acid taste. Miscible with water or alcohol. *Dose, 2 c.c., 30 minims, U.S.P.; 2 to 4 c.c., ½ to 1 dram, B.P.

Acetum. Vinegar.—Corresponds in strength to the preceding.

Potassii Acetas (Pot. Acet.), U.S.P., B.P., K₂C₂H₃O₂.—White powder or crystalline masses; odorless; saline taste. Deliquesces, and hence should not be dispensed in powders. Very soluble in water (1:0.3); freely sol. in alc. (1:2.9). *Dose, 1 Gm., 15 gr., U.S.P.; 1 to 4 Gm., 15 to 60 gr., B.P.; diluted.

Sod. Acet., U.S.P., Na₂C₂H₄O₂ + 4H₂O.—Colorless crystals or granular powder; odorless; saline taste. Efflorescent. Very soluble in water (1:0.8); sol. in alc. (1:19).

*Dose, 1 Gm., 15 gr., U.S.P.

CITRATES

General Statement—These are used especially as alkaline diuretics. Sodium citrate can be administered, i.e., in diabetic coma, in large doses, 30 to 50 Gm. per day, without digestive disturbance or diarrhea (Lichtwitz, 1917). Citric acid (about 1 per cent.) is used as a refrigerant drink in fevers, etc. It is also used as prophylactic against scurvy; often as lemon juice, which contains about 8 per cent. A large lemon contains about 4 Gm., ordinary lemonade about 0.5 per cent. The syrup is a useful flavor.
Fate.—If sodium citrate is fed to cats and dogs, the blood and urine contain only traces. When injected into a vein, the citrate disappears rapidly from the circulation. None escapes into the urine with intravenous injection up to 0.5 gm. per kg. After hypodermic injection in rabbits, about 12 per cent. is excreted in the urine with cats, 50 per cent. with dogs, 40 per cent. (Salant and Wise, 1916).

Normal Occurrence in Urine.—Normal human urine contains about 0.5 gm. per day (Amberg and McClure, 1917).

Action on Calcium.—The citrates form double salts with calcium, which do not liberate Ca ions. Their intravenous injection (not oral administration) produces the typical effects of Ca deprivation (Sabbatani, 1901; Viteinghoff-Scheel, 1902; Martin, 1904; see Calcium). The injection of minute quantities into the brain produces the convulsive effects. Repeated hypodermic injections of increasing doses create considerable tolerance (Robertson and Burnett, 1912).

Coagulability of the Blood.—Citrates, like other Ca inactivators, render the blood non-coagulable in vitro. When moderate doses (10 to 50 c.c. of 10 per cent., for man) are injected intravenously, however, the coagulation time of the circulating blood is definitely shortened (Wel, 1917); returning to normal within 24 hours (Lewisohn, 1917). The mechanism has not been explained. With oral administration of 1 to 2 Gm., Coleman, 1909, describes a doubtful delay in coagulation.

Use in Transfusion.—Well, 1915, introduced the use of "citrated blood," the blood of the donor being kept uncoagulated by the addition of sodium citrate. This may be injected at once, or preserved for a time. Wassermann, agglutination, hemolysis, etc., tests must be made as usual.

The technic and advantages of citrate perfusion are discussed by Sydenstricker et al., 1917; Lewisohn, 1917; Bernstein, 1917, etc.

Dosage.—Lewisohn, 1915, 1916, advised 0.35 per cent. of sodium citrate, and that the total dosage should not exceed 5 gm. Within this limit, the citrate produces no systemic disturbance.

The addition of 0.2 per cent. of citrate to shed blood prevents coagulation completely, even for 48 hours; whilst 0.1 per cent. does not hinder it at all. 1 per cent. of citrate (1 c.c. of 10 per cent. citrate per 10 c.c. of blood) keeps the blood non-coagulable for two weeks; but this injured the corpuscles and with large transfusions in clques, the total dose may approach rather close to the dangerous limit.

Acute Toxicity.—In animals, the intravenous toxicity varies with the rate of injection. The oral toxicity is low (Salant and Wise, 1916).

"Reactions." Following the Transfusion on Citrated Blood.—Somewhat over half of the citrated-blood transfusions are followed by a fairly severe chill and fever of about 2.5°F., in half an hour, returning to normal in 4 to 8 hours. This reaction has little practical importance, and is apparently due to alterations produced in the corpuscles (Drinker and Brintingham, 1918).

In this series, 200 to 900 c.c. of the blood was drawn into 15 per cent. sodium citrate corresponding to 2.5 Gm. of the citrates, as 0.3 to 0.45 per cent. The febrile reactions have no relation to the purity of the citrate. They are set produced by the plasma, so that the corpuscles must be the toxic element. They are seen with the injection of washed citrated corpuscles, thus excluding immunological "incompatibilities."

Apparently the citration causes a change in the corpuscles, and perhaps in the phllets, which renders them more toxic. Presumably this is due to a change in permeability by the calcium deprivation.

Centrifugation of Blood injures the corpuscles mechanically, resulting in immediate or delayed hemolysis. This is especially marked with dogs, less with rabbits or sheep. Human corpuscles are quite resistant. Protection is afforded by viscid solutions, such as plasma, or better gelatin (1% per cent.). Human corpuscles do not require this protection. The resistance to mechanical injury is not related to the osmotic resistance. Drawn blood gradually hemolyses, even at
ORGANIC ACIDS AND THEIR SALTS

Gelatin does not protect against this. Preservation is best secured by sugars (2 per cent. of treacle or 2 per cent. of dextrose). This preserves blood suitable for injection for over two months (Rous and Turner, 1915).

Sodium Citrate in Hemophilia.—Intravenous injection, produces an immediate and marked slowing of the coagulation-time. This is followed in one to two days by return to the original, or even by a slower coagulation. Intramuscular injection has no effect (Ottenberg, 1916).

Other Anticoagulants.—In laboratory experiments, the coagulability of blood can easily be diminished or abolished. Leech extract has this effect, whether it is injected, or added to shed blood; albumoses, only when injected; citrates, oxalates, fluorides, concentrations of other salts, formaldehyde, hydrocyanic acid, etc., only on shed blood (by removing the calcium or inhibiting the fibrin ferment). None of these drugs can be used effectively on patients, except by local application.

Clinical Danger of Intravenous Hirudin.—Enzymanns claimed to have used 0.3 gm. intravenously with 14 patients, without toxic symptoms. Lewisohn, 1915, however, obtained alarming symptoms after 0.1 gm. of Hirudin-Saccharin.

Coagulation of Milk.—The inactivation of calcium by citrates also prevents the clotting of milk. Their addition to cows' milk produces a looser curd in the stomach. This is utilized in infants (1 to 3 gm. of citrate per ounce of milk), when ordinary milk is not well borne (cures in vomits and stools). It should be reduced or omitted as soon as the need is passed (Cotton, 1906, R. Curtis, 1916).

Excised Intestines.—Strong solutions depress all portions of the intestine; weaker concentrations stimulate the small and depress the large (Salant et al., 1915).

Rabbits' large intestine are depressed by all concentrations. With cats, the small and large intestines are both depressed (Salant and Schwartz, 1917).

Fruit Acids.—The acidity of fruits is due mainly to citric acids; other acids occurring only in small quantities. Tartrates are important only in grapes (Bigelow and Dunbar, 1919).

Infantile Scurvy.—The antiscorbutic effects of orange and lemon juice are not due to the citric acid; for citric acid itself is ineffective (Chick and Hume, 1917; Hess, 1918); whereas scurvy is cured by decoctions of orange peel (Hess, 1918), which are practically devoid of citric acid, or by orange juice from which the citric acid has been removed (Harden and Zilva, 1918).

Adult Scurvy.—This is probably analogous to the infantile form, and at least is relieved by the same dietary measures. The antiscorbutic factors exist only in fresh foods, and are destroyed by canning, pickling or drying, and greatly weakened even by cooking (Stefanoff, 1918).

PREPARATIONS—CITRATES

*Acidum Citricum, U.S.P., B.P.; Citric Acid, C₆H₈(OH)(COOH)₂ + H₂O.—A tri-basic acid obtained by neutralizing the juice of limes or lemons. Colorless, translucent prisms or a white powder; odorless; having an acid taste; efflorescent in warm air. Very sol. in water (1:5.9); freely sol. in alc. (1:1.8). Dose, 0.5 Gm., 8 gr., U.S.P.; 0.3 to 1.5 Gm., 5 to 20 gr., B.P. (*Syn. Acid. Cit.—See Index.)

Lig. Ammon. Cit., B.P.—Dose, 8 to 24 c.c., 2 to 6 drams, B.P.

*Policicit Citras (Pot. Cit.), U.S.P., B.P., K₂.C₆.H₈.O₆ + H₂O.—Transparent prisms or white granular powder; odorless; cooling saline taste. Very sol. in water (120:1); very slightly sol. in alc. Dose, 1 Gm., 15 gr., U.S.P.; 1 to 4 Gm., 15 to 60 gr., B.P.

Liq. citricum, U.S.P.—5 per cent. of the anhydrous citrate. Must be recently prepared.

Dose, 15 c.c., 4 drams, U.S.P.

Sed. Citro-Tart. Eff., B.P.—Dose, 4 to 8 Gm., 1 to 2 drams, B.P.

MALATES

Fate.—These are mostly destroyed, even on hypodermic administration, but from 3 to 6 per cent. pass into the urine. They produce much less damage than tartrates or citrates (Wise, 1916).
SUCCINATES

Leucocytes.—Hypodermic injection of 0.1 c.c. of 1 per cent. sodium succinate in nas is said to increase the leucocyte count of the blood by 20 to 70 per cent. (Hammett, Ke cracking, 1917).

Heart.—Direct application of concentrated solutions depresses the heart, similar to tartrates (Salant and Livingston, 1917).

LACTATES

These are but slowly absorbed and therefore act as saline cathartics. They are completely burned in the organism, and have no other action (Faust, 1910). It has been claimed that they somewhat limit nitrogen metabolism, after the manner of fats. For Lactic Acid, see Index.

FORMATES

Local Action.—Free formic acid occurs in several animals (ants, etc., Faust, 1910) and plants (nettles), and is partly responsible for their irritant effects. (Becham, 1915, concludes that the effects of nettles are not due to formic acid.) Formic acid resembles acetic acid, but is more volatile, more irritant, more antiseptic and more resistant to oxidation. It has a popular reputation as a counterirritant, but is probably not superior to other irritants. It is usually employed in the form of the Spiritus Formicarum, etc., corresponding to 1 per cent. of the absolute acid in two-thirds alcohol (this was formerly obtained by macerating ants). Its antiseptic action has been utilized for the preservation of food; 0.1 to 0.15 per cent. of free absolute acid suffices (Lebhin, 1906). The formates are not antiseptic.

Systemic Actions.—Formates act essentially like equal doses of acetates.

Formic Acid on Oral Administration.—Even formic acid behaves quantitatively like acetic acid. Water containing 0.001 to 0.25 per cent. of either formic or acetic acid, administered to rats for many weeks, in daily dosage up to 0.02 c.c. of acid per Kg. of body weight (equivalent, in man, to 6 liters of 0.2 per cent. acid per day) produced no effects whatever; not even diuresis. Twice this dosage interfered materially and progressively with growth and appetite; both acids again behaving alike (Sollmann, 1921). Lebhin also found formic acid practically harmless.

Formates by Mouth.—The toxicity is low, so that 6 to 10 Gm. of sodium formate may be taken daily for some time (Fleig).

Eppinger, 1913, administered sodium formate, 3 to 4 Gm. daily, to three patients. Two felt no discomfort; the other developed albuminuria and hematuria, persisting for five days; but this must have been a coincidence.

Action after Absorption.—The formates again act practically as indifferent salt. The general circulation is not affected by quite large doses. Enormous doses depress the heart (Liviamento, 1906). They are said to produce methemoglobinemia (Croser and Seligmann, 1907). Diuresis may result (Fleig); doubtless due to simple salt action. Stimulant effects of various kinds have been claimed, but shown to be absent (Fleig, 1907, literature).

Therapeutic Uses.—At one time, formates were exploited rather fantastically as a sort of elixir of youth, destined to confer on man the vigor and indefatigability of insects; and to cure various ailments, mainly of the neurasthenic type (Garrique, Clement, Huchard, 1902; H. Stern, 1906). Fleig exposed the uncritical nature of the evidence and showed the results were due solely to suggestion.

Fate.—Formates are oxidized less readily than other organic salts, so that a greater proportion (up to two-thirds) appears unchanged in the urine. With smaller doses, the destruction may be more complete (Poli). The oxidation occurs mainly in the liver (Fleig, 1907).

Normal Occurrence.—A small quantity of formates occurs normally in mammalian tissues. In man, the normal daily urinary excretion is 15 to 120 mg. This indicates that considerable quantities are formed in intermediate metabolism, probably of all classes of foods. It is also formed from formaldehyde and methyl alcohol, not from ethyl alcohol (Dakin, Janney and Wakenan, 1913).

PREPARATION

Acidum Formicum.—The acid official in foreign countries contains 25 per cent. of HCO₃H. The dose is stated as 1 to 20 drops.
METALS AND THEIR SALTS

**General Statement.** — The different metallic salts have many features in common. They combine with proteins, and therefore act locally as astringents, irritants, corrosives and antisepatics. After absorption, their effects are chiefly circulatory, especially on the blood vessels, but also on the heart. Changes in the capillaries are characteristic, and lead to phenomena analogous to those of inflammation. Their excretion by the kidneys results in nephritis. Being slowly excreted, they readily produce chronic poisoning, resulting in nervous and metabolic disturbances.

The toxicity of the different metals depends largely on their absorbability, which varies greatly. Iron salts, *e.g.*, are ordinarily non-toxic because only traces are absorbed.

Metallic poisons are generally more toxic to herbivora than to carnivora—probably because they remain longer in the alimentary canal of herbivorous animals, allowing greater absorption.

**Relative Absorbability of the Metals.** — Arsenic, mercury, and uranium are the only metals the absorption of which is of an extent sufficient to cause acute systemic poisoning with non-corrosive doses. Phosphorus, which behaves pharmacologically in many respects like metals, is absorbed still more readily. Other metals are absorbed much more slowly. To this class belong lead, silver, tin, and iron. Any metallic salt, if given in strong solution, will cause *corrosion* of the mucous membrane of the alimentary canal and will then be absorbed, and would exert its systemic action were it not that the local effects often kill before the systemic can come into play.

**Habitation to Local Action.** — If the administration of a metallic salt is begun with small doses and gradually increased, it becomes possible to administer without local effect doses which would at first have produced corrosion (Hausmann, 1906). Habitation also diminishes the absorption of arsenic, but not of antimony (Cloetta, 1906 and 1911).

**Habitation of Lower Organisms.** — Yeasts, bacteria and protozoa readily acquire considerable tolerance to the various metals. This may be transmitted for generations, and may or may not extend to other metals. The experiments of Neubau, 1910, with *pseudomonas*; and the trypanosome studies of Ehrlich, 1910, present many interesting facts.

**Solubility and Absorption.** — To be absorbed, the metal must be in soluble form; but it is to be borne in mind that the solubility in the alimentary canal is not necessarily the same as the solubility in water in a test-tube. The combination of the metal will usually be changed in its passage through the digestive tract. In the stomach it will be converted largely into the chlorid; in the intestines into the carbonate and sulphid. The metallic salts also enter into double combinations with proteins, and these are often soluble in an excess of the latter. In these ways such insoluble compounds as mercuric oxide, mercurious chlorid, lead sulphate, and silver chlorid, may be brought into solution.

**Absorbability through Intact Skin.** — Lead, copper and zinc oleates are said to be absorbable through the skin (C. Voegt and Barckhardt, 1910).

**Ion-action.** — The characteristic effects of the metals are produced only when they are ionized. The uncombined metals and molecular organic compounds (for instance, the organic arsenic derivatives) therefore do not produce the typical actions of their metallic ions directly.
They may cause effects of their own, differing from those of the ions; or they may be inactive. Eventually, however, they are usually transformed into ionized compounds, and therefore gradually develop the ordinary actions, but much more slowly. The non-ionized compounds are often differently distributed in the body, so that their actions may differ from those of the ordinary salts, even when they are subsequently dissociated. The lead tri-ethyl, *f.*., simulates chronic lead poisoning (Harnack). The organic arsenic compounds are important examples.

**Intravenous Injection of Metallic Salts.**—The systemic actions of most metals are studied mainly by injecting them intravenously, since the slow absorption and the strong local actions would obscure the remote effects, if the metals were given by the ordinary channels. For the intravenous injection, such metallic salts must be chosen as will not precipitate the blood. Double salts (such as iron-ammonium citrate, etc.) or metallic albuminates may meet this requirement. In some cases it is necessary to have recourse to some non-ionic compounds of the metal, from which the ionic metal is liberated in the body.

**Delayed Action.**—When a non-precipitant preparation is injected directly into the blood the symptoms in many cases do not arise at once, but are developed quite slowly, sometimes only in the course of several days. This is due to the fact that the metals do not act in the blood, but only after they have been absorbed into the cells; and this absorption is so slow that it may take several days to accumulate sufficient metal to produce any action. The metal may by this time have disappeared entirely from the circulating liquids (White, 1880).

It would appear also that the symptoms do not arise immediately even after the poison has reached the cells. Tartar emetic, when injected in appropriate doses into a vein, disappears from the blood in ten minutes, but the first symptoms may be seen only after some twelve hours. This corresponds with the behavior of toxins and of many other poisons.

**Storage in Cells.**—The metals enter into firm combination with the protoplasm and accumulate in the cells, especially of the liver, until these contain much larger quantities than the surrounding medium (Bokorny, 1905).

**Cumulative Action.**—The excretion of the metals is usually even slower than their absorption, they would therefore often a cumulative action; doses too small to produce any immediate effect will cause serious poisoning if long continued. Pb, Hg, and As are prominent examples. A single large dose may, on the other hand, produce chronic poisoning.

**Excretion.**—The metals are excreted partly by the kidneys, but the main part leaves through the intestines, especially the large. The epithelial cells are the channel of this excretion, and not to any extent the bile, as was at one time supposed. A *gastroenteritis* may result from local action even when the poison has been given intravenously. On this account tartar emetic, for instance, acts largely locally even when administered intravenously or hypodermically.

**Metal Nephritis.**—The amount of the metals excreted by the kidneys is often sufficient to cause a marked nephritis, characterized by albuminuria, casts, etc. The nephritis begins usually in the epithelium of the convoluted tubules and spreads from here to the glomeruli. If the poisoning is chronic, the nephritis may become intestinal and lead to renal cirrhosis.

Nephritis has been described in poisoning by the following metals: Ag, Al, As, As, Be, Bi, Cd, Ce, Co, Cr, Cu, Hg, Mn, Ni, P, Pb, Sh, O, W, Zn. There may also be renal glycosuria, *i.e.*, the appearance of sugar in the urine without hyperglycemia (Lezzi, 1914).

**Circulatory Effects.**—All metals produce a very marked fall of blood pressure, which is due partly to a *paralysis of the blood vessels* and partly to a *direct action on the heart.*
SALTS OF METALS

The metals, aside from silver, may be divided into two principal groups; the first group acting mainly peripherally on the blood vessels, the second group acting peripherally on the heart. To the first group belong arsenic, antimony, uranium, bismuth, iron, manganese, selenium, tellurium, aluminum, tin, nickel, cobalt, gold, and platinum (Wohlwill, 1907), to the second group, lead, phosphorus, copper, zinc, cadmium, mercury, vanadium, cerium, and thallium.

In the perfused heart, all metals (in the form of lactates) produce block and diastolic standstill (Vogtlin, 1915).

Nervous Phenomena.—The serious circulatory disturbances lead to central and peripheral nervous symptoms. Direct acute nervous actions are not common in mammals, except perhaps with silver.

Frogs show with most metals a paralysis, preceded by a slight stimulation. The transiting action predominates with Ni, Co, and Pt. Whether the metals have any direct effect on metabolism can not be decided with our present methods, because of the disturbances introduced by the intestinal and renal irritation, and by the circulatory changes.

COLLOID METALS

These occupy a peculiar position. Colloid metals may be obtained by establishing an electric arc between metallic wires under water; very fine particles of the metal being thrown off and forming a colloidal solution. Similar solutions may be obtained from solutions of metallic salts by certain reducing agents. Colloid solutions of Pt, Ag, Hg, Au, Bi, Cd, Pd, and Ir have been prepared by these methods. The metal exists in these solutions, not as ions, but in true metallic conditions; it is, however, so finely subdivided that it remains permanently and evenly distributed through the solution. It is precipitable by salts, in the same way as other colloidal solutions. The chemical reduction gives equally fine particles and can be used to make more concentrated solution than the electric (Voigt, 1914).

Colloid solutions can not produce the ion-actions of the metals directly. The colloid condition, however, gives them catalytic properties, i.e., minute quantities may induce reactions in large quantities of other substances (e.g., conversion of alcohol into acetic acid), the metal taking no part in this transformation. This catalysis is hindered by many poisons, just as is the action of true ferments. The metals pass quite readily from the colloid into the ionic condition, e.g., by the action of bacteria, and may then exert the ordinary action of the metals. Since this conversion occurs but slowly, these actions will be mainly local, and will produce a minimum of irritation.

Absorption and Fate.—It is questionable whether the colloid metals are at all absorbed unchanged.

The problem has been studied chiefly with colloidal silver. After intramuscular or peritoneal injection, the absorption is quite slow, and not exclusively by the leucocytes (Voigt, 1916). If injected intravenously, they sojourn only a few minutes in the blood (Niculescu, 1912), and are then deposited, especially in the liver and the hemopoietic and excretory organs (Voigt, 1914, 1916).

Protein Stabilizers.—Colloidal metals for clinical use (for instance Collargol) are often “stabilized” by the addition of proteins. These may produce active or passive anaphylaxis (Bottner, 1918; Handl and Karsner, 1920). It is quite possible that the therapeutic and toxic “reactions” are due to the injection of the foreign protein. This would account, for instance, for the erythema observed in a patient by Nagai, 1919.

Pharmacologic Actions of Colloid Metals.—Their gradual transformation into the ionized form will eventually produce the ordinary systemic effects of metals. They have been used, hypodermically and intravenously, for this purpose, but without serious advantage. (Solutions should not be made isotonic with salt, since electrolytes cause precipitation.) They also produce other rather indefinite and inconstant effects, probably attributable to the colloid condition: hyperpyrexia, first hypo-, then hyperpyrexia, renal and intestinal irritation, and fatal coma (Foé and Agezotti, 1908 and 1909; Gros and O’Connor, 1911). They may be followed by increased excretion of nitrogen and uric acid (Assell and Isar, 1907).

Therapeutic Use Against Infections.—Colloid silver particularly has been extravagantly lauded as an internal antiseptic in puerperal and other septicemias and infections; but the claims do not stand critical examination (Report, Courn. Pharm. Chem., 1909; de Arric, 1912). Gros and O’Connor found that colloid metals, like charcoal, adsorb
Poisons, alkaloidal as well as toxins, and therefore decrease their toxicity, but the decrease is insignificant, and does not occur at all unless the poison was treated before being injected. Phagocytosis is perhaps somewhat increased for some bacteria, but not for all (Arrie, 1925). Colloid silver or mercury is fairly antiseptic, but not germicidal (Marshall and Kiloh, 1915).

**Dangers.**—Colloid silver preparations are apt to deteriorate rapidly into the insoluble form, and may thus produce embolism (Rittershaus, 1903; H. J. Hamburger, 1909). A number of deaths have occurred probably by vascular embolism from the injection of collargol into the renal pelvis for x-ray diagnosis (Eisendrath, 1914). Buerger, 1914, finds that these injections may penetrate the renal parenchyma to the surface of the kidney, and lead to necrotic and supplicative foci.

**Chemotherapy of Cancer.**—This started with the announcement of Wassermann, Keyes, and more recently, 1917 and 1918, that they had succeeded in causing the disappearance of rat tumors by the intravenous injection of selenium-cosin compounds. Since then, similar favorable results were reported for colloidal copper, platinum, sulphur and some other colloids and organic metal compounds (Neuberg and Caspari, 1912; Neuberg, Caspari and Loche, 1925; L. Loeb and co-workers, 1917 to 1914). Even human tumors seemed to show some retrogression. However, the results do not withstand criticism. Uldenbuth, 1912, and Walker, 1913, failed to confirm the animal experiments with cosin-selenium. Keyser's further experience (1916) also convinced him that cure of animal tumors by the various metals occurs in only a small percentage of cases; that they are ineffective against visceral or growing tumors; success being confined to large subcutaneous tumors, which they cause to soften and liquefy. Well, 1915, suggests that they accumulate in the necrotic portions of the tumors, as do lodides and dyes, and there lead to the liquefaction of the necrotic tissue.

As to the human cancer, the reported improvement has been essentially symptomatic only, and this has little significance. Well, 1917 and 1919, points out that the only admissible sign of improvement is reduction of the size of the tumor; and from this standpoint, the clinical reports are negative. Loeb (McClurg, et al., 1915) concludes that a cure can not be expected. Keyser also considers that the effective dose in animals is so near to the fatal, that no results could be expected from a safe dosage.

**INORGANIC ARSENIC COMPOUNDS**

**General Statement.**—Arsenic compounds act locally as mild and slow corrosives and have been employed in superficial cancer. Systemically, they relax the capillaries and increase their permeability, thus stimulating inflammation. This change is most conspicuous in the splanchic area. In acute arsenic poisoning, it results in extreme gastroenteritis, closely resembling cholera.

This dilatation of capillaries introduces changes in the circulation which cause secondary disturbances in the function of more remote organs, particularly in the nervous system; and further, *fatty degeneration* of the cells, especially in glands and muscles, with other disturbances of nutrition and metabolism, particularly in chronic poisoning. There may also be a direct paralysis of the *heart*, both ganglionic and muscular.

Milder degrees of the same action may stimulate metabolism beneficially. This might explain the therapeutic uses of arsenic in malnutrition, anemias and skin diseases; but the mechanism of their action, and indeed the results, are somewhat in doubt. There are also characteristic effects on the bones and bone-marrow. Arsenic, especially in the organic forms, is highly effective against protozoan infections.

**Arsenous and Arsenic Compounds.**—Trivalent As (arsenites) is generally much more toxic for protozoa, bacteria and yeast cells than is pentavalent As (arsenates) (Klonka, 1917). This holds also for the different valence in organic compounds, and for the corresponding antimy valencies (Friedberger and Jouamiglu, 1917). It has been assumed that the 5-valent As in non-toxic until it has been reduced to the 3-valent.
INORGANIC ARSENIC COMPOUNDS

The occurrence of a partial reduction was demonstrated by Binz and Schulz, 1879.

Relative Toxicity of Arsenic Compounds.—With intraperitoneal injection into guinea pigs, the toxicity decreases in the order of: arsenites, arsenates, colloidal arsenic, atoxyl and cacodyl (Laynoy, 1918).

Radiomata.—Shulz, 1884, and Boen, 1887, attempted to explain the arsenic effects as a alteration and reduction of the cells, due to the easy passage of arsenous and arsenic compounds into each other (which Schulz, 1892, demonstrated on organ-emulsions). Husmann, 1892, pointed out that if this were true, both forms should have the same toxicity. The difference is not great for mammals, but very considerable for lower animals and plants (O. Loew). The explanation is therefore not tenable. It is now generally believed that the arsenicals hinder protoplasmic oxidation, in an unknown way; although Schaefer and Boehm, 1873, showed that arsenic has little effect on ordinary ferment.

The ratio of toxicity of arsenous acid: arsenic acid varies for different tissues. With intravenous injection in rabbits, it is as 8:10 for the excised frog's heart, as 3:11. The arsenous is also more toxic for the excised intestine of rabbits. These different ratios indicate that the toxicity of arsenic acid is due to reduction to arsenous acid, which varies for different species (Joachingolu, 1915).

Resistance of Species.—Arsenic is toxic to all animals which possess a central nervous system; also to most of the higher plants, but not to all the lower organisms. Its antiseptic action is comparatively small. It can not therefore be classed as a general protoplasmic poison. New born salamanders show a very great tolerance. Among mammals, the resistance is greatest in mice, then come the hedgehog, rabbit, dog and cat (Willetts, 1913).

The toxicity is the same for splenectomized as for normal mice (Towles, 1916).

Local Actions.—The arsenicals are not precipitant and therefore irritate only weakly, even on wounds or mucous membranes; but the cells die slowly after prolonged contact.

This is sometimes used for killing exposed dental nerves; and as salves for superficial epidermis; and from 13 to 140 mm. after strophantus injection (Sollmann).

Asphyxia or strophantus injection produce the normal pressor response (the pressure rising, for instance for 60 to 140 mm. through asphyxia; and from 13 to 140 mm. after strophantus injection (Sollmann).

The fall can therefore not be explained by cardiac failure and arterial vasomotor depression. These occur only late in the poisoning, as secondary results of the low blood pressure. The cause must be looked for in paralysis of the capillaries; or in diminution of the effective volume of blood by transudation of plasma.

Heart.—In the excised (Langendorff) heart the amplitude is first increased, then diminished; the rate may be slowed, quickened or arrhythmic. Arsenites are more toxic than arsenates, and these more than the organic. Of the latter, cacodylate is the most potent; arsphenamin and its oxidation products are inactive (Archangelski, 1912).

In intact animals the cardiac action of the arsenicals is relatively unimportant; for the heart is able to maintain a fairly high pressure if the aorta is clamped (Boehm and Unger, 1874).

Vascular Action.—The vasodilation is most conspicuous in the splanchic area; but the blood pressure falls even when the intestines are tied off, so that the muscular vessels are also dilated. The dilution can be demonstrated by perfusion of excised organs. It is therefore peripheral. The vessels, however, continue to react to splanchic stimulation till very late; and to epinephrin even after the splanchic response is lost (A. Loeb, 1912). The arterioles must therefore still be capable of contracting.
Paralysis of Capillaries.—For this reason it is assumed that structures beyond the arterioles—namely, the capillaries—are the seat of the paralysis. This view is favored by the fact that they have become more permeable. Intravenous injections of large quantities of salt solution will cause edema in animals poisoned with As, but not in the normal (Magnus, 1890; other capillary poisons are discussed by W. Hessner, 1907). The thoracic lymph flow is increased by arsenic, the phenomena being similar to those of peptone (Yanagawa, 1916).

These changes in the capillaries explain partly the therapeutic action, and the whole course of the poisoning. Since increased permeability of the capillaries is one of the essential features of inflammation, the phenomena of arsenic poisoning are similar to those produced by an irritating inflammation, although the primum cause is different. However, arsenic inhibits the migration of leucocytes in the inflamed mesentery of frogs (Ikeeda, 1916).

Gastroenteritis.—The first and principal symptoms of acute arsenic poisoning are those of violent inflammation of the digestive tract.

This suggested that arsenic acts as a corrosive. However, the autopsy rarely shows extensive corrosion, and it is known that the corrosive action occurs extremely slowly. Furthermore, the gastroenteritis may be obtained with at least equal readiness if the arsenic is injected into the circulation or subcutaneously. This would not definitely exclude all local action, since some arsenic is excreted into the alimentary canal; but the quantity is not nearly enough to account for the symptoms.

The inflammation is really due to the systemic action on the capillaries, which is strongest in the intestines, no matter how the arsenic has been introduced. The capillary paralysis results in the production of an exudation into the connective tissue. This raises the epithelium (just as would a blister on the skin), and causes it to be thrown off in shreds or false membranes. The exudation is then poured into the lumen of the intestine and largely coagulates. This distention, as well as the circulatory changes, causes increased peristalsis and watery diarrhea; and the shreds of mucus and coagulated exudation give to the evacuation the character of "rice-water" stools (Boehm and Pistorius, 1882).

The pathology of this condition is exactly the same as that of Asiatic cholera, and without a history it is impossible to distinguish between the two conditions except by characteristic examination of the discharges.

The extreme distention of the capillaries may lead to their rupture, to the formation of echymoses, or possibly bleeding into the intestine or stomach, and consequently bloody vomiting or diarrhea; but this is by no means always the case.

Kidneys.—Arsenic produces nephritis, at first mainly vascular (Schlayer and Hedinger, 1907), but always with more or less involvement of the epithelium (MacNider, 1912; O'Hare, 1915).

The vessels of the kidneys participate in the capillary dilatation. The glomerular capillaries are swollen so as to fill the capsule; the urine is albuminous and scantly, and can not be increased by caffeine (Hellin and Spiro, 1897). The retention of albumin in the blood is relatively slight (Karsner and Denis, 1914).

The types of nephrites from different arsenic compounds, and the actions of arsenicals on the adrenals are described by L. Pearce and Brown, 1915.

Absorption.—This occurs readily, to some extent even from the intact skin. Poisoning may therefore result from the external use of arsenical cosmetic preparations. With hypodermic injections, the diarrhea often sets in within an hour.

Excretion.—This occurs by all the usual channels—urine, feces, sweat (Tachau, 1917), milk, and epithelium of the skin (Heffter, 1905). With oral administration, the main part leaves by the feces; with hypodermic by the urine. The excretion is always slow and incomplete, especially with prolonged administration (Croner and Seligmann, 1907).
INORGANIC ARSENIC COMPOUNDS

Time of Excretion.—The excretion begins in two to eight hours after the administration, but lasts for a long time—three to ten days, after a single dose; to seventy days when it had been given continuously. In rabbits' urine it was found for 130 days, in dogs for 160 days, after the administration was stopped. The elimination and retention were studied by Dutcher and Steel, 1914.

Distribution in Tissues.—The arsenic is stored in all the tissues, but especially in the liver, kidneys and heart; less in the skeletal muscles and brain (Blazev and Denigès, 1907; Eckley, human, 1912). In the liver of dogs it is found as an arsenical nucleo-protein (Slowisof, 1902). The cerebro-spinal fluid contains at most traces in normal individuals (Eckley), more in meningitis (Finel and Leroid, 1913). Arsenic also passes accidentally into the circulation to the fetus. It is just as toxic when injected into the mesenteric, as by the jugular vein, showing that the liver neither neutralizes nor retains it. It is less toxic on hypodermal injection, since it enters into more slowly dissociated compounds with the tissue elements.

Deposition in Hair.—After the administration of arsenic, the hair contains detectable quantities, in firm combination. The deposition is slow but persistent. Therefore none is found in acutely fatal poisoning, the earliest demonstration being after two weeks. It may then persist for months or years, long after the metal has disappeared from the liver and bones (Heffter, 1913).

Normal Occurrence of Arsenic.—A. Gautier, 1859, found minute traces of arsenic in normal tissues. Its universal presence was confirmed by Bertrand and all those who worked with sufficiently delicate methods. In man, it occurs especially in the thyroid (0.15 mg.); also in the thymus, brain, and skin. It appears to be in organic combination with the nuclein. None is found in the liver. This arsenic is introduced with the food and especially the drinking water. (According to the Royal Commission, 1903, the quantity of arsenic in food should not exceed 0.5 mm. gr. per pound, or in liquids, per gallon.)
The quantity of arsenic normally present in the intestinal canal never exceeds 0.05 mg. Larger quantities point to poisoning (Gautier, 1904).

The urine generally contains traces, up to 0.5 mg. per day, depending mainly on the arsenic content of the food (I. Bang, 1906).

Etiology of Arsenic Poisoning.—Arsenic was at one time used very extensively for criminal poisoning, especially in the seventeenth century. An Italian woman, Toffania, carried arsenic with her greatest refinement, using under the name of “Acqua Toffana” a mixture of arsenic and piomans obtained from the putrefied juices of animals poisoned with arsenic.

In the present time arsenic is less used with criminal intent, the most frequent forms of poisoning being suicidal or accidental. This may be attributed to the perfection of medical means of detection, which allow of the discovery of the minutest trace. Accidental poisoning has been lessened to some extent by requiring the preparations of arsenic sold at retail to be colored either with lamp-black or indigo, so that they do not have the innocent appearance of a white powder. This is also of some importance in diagnosing the poisoning, the color of the vomit calling attention to it. But accidental and suicidal poisoning is still very common, since arsenic is so extensively distributed. It is easy to obtain it as a rat and fly poison. It is frequently used in the arts. Paris green is a preparation whose sale is almost unrestricted. A great many of the cosmetic preparations on the market contain arsenic and have given rise to accidents. The use of arsenic compounds, such as Schweindurth green, as pigments has been absolutely prohibited but great many of the coal-tar dyes, which are popular at the present time, employ arsenic in their preparation, and very frequently this is not entirely removed. Formerly wall paper dyed with arsenic compounds was a common source of arsenic poisoning, but this has now largely disappeared.
The arsenic is given off from these papers as dust. However, undoubted cases of poisoning have also occurred when the arsenical paper was completely covered by a harmless preparation. In some, some volatile arsenic compound must have been formed.
Most modern wall papers still contain minute, but practically insignificant traces (Scholz, 1913). The permissible limit of arsenic in papers is placed at 0.1 gr. per square yard; but this is probably not quite harmless. The Bureau of Chemistry of the United States Department of Agriculture has analyzed a number of papers on the American market (Haywood and Warner, 1904). Over 50 per cent. of these contained less than 0.045 gr. per square yard, and are therefore safe. Furs, rugs, and fabrics were less satisfactory. Black stockings particularly often contained quantities of arsenic (above 0.01 gr. per square yard), which must be considered dangerous, considering their intimate contact with the skin.

Prunis, after the use of arsenical insecticide sprays (Bordeaux mixture, lead arsenate), contain arsenic (and lead), for long periods (Soutzig, 1915). The quantities, however, are probably unimportant.
Course of Acute Arsenic Poisoning.—This may be very rapid: In fulminant cases, the withdrawal of the blood from the general circulation into the splanchnic area may produce prompt collapse, and death before the enteritis has time to develop (corresponding to "dry cholera"). Usually, however, the symptoms do not appear for from one-half to one hour after the arsenic is taken, and then run through eighteen hours to three days sometimes four to fourteen days.

Acute Symptoms.—The suspicion of the patient may have been aroused by the sweetish astringent taste of the substance. Almost the first symptoms are vomiting and profuse and painful diarrhea. The withdrawal of water from the body leads to great thirst, dryness of the mouth and throat, and difficulty in swallowing and articulation. The urine is diminished and often bloody and albuminous. The nervous symptoms consist in vertigo, headache, and pain in the limbs. There will be cyanosis and cold extremities. Toward the end occur syncope, coma, clonic and tonic spasms, and a general paralysis. Death usually occurs by exhaustion as a result of the prolonged gastroenteritis, as in cholera.

In the subacute poisoning the inflammation of the mucous membrane of the alimentary canal is prominent. Inflammation of other mucous membranes also becomes conspicuous, and shows as conjunctivitis, coryza, stomatitis, salivation, and pharyngitis. Skin eruptions make their appearance if the arsenic poisoning is at all prolonged. In this case there are also symptoms arising from the central nervous system, as well as neurites.

The diagnosis of acute arsenic poisoning is made by the violent gastroenteritis. This can usually be distinguished quite easily from that produced by acids and alkalies, by the history of the case, absence of corrosion in the mouth, and furthermore by the lesser prominence of the local symptoms. The very quick onset distinguishes it from other metals.

Autopsy Findings.—The patient appears emaciated from the withdrawal of fluid from the body by the profuse diarrhea, and this even if he retains a fair amount of adipose tissue. The appearance of the alimentary canal with its large amount of fluid and the presence of shreds of mucus and false membrane, with usually no pronounced corrosion, are characteristic. Microscopically gastroadenitis and cell infiltration are often seen.

The body after arsenic poisoning usually putrefies very slowly and may become mummified, which always causes a suspicion, although it is not at all a proof of such poisoning. The positive proof can be furnished only by the chemical examination. It must not be forgotten that arsenic is frequently introduced into the body in the embalming fluid.

Fatal Dose.—This varies, especially with the solubility of the preparation, etc. Of the trioxid, 5 to 50 mg. are toxic; 0.1 to 0.3 Gm. are usually fatal; but recovery may occur after much larger quantities. The mortality is 50 to 75 per cent. (Lewin).

Treatment of Acute Poisoning.—Acute arsenic poisoning is best treated by lavage with warm water, emetics, or purgation. The chemical antidotes are of doubtful value.

Ferris Hydroxidum cum Magnesii Ossido (see Index) was long considered the best antidote, the ferric hydrate and arsenic forming a compound which was deemed almost

---

1 See plates 40 and 50 of E. v. Hofmann: Atlas of Legal Medicine, W. B. Saunders Co.
soluble. De Buschel, 1907, believes, however, that the compound is even more sol-
ble than arsenious acid, and that it is quite useless. So also is hydrogen sulfi-
date. The hypodermic injection of magnesium sulfate has saved animals from fatal doses of
arsenic, even when the latter was also injected hypodermically. Presumably, diffi-
cult soluble arsenic-magnesium compounds are formed (Sicher, 1912). However, an
antidote must be used very promptly, and the effective dose of magnesium is
arsenic is not as large as of sodium.

Arsenintretted Hydrogen (AsH₃).—This is an extremely toxic gas, so that a few
bubbles may be fatal to man. It is produced in head-burning; by the action of impure
phosphorus acid on metals; from ferrousilicon, etc. It may produce the ordinary arsenic
epithema, but the toxic effects are mainly due to hemolysis. It combines with the
moglobin (Meissner, 1915), and destroys the corpuscles. The symptoms are often
laidy, and start with malaise, collapse, fainting fits, etc. This is followed by bloody
vomiting; icterus, painful liver and kidneys; occasionally by asyemia (Stadelmann, 1882).
Vere cases may die during the earlier stages with convulsions, delirium and coma.
Gas has a characteristic garlic odor.

*Ferrousilicon.*—This is a mixture of Fe and Si compounds, used in the manufacture
of steel. In the presence of water or moist air (as in shipment) it liberates phos-
owetted and arsenintretted hydrogen, which have produced fatal poisoning (J.A.M.A.,
781, 1910). The grades containing 30 to 70 per cent. of silicon are much more sub-
tive to the decomposition, and are therefore more dangerous than those containing a
water or smaller percentage.

Garlic Odor with Arsenic.—This is a rather characteristic feature under certain
additions. It is noted when the metal is burned in air to As₂O₃. Mounds growing on
on wall paper and other arsenicals produce it by forming ethyl arsine, As₂C₂H₂H. H.
ulodor is sometimes observed in the arsenic vomitus (Gumprecht), and is probably
e to reduction products. Garlic breath does not occur, or very rarely, in the ther-
apeutic administration of inorganic arsenic compounds, but is very strong after the use
or cadmates.

*Habituation.*—The mountaineers of Styria and certain other regions consume arsenic
e slowly, so much so that the general stimulant and toxic effects are apt to be
egregious. There is no absolute immunity in these cases, and the apparent
vidence that they gradually accustom themselves to use with immunity quantities
arsenic (to 0.4 Gm.) which would produce very serious toxic, irritant and cumulative
te in other individuals (Schefer, 1865; Knapp, 1875). This tolerance can also be
duced in dogs and rabbits. Gloetza, 1906, attributes it to lessened absorption from
alimentary canal; Haukmann, 1906, to increased excretion. The latter also showed
at the corrosive action on the intestines is decreased by habituation. Withdrawal
es not cause any abstinence symptoms, even if the arsenic has been consumed for
ars. Jouchemogu, 1916, finds that the absorption of small doses, in dogs is not
inished by habituation; but that it is rather increased in accordance with the larger
. However, habituation leads to increased resistance of the intestinal mucous
m the inflammatory and necrotic actions of arsenic, which would promote the absorption
xic doses. For this reason, the absorption of large doses is smaller in habituated
imals.

*Chronic Arsenic Poisoning.*—In this, chronic gastro-intestinal catarrh
velopes, possibly with ulceration. The less intense but persistent capil-
ry paralysis gives time for widespread fatty and other degenerative
anges. These affect first the endothelium of the capillaries, later
the testinal epithelium, and finally the cells of other organs—liver, kidney,
tart-muscle, etc. The increased size of the fatty liver may cause pres-
re on the bile-ducts, consequently reabsorption of bile and icterus.
her is a considerable tendency to the development of local effusions;
elling of the eyelids is fairly characteristic.

Impaired nutrition or toxic actions on peripheral nerves give rise to
yneuritis, with atrophy of the muscles, disturbance and paralysis of
sation, and of the special senses (blindness). The voice is frequently
etered, from the paralysis of the vocal cords. The skin is also particu-
arily affected. This action results in acroc-uous eruptions, exfoliation, and
alling out of hair and detachment of finger-nails. Herpes zoster some-
mes develops. In a few cases a peculiar cutaneous melanosis can be
iced. This is not due to a deposition of arsenic, but to the formation
of organic pigment granules in the epidermis and the exterior layers of
the mucous membranes, especially the conjunctiva, may also suffer.

The diagnosis of chronic arsenic poisoning may be somewhat difficult because the
symptoms are sometimes quite obscure or resemble very closely those produced by
chronic lead poisoning. There is some difference in the electric reaction of muscle and
the absence of the blue line on the gums, which are characteristic of lead. But in other
cases of the acute or chronic form the chemical examination is the only absolute means
of making the diagnosis.

Chronic arsenic poisoning is treated by withdrawing the cause; the same measure
may also be used as for chronic lead poisoning.

Cause of Nervous Phenomena.—There are not solely due to ischemia, even in acute poisoning, but must be partly direct; for they occur also in frogs, whose nervous
functions are not immediately influenced by the blood supply.

Therapeutic Use in Nervous and Rheumatic Conditions.—Arsenic has
been used in chorea, neuralgias, and the various rheumatic and arthritic
diseases. Its effects are usually not striking, and may probably be
referred to the general tonic action.

Effects on Metabolism.—These resemble phosphorus: Therapeutic
doses check oxidation, and favor nutrition and growth, even in adults.
The bones become larger and more compact. The condition of the skin
is especially improved. The blood formation seems stimulated under
suitable conditions.

Excessive doses, as with phosphorus, lead to increased excretion of
nitrogen, loss of weight, lessened gas metabolism, fatty degeneration of
tissues, acidois, decreased functionation of organs, destruction of blood,
citerus, inability of the liver to form glycogen.

Hepatic Degeneration.—A further analogy with phosphorus poisoning consists in
fatty degeneration of the liver cells, more marked with inorganic than with organic ar-
senic compounds. With intravenous injection, this is localized around the central vein,
with hypodermic, it is more general (Ullmann, 1914).

Tissue Degenerations.—Toxic doses produce degenerative changes also in the kidney,
capillaries and blood. Pathologic tissues—malignant lymphoma, syphilitic gumma,
etc.—are more susceptible and may be attacked even by therapeutic doses. Exper-
imental tumors may also be liquefied and destroyed (Neuberg, Caspari and Loche, 1911).

Factors Concerned in the Metabolic Actions.—The metabolic effect is quite variable
and depends upon a number of mutually opposed causes. Among these are: the capil-
lary dilatation; supposedly a direct action of arsenic upon the cells; and the action of
the gastro-intestinal canal and on the kidneys. Small doses of arsenic increase the
gastro-intestinal secretion (Kochman, 1912); larger doses cause irritation, colic and diarrhea. In
common with other intestinal irritants, it increases the output of uric acid (Abel, 1915).

The interaction of these factors may produce different results, so that the experi-
mental data must be interpreted cautiously. As with all metabolic effects, only the
gross features are known; the detailed actions on special organs would probably be even
more important.

Therapeutic Use in Blood Diseases.—Arsenic is employed with limited
success in various leucemias and anemias, especially in pernicious anemia,
and with iron in chlorosis. The results are generally referred to an action
on the bone-marrow, but in some cases may be parasiticidal. This is the
basis of its use in malaria and syphilis.

Arsenic in Leucemia.—The results are not brilliant, but it usually improves the
general conditions somewhat. The early, milder stages are most promising (Bohn,
1914). Sometimes marked rapid improvement occurs, as with radium or x-irradiation (Thayer); but this is exceptional.

Arsenic in Syphilis.—This is not entirely new. Arsenic was used in the days of
Fallopia, and intermittently since. The difficulty lies in the toxicity of efficient
INORGANIC ARSENIC COMPOUNDS

865
doses. Herzfeld, 1911, advises the painless hypodermic or intramuscular injection of 1 per cent. sodium arsenite.

Actions on Bone-marrow and Blood Formation.—In normal animals, the effects of arsenic on the marrow are mainly destructive; fat, develop, and multiplication of the capillaries; increase of the leucoblastic cells (in contrast to leucorrhagia). Larger doses cause hyaline degeneration and anemia. Similar changes are produced by other metals, organ extracts, peptones, etc. (Stockman and Charteris, 1903).

Forbes, 1915, has also brought evidence that ordinary doses of arsenic do not normally stimulate the production of corpuscles. It is conceivable, but not demonstrated, that it acts more positively in anemia. von Hoeslins, 1913, claims generally restoration of hemoglobin and erythrocytes, decrease of lymphocytes and increase of neutrophils. Its clinical effects might also be explained by the antithymolactic action, which has been demonstrated by Dunn and Fletcham, 1917. The viscosity of the blood is sometimes slightly increased (Parmachidis, 1912).

Resistance of Erythrocytes.—As judged by hypotonic hemolysis, this is increased by therapeutic doses of arsenic in anemias. Hill, 1915, suggests this as an explanation of the clinical improvement.

Bones.—Arsenic leads to thickening of the bones and filling up of the Haversian canals (Gies, 1877), which may possibly justify its use in rickets and osteomalacia.

Skin.—Arsenic is extensively used, externally and internally, to improve the nutrition of the skin and hair, and in non-parasitic chronic skin diseases. It should never be used in acute inflammatory conditions. The results are often disappointing.

Hartnell, 1908, considers it most successful in recent, slowly spreading psoriasis; in chronic stationary lichen; and of limited value in pemphigus. Its injurious use is often very harmful to the skin (pigmentation, etc.). Arsenic is used extensively in veterinary practice, to improve the appearance of cattle, by brightening the coat and increasing the subcutaneous (also the peritoneal) fat.

Glycosuria.—Arsenic treatment (not salvarsan) lessens alimentary glycosuria in dogs. It has no effect on epinephrin glycosuria (Regemann, 1912). It has been tried in human diabetes, but without much success. Arsenic poisoning causes rapid loss of glycogen from the liver, and leads to the formation of lactic acid. Small doses increase, larger doses retard autolysis (of the liver); Laquer and Ettlinger, 1912. Small doses increase the catalytic action of the blood; larger doses have little effect (Duncker and Jodlbauer, 1911).

Cachectic Conditions.—Arsenic is employed as a tonic in a variety of these conditions, especially after malaria; in tuberculosis, and in asthma. Although it is easily understood how it may be of benefit, its actual use must be entirely empirical. We do not know sufficient about the nature of these conditions, nor can we predict the action of arsenic with sufficient certainty, to be able to foretell its results.

Dosage.—The ordinary tonic dose of arsenic trioxid is 1 to 2 mg., 1/60 to 1/50 gr.; of the liquid preparations, 2 to 3 drops, three times daily. For more energetic effects, it should be aimed to establish a tolerance by beginning with small doses, and gradually increasing these until some local manifestation of the arsenic appears—usually diarrhea, colicky pains, or conjunctivitis or swelling of the eyelids. As soon as these are seen, the amount must be diminished. The starting dose may be 3 drops of Fowler’s solution, or 5 mg. of the oxld, three times daily, increased by 1 drop, or 1 mg., every day. All the official liquid arsenic preparations contain 1 per cent. They may be given in water; the trioxid in pills, often with iron.

PREPARATIONS—INORGANIC ARSENICALS

Arseni Trioxidum (Arsen. Triox.), U.S.P.; Acidum Arseniosum (Acid. Arsen.), B.P.; Arsenic Trioxid, Arsenious Anhydride, Arsenous Oxid, Arsenious Acid (White 15
Arsenic), As₂O₃.—White powder, or irregular masses of two varieties; one, amorphous, transparent and colorless, like glass; the other, crystalline, opaque and white, resembling porcelain. Both are odorless. Slowly sol. in 30 (glauxy) or 100 (powdered or porcelain) parts of water; in 15 boiling water; sparingly in alc. Freely sol. in hydrochloric acid and alkalies. Dose, 2 mg., 140 gr., U.S.P.; 1 to 4 mg., 0.4 to 0.14 gr., B.P.; maximum dose, 5 mg., gr. 3/12.

*Liquor Acidi Arsenioci (Liq. Acid. Arseni.), U.S.P.; Liq. Arsens. Hydrochlor., B.P.—1 per cent. of As₂O₃, 0.5 per cent. HCl. Clear, colorless, acid liquid. Incompatibilities (of all arsenic solutions): Salts of iron and of magnesium; lime-water; tannins. Dose, 0.3 c.c., 5 minims, U.S.P.; 0.12 to 0.5 c.c., 2 to 8 minims, B.P.

Arseni Iodidum (Arsen. Iod.,) U.S.P., B.P.; Arsenous iodid, AsI₃.—Orange-red, inodorous, crystalline powder. Sol. in water (1:12), with partial decomposition. Dose, 0.3 mg., 15 gr., U.S.P.; 1 to 0.5 mg., 0.4 to 0.14 gr., B.P.

Liquor Arsenii et Hydriargyri Iodidum (Liq. Ars. et Hydarg. Iod.,) U.S.P., B.P. (Donovan's Solution).—Represents 1 per cent. each of Aa₁₃ and Hg₁₃. Dose, 0.1 c.c., 15 minims, U.S.P.; 0.3 to 1.2 c.c., 5 to 30 minims, B.P.

*Liquor Potassii Arsenioci, (Liq. Pot. Arseni.), U.S.P.; Liquor Arsenicalis (Liq. Arsien.), B.P. (Fowler's Solution; Liquor Kali Arsenicos).—Potassium arsenite, corresponding to 1 per cent. of As₂O₃, colored and flavored with Co. Tr. Lavender. A clear or faintly opalescent liquid with a pink color and a slight odor of lavender. It is slightly alkaline, and therefore incompatible with alkaloidal salts (in addition to the incompatibilities mentioned under Liqu. Acid. Ars.). Dose, 0.2 c.c., 5 minims, U.S.P.; 0.12 to 0.5 c.c., 2 to 8 minims, B.P. Maximum dose, 0.5 c.c., 8 minims.

*Sodii Arsens (Sod. Arsens.), U.S.P. Na₃H₂AsO₄ + ½H₂O—Colorless, transparent prisms. Freely sol. in water (1:1.5). Dose, 5 mg., 14 gr., U.S.P. Maximum dose, 10 mg., 34 gr.

Sodii Arsenii Elixir (Sod. Ars. Elixir), U.S.P.; Sod. Ars. Anhyd., B.P.—Freely sol. in water (1:3.1). Dose, 3 mg., 15 gr., U.S.P. 1.5 to 6 mg., 0.4 to 0.14 gr., B.P.

Liq. Sod. Arsens., U.S.P., B.P.—1 per cent. of Na₃H₂AsO₄. Dose, 0.2 c.c., 5 minims. U.S.P.; 0.12 to 0.5 c.c., 2 to 8 minims, B.P.

ORGANIC ARSENIC COMPOUNDS

General Statement.—The organic compounds of arsenic contain the metal in non-ionic form. This is more or less readily liberated in the organism, with the gradual production of the ordinary arsenic effects. In detail, however, these differ considerably from those of inorganic arsenic compounds, partly because the whole organic molecule may act as such, and partly perhaps because the organic side-chains alter the penetration and therefore the selective action of the arsenic, so that this is liberated in the cells which it does not ordinarily reach in effective concentration. At all events, the differences from inorganic arsenic are mainly quantitative rather than qualitative. In the body, the organic compounds are less toxic to mammals and more toxic to protozoan parasites. In this way they become available for combating trypanosomes, syphilis, spirilloid and other protozoan infections.

However, while arsenic trioxide kills the protozoa in test-tube cultures, the currently used organic arsenic compounds are practically ineffective outside of the body. In order that they may become effective, they must be altered in the tissues. The active decomposition products are not well known, but they must contain trivalent arsenic, which is vastly more toxic to protozoa than is pentavalent arsenic.

Chemie Structures.—Carbonyllic Acid and Arsanlic Acid (Atosyl) are derivatives of arsenic acid, and therefore contain the pentavalent arsenic. Arsenphenin (Salvarsan, Dioxy-diamino-arsoeno-benzol) contains trivalent arsenic, which acts much more powerfully on the parasites.
ORGANIC ARSENIC COMPOUNDS

Their structure is illustrated by the formulas:

\[
\text{Arsonic Acid: O-As(OH)\_2; } O = \text{As-OH} \\
\text{Cacodylic Acid: O-As(CH\_3)\_2OH.} \\
\text{Arsenic Acid: O-As(C\_2H\_5)\_2NH\_2(OH\_2)(Ataxyl).} \\
\text{Acetylarsenic Acid: O-As(CH\_3)\_2NH\_2(CH\_3CO\_2)(OH\_2) (Arsacetin.} \\
\text{Dioxy-diamino-arsenic benzoyclic (Arsphenamin).}
\]

\[
\begin{align*}
\text{As} & = \text{As} \\
\text{NH\_2} & = \text{NH\_2} \\
\text{OH} & = \text{OH} \\
\end{align*}
\]

**Arsenic Content.**—Arsenic trioxide contains 73.74 per cent. of arsenic; crystallized sodium arsenate, 24 per cent.; sodium cacodylate, 33.6 per cent.; sodium arsenate (ataxyl), 22 to 26 per cent.; arsphenamin, 31.6 per cent.; neo-arsphenamin, about 20 per cent.

**Chemotherapy.**—This term has been restricted, somewhat arbitrarily, to the parasiticidal treatment of infections by chemical agents; **Internal Antisepsis** is perhaps a more descriptive title.

Other examples of chemotherapy are the specific effect of quin in malaria, of mercury in syphilis, and possibly that of the salicylates in rheumatic fever. These were all empirical discoveries; the occasional use of arsenic in syphilis, trypanosomiasis, etc., was also haphazard. The recent development of this field is due mainly to the systematic work of P. Ehrlich and his pupils.1

**Affinity of Chemic Substances and Living Protoplasms.**—The numerous antisepsins which are universally effective against infective agents outside of the body are not generally available for internal therapy, because they have, for the most part, a greater affinity for the protoplasm of the host than for that of the parasites (Becchold and Ehrlich, 1906). They are more "organotropic" than "parasitotropic," and therefore more injurious to the host than to the parasite. The problem of chemotherapy is therefore largely one of specific selective affinity (penetration or otherwise), between the specific living cells and specific chemical substances. These differences are mainly quantitative, but they vary greatly for individual substances (as illustrated, for instance, by the vital staining of tissues; the triple stain for leucocytes; the methylene blue stain for nerves, etc.). While therefore the existence of a harmless universal internal antisepst is highly improbable, it is quite conceivable that a series of specific substances may exist which combine a relatively high toxicity for a certain parasite with a relatively low toxicity for the cells of the host. This hope has not been realized for most bacteria, which have generally a very high resistance. The protozoan parasites, on the other hand, are much more susceptible, and the efforts of Ehrlich in this direction have been highly successful.

**Trypanosome Experiments.**—The experimental therapy of protozoan infections was most conveniently investigated on the Trypanosomes, which by their different species, produce the tropical "sleeping sickness," and similar diseases in animals. Ehrlich and Shiga, 1904, studied the influence of a great variety of substances on trypanosome infections of white mice. The search was at first haphazard; but when partly successful results were obtained, it was sought systematically to improve these by altering the side-chains so as to increase their specific affinity for the chemoreceptors of the parasites. The effective agents found by Ehrlich and by independent workers belong to four groups: (1) Benzidin Dyes (Trypan red, etc.); (2) Basic Triphenylamin dyes (Malachite Green, Parafuchsin, etc.); (3) (Arsenic Compounds; and (4) Antimony and Bismuth compounds.

These investigations were important mainly by elucidating the general principles of chemotherapy; for it was soon found that the detailed results could not be transferred directly to man: Agents which were effective in one species of host were often much less effective in another. The dyes in particular were not practically available; since they cause intense coloration of the body, irritation and necrosis of the skin, and severe cachexia. These objections do not hold for the arsenic or antimony compounds; but with these also the efficiency for man can not be deduced from the animal experiments.

3 The chemistry of these dyes is discussed by H. Schweitzer, Science, Dec. 9, 1910.
Acquired Resistance.—One of the most important results was the discovery that the afflicted patients usually become temporarily the parasites resistant ("fast") to the agents of the same group, although they preserve their susceptibility to drugs of the other groups, which act upon other receptors (Ehrlich, 1907). In this way the trypanosome species may be divided into three principal groups: (1) Arsenicals; (2) Penicillin; and (3) Acid azo-dyes of the benzopurpurin series (trypan red and blue). There are a few significant exceptions to these laws; Pyronil, which contains no arsenic, induces resistance to arsenic acid. Arsenic trioxide does not render the trypanosome resistant; bacteria acquire resistance to inorganic arsenic, and are then also resistant to antimony (H. Marks, 1910). The arsenic resistance of trypanosomes extends only to animals, and can not be demonstrated in vitro. Ehrlich explains this by a lessened avidity of the parasites for arsenic, so that they do not compete with the tissue for the arsenic. This diminution of arsenic avidity is a graded process, and the trypanosomes may be made "fast" either against the weaker or the active arsenicals. This insusceptibility is preserved for many generations, even if the resistant parasite is passed through a succession of hosts. It is therefore worse than useless to employ small doses, since these would only render the organism less susceptible to further treatment. In the phraseology of Ehrlich, one must aim at a Therapie Magna Sterilitas; at killing all the protozoa with a single massive dose of the antiseptic. When this can not be done, the result may sometimes be attained by employing, simultaneously or successively, two or more agents belonging to different groups (f.e., Atoxyl and mercuric nitrate and thiosemicarbazides, 1907).

Arsenic in Protozoan Infections.—Arsenic has had some reputation in syphilis since the times of Fallopius (Herzfeld, 1911), and the caducateyl was employed in this disease by Gautier in 1866. Arsenic was also used in malaria with fair success. These instances were, of course, entirely empirical. Experimentally, Lavener and Mendel, 1902, found that arsenic acid causes the temporary disappearance of trypanosomes from the blood of infected mice. It has also been tried in human cases (Merek’s Reports, 21:233) but the really effective dose is too dangerous. A more selectively parasitically modified ofluid was found by H. W. Thomas, 1902, in Arsanilic Acid (Axymin). The injection of ineffective doses may gradually render the parasites resistant ("fast") to the agents of the same group, although they preserve their susceptibility to drugs of the other groups, which act upon other receptors (Ehrlich, 1907). In this way the trypanosome species may be divided into three principal groups: (1) Arsenicals; (2) Penicillin; and (3) Acid azo-dyes of the benzopurpurin series (trypan red and blue). There are a few significant exceptions to these laws; Pyronil, which contains no arsenic, induces resistance to arsenic acid. Arsenic trioxide does not render the trypanosome resistant; bacteria acquire resistance to inorganic arsenic, and are then also resistant to antimony (H. Marks, 1910). The arsenic resistance of trypanosomes extends only to animals, and can not be demonstrated in vitro. Ehrlich explains this by a lessened avidity of the parasites for arsenic, so that they do not compete with the tissue for the arsenic. This diminution of arsenic avidity is a graded process, and the trypanosomes may be made "fast" either against the weaker or the active arsenicals. This insusceptibility is preserved for many generations, even if the resistant parasite is passed through a succession of hosts. It is therefore worse than useless to employ small doses, since these would only render the organism less susceptible to further treatment. In the phraseology of Ehrlich, one must aim at a Therapie Magna Sterilitas; at killing all the protozoa with a single massive dose of the antiseptic. When this can not be done, the result may sometimes be attained by employing, simultaneously or successively, two or more agents belonging to different groups (f.e., Atoxyl and mercuric nitrate and thiosemicarbazides, 1907).

Sodium Cadocultate

General Statement.—The effects of cadocultate (dimethylarsenic acid) are essentially those of the inorganic arsenic, to which it is partly reduced in the body. Since this reduction occurs but slowly, the action is more prolonged and less toxic, and the local irritant effects are avoided. It has therefore some advantages over the other arsenicals. On the other hand, the degree of reaction, and therefore of the effect, is variable; and the caducateyl, especially when given by mouth, imparts a garlic odor (from cadocultate oxid, As₄(S₂H₄)₂O, to the breath, sweat, urine, etc. To avoid the more rapid reduction in the stomach, intestines and liver (Heffer, 1901), it is usually administered hypodermically or intramuscularly. Excessive doses produce toxic symptoms, due mainly to the inorganic arsenic (Schulz, 1879; Heffer, 1901; Dawes and Jackson, 1907), although the cadocultate molecule may conceivably play a part.

Therapeutically it is used in the same condition as inorganic arsenic. The dosage is from 0.025 to 0.15 Grm., ½ to 2½ gr. per day, as pills, or
hypoderminically, as a freshly prepared warm sterile solution; also by enema. In *syphilis*, Oppenheim, 1907, and J. B. Murphy claimed some success (single intramuscular injection of 2 to 4 gr.; but Cole, 1916, showed it to be inefficient even with doses that produced albuminuria and hematuria (intravenous injection of 0.5 Gm. every 3 days for 4 to 6 doses).

**Fate of Cacodylate.**—A part is excreted unchanged in the urine (on hypodermic injection, 6 to 10 per cent., Dawes and Jackson); but the greater portion undergoes reduction first to the volatile cacodylic acid, and a small part finally to inorganic arsenic.

**A bibliography** of Cacodylate is given by de Biebler, 1907. It was introduced into therapeutics by Sauter, 1899. The clinical side actions are discussed by Seifert, Nebenwirk., 1915, page 172.

**PREPARATION—CACODYLATE**

*Stiidi Cacodylas* (Sod. Cacodyl). U.S.P.—About 73 per cent. of sodium dimethylarsenate, Na(CH₃)₂AsO₄. White, deliquescent prism or granular powder, without odor or taste. Very sol. in water (1:0.5); freely sol. in alc. (1:5). Dose, 0.06 Gm., 1 gr., U.S.P. In pills, hypodermically, or by enemas. **Maximum dose**, 0.2 Gm., 3 gr.

**SODIUM ARSANILATE (ATOXYL)**

**General Statement.**—This salt, C₆H₅(NH₂)₄AsO·OH·Na₈ (sodium aminophenyl-arsenate), may be derived from sodium arsenate by replacing one hydroxyl by anilin. (It was at first believed to have a different constitution.)

Under the dangerously misleading name of “Atoxyl” (for the substance is quite dangerous) this salt has received considerable prominence as an organic form of arsenic, effective in all conditions in which arsenic is indicated; especially in sleeping sickness, in which it is superior to other arsenicals; and in syphilis and other protozoan affections, in which it is inferior to arsphenamin (Tomaszewski, 1908; Greven, 1910).

In sleeping sickness it causes prompt disappearance of the trypanosomes from the blood, but they may recur, so that the injection must be repeated every seven days (R. Koch, 1907, Deut. Med. Wochenschr., 33:1889. This paper discusses also the details of dosage and administration). Kopke’s (1906) clinical results were less favorable. The parasites become gradually resistant. B. Moore, Nierenstein and Todd, 1907, therefore recommended alternation with mercury which acts on another stage of development (Hodges, 1908).

The chief objection to “atoxyl” is the fairly frequent occurrence of toxic effects, especially permanent blindness, from therapeutic doses. These, as well as the therapeutic actions, are mainly due to the reduction products which are formed in the organism.

Sodium arsanilate should not be given by mouth, since it would be decomposed and rendered more toxic. The hypodermic dosage is from 0.07 to 0.2 Gm. every other day. The injections are said to be non-irritant.

**Toxic Effects of Atoxyl in Man.**—Acute symptoms occur especially with doses exceeding 0.5 Gm. They resemble partly those of ordinary arsenic poisoning, and consist in nausea and vomiting; colic, vertigo, general weakness and somnolence; nerves, pain in limbs; deafness, retention of urine, sometimes nephritis; iritis, and not uncommonly permanent optical atrophy (Hallopeau, 1907; Fortey, 1913). Chronic Poisoning presents the ordinary phenomena of chronic arsenic intoxication. The Clinical side actions are discussed by Seifert, Nebenwirk., 1915, page 178.

**Optic Effects of Atoxyl (and Arscetin).**—The eye symptoms usually appear within a few weeks (in Koch’s series only when the dosage exceeded 0.5 Gm.). They begin with scintillation, cloudiness, diminished vision, and contraction of the visual field.
Protein Metabolism.—Boyd, 1913, found in two human cases that arsenal ate
the excretion and causes the retention of nitrogen.

Toxic Effects of Atoxyl on Animals.—The acute toxicity of atoxyl is perhaps no
fortieth of that of inorganic arsenic; and injections have no acute effects on blood
pressure. However, they produce chronic effects and arsenic lesions, the distribution
of which varies quantitatively in different animals (Igersheimer and Itami, 1909): dogs
show mainly characteristic renal hemorrhages with secondary nephritis; cats exhibit
mainly nervous symptoms with histologic lesions in the brain and cord. Rats and
rabbits are intermediate. The distribution of the arsenic corresponds with the dif-
ferences in effects. In cats, f.d., the arsenic is found mainly in the nervous system; in
dogs, in the parenchymatous organs (Igersheimer and Rothmann, 1911). Mammals
also show the optic degeneration, both on local and systemic administration. (The
toxicity of atoxyl has also been investigated experimentally by Ciani, 1908.)
In frosi, Sanno, 1911, found that the toxicity is greatly increased by raising their
temperature, presumably by favoring its transformation into more toxic products. (A
similar influence is found with colchicin.)

Difference in the Actions of Inorganic Arsenic and Atoxy.—The atoxyl effects run
a slower course, and are devoid of the local actions of inorganic arsenic. This might
be due simply to the slow liberation of inorganic arsenic. Some of the other differences,
such as the optic changes, are more characteristic. They might be attributed to the
distinctive localization of the arsenic. It is possible, however, that they are produced
by some organic decomposition product. Artificial reduction products are much more
toxic than the arsenate, to mammals as well as to protozoa.

Reduction.—Since arsanic acid is itself practically non-toxic to trypanosomes, it
follows that it must undergo some change in the tissues. The degree of decomposition
varies with the dosage and toxicity, vary in different animals. The decomposition
products have not been isolated, but it is probable that they must contain the arsenic
in trivalent form. (Rothermund and Dale, 1912, however, believe that it is directly
trypanocidal.) The artificial reduction products, which vary according to condition,
are much more active than the arsenate, and paraminophenylarsenous acid kills the
parasites in the test-tube. H. T. Terry, 1932, has found that emulsions of liver and
blood reduce arsenate into directly effective products.

Excretion.—After a single dose of arsenate, the arsenic is excreted promptly and
exclusively by the urine (Croner and Seilgmann, 1907). With continued administra-
tion, the excretion is somewhat more prolonged; the greatest part leaves within
days (Simonot, 1910), but traces continue to be excreted for three weeks (Welande,
1909). The effects are therefore somewhat cumulative. A small part leaves by the
feces. Only a small proportion is excreted in inorganic form.

A relatively large part of the arsenate remains for a long time unchanged in
the blood and tissues (Simonot, 1910), but a part is fixed and changed in the cell.
The characteristic distribution in different animals is described by Igersheimer and
Rothmann, 1909.

PREPARATIONS—ARASILATES

Sodii Arasilatus, N.N.R. (Atoxy).—Occurs as white, odorless crystals, of faintly
salty taste. Readily sol. in water (1:5 or 6). Dose, 0.02 to 0.2 Gm., 1/5 to 1 gr. hyp-
dermically every other day, gradually increasing if necessary until the single dose
reaches 0.65 Gm., 10 gr. and until a total of 0.5 Gm. (100 gr.) has been given. It
must not be administered by mouth.

Arsacitin.—Sodium acetyl araslate, C H (NH-C=O)-O=OH-ONa + H2O.
Is less toxic acutely than araslate, and is highly paraesthetic in mice. In man,
however, it is no more effective than the original substance, and is equally liable to cause
blindness (J.A.M.A., 1910, 54:1550); and it is even more apt to produce renal irritation
(Horchen, 1920). Its only advantage is the greater stability, so that it can be sterilized
without decomposition. The dosage, hypodermically, is 0.1 to 0.5 Gm.

Ehrlich, 1907, noticed that some mice treated with arsenic acquire the curious
waltzing gait.

ARSPHENAMIN AND NEO-ARSPHENAMIN

Composition.—Arspenamin (Salvarsan, “606,” Arsenobenzol), is
diamino-dihydroxy-arseno-benzyl hydrochlorid.
**ARSPHENAMIN GROUP**

**Arsphenamin Base and Salts.**—Arsphenamin may act either as a base or as a dibasic acid, as follows:

\[
\begin{align*}
\text{As} & = \text{As} \\
\text{NH}_3 & \text{OH} \quad \text{NH}_3 \quad \text{OH} \\
\text{Neutral base} \\
\text{As} & = \text{As} \\
\text{HCl.NH}_3 & \text{OH} \quad \text{NH}_3 \quad \text{HCl} \\
\text{Dihydrochlorid} \\
\text{As} & = \text{As} \\
\text{NH}_3 & \text{OH} \quad \text{ONa} \quad \text{NH}_3 \quad \text{OH} \\
\text{Monosodium salt.}
\end{align*}
\]

Neo Arsphenamin (Neoosalvaran "914") is a soluble preparation, viz., Sodium arspheinamin-methanol sulphoxylate,

\[
\begin{align*}
\text{As} & = \text{As} \\
\text{NH}_3 & \text{OH} \quad \text{NH}_3 \quad \text{CH}_4 \text{O.SONa} \\
\text{mixed with inert inorganic salts, so that 3 parts of neoarpsenamin approximate in} \\
\text{arsenic content 2 parts of arspheinamin.}
\end{align*}
\]

**Experimental Results.**—The introduction of arspheinamin was the direct outcome of the chemo-therapeutic studies of Ehrlich. The substance was prepared by Bertheim, and tested by Ehrlich and Hata, 1910. They found that a single injection of a harmless dose freed animals completely and permanently from spirillosis and certain other protozoan infections, including syphilitic spirochetes.

W. H. Brown and Pearce, 1916, warn against the transference of results from the protozoa of one disease to other diseases, and recommend scrotal syphilis of rabbits as a test object.

**Spirochetal Cultures.**—These are killed by the following concentrations of antiseptics (Akatsu, 1917):

- Mercuoric chloride ........................................... 1:100,000
- Arspheinamin ................................................ 1: 7,500
- Neo-arspheinamin ........................................... 1: 2,500
- Phenol .......................................................... 1: 2,500
- Formaldehyde (absolute) .................................. 1: 1,800
- Tolidin in KI ................................................ 1: 75

The susceptibility of spirochetes is materially greater in the presence of enzymes from the liver, and especially from the blood (Brontenbrenner and Noguchi, 1913). Bacteria are generally not very susceptible, but according to Koos, 1912, arspheinamin is directly germicidal to anthrax, even in living animals. It is ineffective in rabbits (Mejia, 1913).

**Drug-fastness of Spirochetes.**—Various species, including pallida, by continuous cultivation in poisoned media, acquire rapidly a considerable but not absolute tolerance to increasing concentrations of arspheinamin, mercuoric chloride and tolidin. However, this fastness is lost completely in a few generations, and is therefore of little practical importance (Akatsu and Noguchi, 1917).

**Therapeutic Results in Man.**—Arspheinamin has been completely successful in *malignant fevers* (Iversen, 1910), in frambesia, and in yaws (Nichols, 1910). The degree of its usefulness in tertiary malaria, sleeping sickness, and certain other protozoan infections; and in leprosy and pellagra is undecided. Wadham and Hill, 1913, have used it successfully in a few cases of amebic dysentery. It has been tried as a substitute for ordinary arsenic, in skin diseases, pernicious anaemia, as a tonic, etc., but without serious advantage.
Results in Human Syphilis.—Arsphenamin has proved remarkably successful, although it has not fulfilled the original hope of complete cure by a single injection. The conditions are evidently not as simple as in experimental animals.

Early Lesions.—Complete success, similar to that in animals, occurs only in specially favorable conditions, when it is injected during the primary stage, the initial focus being excised or destroyed by local mercurial treatment. Ordinarily, the spirochetes begin to disappear in a few hours from the chancre and condylomata, and are completely absent in one or two days; however, they generally reappear after a time. In this way, arsphenamin abolishes promptly the main dangers of contagion—a very important advantage. Its efficiency is in direct ratio to its early use, and its principal field is in the primary stage, where its use prevents the development of secondary symptoms and of positive Wassermann reaction.

Later Active Stages.—In these, it still produces very marked but temporary effects, a single injection often equalizing months of mercurial treatment. Complete disappearance of the syphilitic symptoms is the rule. Surface lesions and ulcers especially are repaired with astonishing rapidity. Malignant cases and those which have resisted mercury may cease promptly to the arsphenamin. However, even these striking results are almost always followed, after a time, by relapses, so that the treatment must be repeated, or supplemented by mercury. In a few cases arsphenamin fails completely; presumably the spirochetes are in some region which is difficultly accessible to the drug. In general, the older the infection, the less is the efficiency.

Arsphenamin is very effective in those late lesions that are "active," i.e., gummatous and periostal (Fordyce, 1916); especially those which have been long treated, and unsuccessfully, with mercury and iodid.

In parasypilitic conditions (tabes, general paresis, etc.) arsphenamin is usually ineffective, although it sometimes produces striking improvement. It is worth trying at the very start of the symptoms. In syphilitic aortitis, arsphenamin and mercury rarely give more than temporary relief (Longcope, 1914).

Hereditary syphilis has been cured through the milk, by injecting the nurse; and congenital syphilis by injection of the mother. Arsenic has been found in the placenta, but it is doubtful whether it is transmitted to the fetus.

Wassermann Reaction.—The efficiency of arsphenamin is reflected in the Wassermann reaction: In a few of the most favorable cases, this becomes and remains permanently negative after a single injection. Much more commonly there is no change for some five days, when it generally becomes negative. This negative reaction is not lasting, but returns in a short time to positive. It may then be again suppressed by further treatment. Lesser, 1911, considers the cure incomplete until a permanent negative reaction is obtained. In less favorable cases, the Wassermann reaction is not altered, although the symptoms may be greatly improved. It is claimed that in a few a temporarily negative reaction may even be roused to a positive one; but this is doubtful (J. T. King, 1916).

Possibility of Permanent Cure.—There is now little doubt that suitable cases are cured by sufficiently large and repeated doses, especially when alternated with mercury.
ARSLENAMIN GROUP

The "clinical cure" does not necessarily mean the complete eradication of the organisms. Warthin, 1918, asserts that syphilis is never cured in the absolute sense; that treatment suppresses the active forms, but leaves surviving spirochetes. These take up a symbiotic existence in which they cause no great damage, but only a slight though constant irritation. The irritable foci are healed, one after another, by fibrosis. However, the tissue is damaged, and the patient eventually dies of myocarditis, aortitis, nervous lesions, or similar changes almost anywhere and everywhere.

Advantage over Other Arsenicals.—The curative action of arsphenamin is also shared by all other arsenic compounds, but it possesses the practical advantage that the effective doses can be introduced with much greater safety.

Advantage over Mercury.—The relative advantages of mercury and arsphenamin are rather evenly balanced, so that arsphenamin has supplemented, rather than displaced, the older drug. Its main advantage is the much more rapid action, which brings the disfiguring or dangerous lesions (especially of the mucosa) under prompt control, limits contagion, and is highly important in malignant cases. The second advantage is that, in combination with mercury, it is more efficient than this drug alone or with iodids. It has a special field in cases in which mercury is ineffective or not tolerated.

Disadvantages of Arsphenamin.—These involve partly the inconvenience, expense, loss of time, relatively complicated technic, and pain of its administration, certain special contraindications, and the not infrequent occurrence of more or less toxic side effects. These are also produced by Neosalvarsan (Wolff and Mulzer, 1912). Fatalities and permanent injury, however, are so infrequent, if proper precautions are employed, that they do not seriously interfere with the usefulness of arsphenamin.

Comparison of Arsphenamin and Neosalvarsan.—It is still doubtful which of these drugs is superior. (Indeed, the advantages appear pretty evenly balanced.) The neosalvarsan has the advantage of easy solubility, and therefore simpler technic. However, it is more readily decomposed, and the products are more toxic, but not as effective. Some believe that arsphenamin is more efficient (Whitehouse and Schuyler, 1913; Nelson and Haines, 1914).

The clinical results are similar for both. Serologically, arsphenamin appears more efficient. It is more frequently followed by undesired reactions (Ormsby, 1917).

Experimentally, neosalvarsan is more likely to produce pathologic lesions and impaired vitality. The minimal fatal dose is irregular, even in the same species (L. Pearce and Brown, 1917). Opinions differ as to the relative local irritation.

TOXIC AND SIDE-ACTIONS OF ARSLENAMIN

Direct Local Irritation.—Intramuscular and subcutaneous injections of acid solutions cause very severe local and neuralgic pains, persisting for several hours or days. These are due mainly to the acidity, and are very much less with the neutral suspensions. However, even with the latter, and with neosalvarsan solutions, there is more or less swelling and infiltration, lasting one or two weeks; and sometimes necrosis, infection, or abscess formation. H. E. Robertson, 1913, describes severe, slowly healing destructive lesions, often complicated by hemorrhages and sloughing abscesses. Sometimes the injections are not absorbed (due to local thrombi, Loche, 1912; Takahashi, 1914), so that the deposit may remain indefinitely. Arsphenamin always leaves an insoluble yellow pigment,
which acts as a foreign body (Robertson). During the intravenous injec-
tions there is often intense, but fleeting pain in the shoulder (endocardial
irritation?).

Acute Effects in Animals.—These resemble ordinary arsenic poison-
ing superficially, although the immediate effects are probably molecular.
They result in fall of blood pressure (mainly cardiac), renal irritation,
anatomical parenchymatous lesions, and nervous phenomena. Toxic
arsenic may play a part in these late phenomena.

Circulation.—The effects vary with the reaction of the solution as well as with the
dose, concentration and rapidity of the injection.

For clinical purposes corresponding to those of the clinical use, there is practically no
immediate effect on the circulation (intravenous injection, anesthetized dogs, mono-
dium salt, 10 mg. per Kg., 2 per cent. or less, injected over several minutes).

If the dosage is increased, or the injection accelerated, definite effects appear.
These consist of slight, but gradually progressive dilatation of the heart, rise of pressure
in the pulmonary artery, and slow fall of systemic blood pressure. If the injection
is rapid, the fall is more sudden, with partial recovery.

The mechanism of these effects is not quite clear. The cardiac depression is evi-
dently the main factor. This is further aided by disproportion between the systemic
and pulmonary circulation; the pressure in the pulmonary artery being sometimes
doubled when the carotid pressure has fallen to half. The changes in organ-volume
are variable, indicating the complexity of the effects. Generally, the spleen and intest-
tines are dilated, the kidneys contracted (D. E. Jackson and Smith, 1918).

The vesic of frogs are constricted (Luithlen).

Cardiac Action.—Excised hearts are depressed. This cardiac action is the common
cause of acute fatalities. The cardiometer may show cardiac dilatation even when the
blood pressure does not fall, the vasocstriction compensating for the weakening
(Luithlen, 1913). The effects are greatly influenced by the concentration and rec-
tion. Acid solutions are especially fatal to the heart, but even alkaline solutions render
it more susceptible to strain (Auer, 1911). The fall is greater when tricresyl insuffi-
ciency exists, but not with acetate insufficiency (Alwena, 1913).

Hemolysis.—According to Corridi, isotonic solutions of neoarsphenamin or acid
solutions of arsphenamin are not hemolytic, but alkaline solutions dissolve the
cpuscles. He prefers neosalvarsan in 0.4 per cent. NaCl to watery solutions for intra-
venous injections, but these must be used promptly or oxidation will occur (desoted
by brown color and turbidity).

Leucocytes. — Rabbits show at first leucopenia, followed in several hours by leucocyt-
osis, especially of neutrophile polymorphonuclears (Corridi, 1912).

Muscle and Nerve.—Joseph, 1917, found that the excitation of frog's muscle is
abolished, both in acid and alkaline solutions, but the action occurs only slowly, and re-
quires high concentrations.

Clinical Effects on Circulation.—Occasionally there are severe reactions (Buni,
1912), but usually doses of 0.3 to 0.6 Gm. produce only slight and inconstant changes
of blood pressure. The heart rate shows slight but lasting increase. There may be a
temporary diuresis. The erythrocytes are temporarily increased. Rolleston, 1911, finds
that neosalvarsan injections are generally followed by a fall of systolic (average
16 mm.) and diastolic (14 mm.) pressure. The formation of white corpuscles (especially
neutrophiles) is stimulated (Razentowski, 1912). Heden, 1913, describes a decrease of
hemoglobin.

Lethal Dose.—According to animal experiments, arsenic in the form of arsphen-
amin is about one-seventh (one-third to one-fourth, Luithlen, 1913) as toxic as in inor-
ganic form (Kochmann, 1912). The fatal intravenous dose for rabbits would cor-
respond for man to about 5 or 6 Gm., or ten times the therapeutic dose. 1 Gm. has been
given clinically without serious results. The acute toxicity of neoarsphenamin is
stated as about half as high (Kerstner, 1912).

Solutions of arsphenamin in serum are much less toxic to rabbits than are watery
solutions (Roeck, 1913).

Influence of Concentration and Reaction of Arsphenamin Solutions.—The concentra-
tion of the solutions does not influence the toxicity, when alkaline solutions are injected
into rabbits; a moderate excess of alkali is also immaterial. Acid solutions are nearly
twice as toxic as are neutral or alkaline solutions (intravenously for rats); and with
acid solutions, the toxicity increases with the concentration (Schaumberg et al., 1911).
Bio-assay.—Absolute purity of arsphenamin and neoarsphenamin is commercially unattainable. All samples contain some inorganic and other arsenic, which is many times more toxic. Life-tests are needed to set a limit to these impurities. These are made at the factories, and controlled by the government, about as in the case of serums.

According to the U. S. Hygienic Laboratory Standard, rats must survive at least 100 mg. of arsphenamin, or 200 mg. of neoarsphenamin per Kg. (details in N.N.R.). G. B. Roth, 1918, found no definite difference between the commercial samples of domestic and foreign manufacture.

It must be borne in mind that rabbits and rats show quite marked individual variations of susceptibility.

Clinical Toxicity.—Some degree of systemic reactions occurs in 1/4 to 15 per cent. of all injections. They are annoying and alarming, but not often dangerous.

Wechselmann, 1914, has collected reports of 140 fatalities. He is inclined to attribute these mostly to the arsphenamin itself, acting on some pathologic conditions, usually renal. This interpretation is not universally accepted.

Grouping of Clinical Arsphenamin Accidents.—The following arrangement is convenient:

A. Immediate: (few minutes).—Anaphylactoid collapse (nitriloid) symptoms.

B. Early: (start in 1 to 4 hours).—Febrile course. Skin reactions.

C. Late: (after 24 hours).—

1. Febrile
2. Herxheimer
3. Arsenical

D. Severe late (about 3 days).—

1. Cerebral Type
2. Icteric Type

E. Neurocurrences.

Group A: Immediate Toxic "Nitriloid" Reactions.—The early reactions bear a general resemblance to vasodilatation ("vasoparesis"); the milder grades to nitrile action; the severer grades to anaphylactic reaction (Swift, 1912).

Symptoms.—These start during, or within a few minutes after intravenous injection. There is a burning ethereal taste; flushing of the face; injection of the conjunctiva; edema of the tongue and eyelids; anxiety, nausea and vomiting; then profuse perspiration. Cough and dyspnea, cyanosis and precordial distress are sometimes present. The pulse is full at first, then weak, with a pallid skin. In severe cases, there is unconsciousness, with scarcely perceptible pulse. Occasionally there are attacks of severe lumbar pain during the injection.

These symptoms may disappear in 1/4 to 1/2 hour; or they may be followed by those of Group B (Fordyce, 1916, Schamberv et al., 1917).

The immediate symptoms rarely are dangerous. Even actual collapse (which is said to be more frequent after the second dose), usually ends in rapid recovery, very rarely in death (Tomaszewski, 1913).

Causes of the "Nitriloid Reactions:"—These have been attributed to a hypothetical impurity: "Xp," to a "colloidal action," precipitation or "anaphylaxis;" to the liberation of arsenic ions; to the formation of hypothetical decomposition products; and to special susceptibility to the arsphenamin as such. The latter is the most probable explanation. The susceptibility, however, depends partly on the conditions of administration, partly on the patient.
"Reactions" occur in \( \frac{1}{2} \) to perhaps 5 per cent. of the administrations; the relative frequency depending mainly on the conditions of administration; especially on giving the drug with the stomach empty, and having the patient rest for an hour or more after the administration. The rate of injection, and the proper alkalination, are also important factors. However, a few patients react invariably even with the most careful technique.

Idiocrasy.—Individual susceptibility varies considerably in animals, and doubtless plays a part in clinical poisoning; but it is not believed to be a very important element (Schamberg et al., 1917).

Patients with tubercular lesions react more frequently (Stokes, 1919).

Role of Impurities.—It has been observed that certain lots of drugs produced an especially large number of "reactions." This suggested that a special unidentified impurity ‘X’ is responsible (Schamberg et al., 1917, Stokes, 1919). It is conceivable that this explanation holds for these special instances; but the large majority of atypical reactions seems to have no relation to special batches of the drug.

In support of his contention, Schamberg points out that arsenomine is a very complex substance, its preparation involving many intermediate stages, whose purity influences the final product. The impurities cannot be removed by recrystallization. An absolutely pure product is therefore not practically attainable, and different samples will vary. The purest commercial samples contain \( \frac{1}{2} \) of 1 per cent. of "arsenoxid" (or under decomposition) which was claimed to be many times more toxic than arsenamin; and varying quantities of other arsena compounds, of different toxicity. Each batch must therefore be tested on animals.

Jackson and Smith, 1918, however, throw some doubt on the feared toxicity of the intermediary products. Those that they examined were considerably less toxic than arsenomine.

Decomposition.—Even dry arsenomine and neascaromine oxidize very readily on contact with air. The oxidation products may be much more toxic, as for instance "arsenoxid" (amino-oxyprenylarsenoxid \( \text{AsO} \)) \( \text{NH}_3 \), Ehrlich and Berthiem, 1912). This is said to be twenty times as toxic as arsenomine.

The dosage forms are therefore marketed in sealed air-free tubes. The contents of a tube should be used at once after opening and under such circumstances should the contents of a tube damaged in transportation or any remnants of the powder from previously opened tubes be used.

Solutions of the drugs also oxidize very rapidly, especially when alkaline. The oxidation products vary and may be either more or less toxic than arsenomine (Schamberg et al., 1917).

Neascaromine decomposes gradually even in the ampuls; sometimes in a few weeks (Roth).

Precipitation and Anaphylaxis.—Arsenomine sometimes precipitates the blood serum, and it has been suggested that these precipitates, or colloidal aggregates somewhat short of actual precipitation, produce anaphylactoid reactions similar to those produced by chemically indifferent colloids such as agar. However, careful comparison of the phenomena in the two cases shows that they differ fundamentally (Hanslik and Kasner, 1920).

McKee, 1912, pointed out that acid solutions of arsenomine precipitate blood serum, and suggested this as an explanation of the reactions. However, acid solutions are now rarely used. Danyza, 1917, claimed that plasma precipitates arsenomine in colloidal form, even from alkaline solutions, the precipitation being more extensive the lower the alkalinity of the solution. He also attributes the atypical reactions to this precipitate. Berman, 1918, states that the serums of patients susceptible to reaction give heavy precipitation with alkaline arsenomine solution; whilst non-susceptible
patients give at most an opalescence. The susceptibility of the patient could therefore be predicted by a test-tube experiment. These statements need confirmation.

Attempts to induce anaphylaxis in guinea pigs by sensitizing injections of arsphenamin have generally been unsuccessful (Berman).

Precipitation of Blood.—Joseph, 1921, observed that acid (not alkaline) solutions, above 0.1 per cent., precipitate blood, in the vessels as well as in the test-tube. The quantity and coarseness of the precipitate depend upon the concentration of the solution, not upon the quantity. In living animals, the precipitate does not pass the pulmonary circulation. With 0.2 per cent., solution, the precipitate is so fine as to be harmless, but with 2 per cent., it may cause fatal pulmonary embolism.

Relation to Repetition of Dosage.—Nitrinitritol crises may occur with the first injection; or they set in with later injections. Once they make their appearance, the susceptibility seems to persist for all later injections (Berman, 1919).

Tuberculosis seems to increase the probability of reaction (Stokes, 1919).

Treatment of Nitrinitrold Reactions.—The resemblance of the symptoms to those of anaphylaxis and nitrite poisoning suggested the use of epinephrin, as prophylactic (1 mg. intramuscularly a few minutes before the arsphenamin) and for treatment (½ to 1 mg. by vein). Apparently good results have been reported (Berman, 1918; Beeson, 1919); but patients hypersusceptible to arsphenamin are sometimes also hypersusceptible to epinephrin; and the effects of the latter may be as alarming as those of arsphenamin (Stokes, 1919; Cole).

Stokes (1919), also claims successful prophylaxis from atropin (1 mg.), or by fractionated injection, giving ½ of the arsphenamin an hour before the remainder of the dose.

Group B: Early Toxic Reactions.—These are quite common. They start within one to four hours, with chill and febrile symptoms, headache, nausea, and vomiting and diarrhea, of greatly varying severity. The temperature is usually between 100 to 102°F. Occasionally there are severe pains in the legs or back.

These reactions also need not cause alarm (Ormsby, 1917). The symptoms usually cede in 12 to 24 hours, leaving some lassitude and weakness. More rarely, the temperature, vomiting and diarrhea may continue for several days. In some cases, the urine is scanty and contains albumen and casts (Schambreg et al., 1917).

Cause of the Febrile Reactions, Water Contamination.—Febrile reactions are especially marked in the presence of infections, even if slight (Wechselmann, 1910), or if stale distilled water is used (Wechselmann, 1911; Swift and Ellis, 1917). Ehrlich assumed that the bacterial products sensitize the body to arsenic. Neisser, 1910, attributed the reaction to the destruction of the spirochete. Perhaps the most probable explanation is that of Luithlen and Mucha, 1913, namely a destructive action of arsphenamin on pathologic tissues.

Kidney Involvement.—This has been claimed to be more frequent in the mixed arsphenamin-mercury treatment. Most clinicians, however, do not consider this mixed treatment as especially dangerous (Fordyce, 1910).

Skin Eruptions.—These may appear in a few hours to several days, and are of various types. The most common are urticarial, scarlatinoid and morbilliform erythemas; or rarely purpura. Sometimes there is only itching.

The eruptions generally subside in a day or two. Later and more persistent eruptions may occur 6 to 10 days after administration; more commonly after intravenous injection (Schambreg et al., 1917). Hemorrhagic Purpura.—Cases, some fatal, are reported by Labbe and Langloss, 1919.
Group C: Late Toxic Symptoms.—Several varieties of intoxication may develop after 24 hours.

Delayed Reactions.—These resemble Group B, except that they develop more slowly.

Reaction in Luetic Tissue and Skin.—The luetic lesions, especially of the trunk, often show a bright red erythema ("Jarish-Herxheimer reaction"). These phenomena set in early and last only a few days. Generally they cause little inconvenience; but it is conceivable that analogous reactions in cerebral or hepatic gummata might be immediately dangerous.

In case of gummata in such situations it is safer to precede arsenic by a course of mercury and iodid.

This type of reaction (which may also occur with mercury alone) has been attributed to the liberation of luetic toxins, while the late "neu- recurrences" are ascribed to the more vigorous activity of surviving spirochetes. The explanation is more or less hypothetical.

Metabolism.—The effects resemble arsenic (Postolov, 1912). Syphilitic patients under treatment show some nitrogen loss on the day following the injection; otherwise the changes are inconstant (Cappelli, 1911).

Group D: Severe Late Intoxications.—Occasionally, severe and even fatal reactions occur about 3 days after administration, with phenomena referable either to the brain or liver.

Parenchymatous Degeneration.—Fatty and necrotic changes are of important occurrence, clinically and in animals. They resemble ordinary arsenic lesions, involve especially the liver (acute yellow atrophy); then the kidneys, heart, nervous system (encephalitis hemorrhagica) and spleen (Busse and Merian, 1912; Morel, Mourguad and Politard, 1912; Schlabsberg, kidney, 1912; Schirgerow, 1912. Mucha and Kern, 1912, claim that even small doses damage the renal vessels and glomeruli). The intestines may also show hemorrhagic and inflammatory changes (Saccone, 1912). The lesions occur especially after repeated injection, and are increased by combination with mercury, uranium, epinephrin or Roentgen treatment (Luithlen, 1913; A. Loev and Wechselmann, 1913).

Luithlen emphasizes the greater toxicity of arsenamin to animals which have been subjected to these vascular injuries, and believes them analogous to the Herxheimer reaction; i.e., that this is a specific effect on vessels previously injured by the luetic process.

Nervous Phenomena.—V. Marschak and Vespremi, 1912, found multiple hemor- rhages and thrombi in the brain, with symptoms corresponding to the encephalitic type of clinical salvarsan poisoning.

Cerebral Type.—This occurs especially after large doses, or when ordinary doses are given in close succession. The symptoms consist in headache, weakness, vomiting, muscular twitching, epileptiform convulsions, suppression of urine, dilation of pupils, absence of reflexes, coma and death in 3 or 4 days. Paralytic symptoms may be observed (Chiat, 1913). Identical effects, with fatal ending and autopsy lesions typical for arsenic, have been witnessed on non-luetic patients (Lube, 1914).

The necropsy generally shows edema of the brain or encephalitis hemorrhagica, also degenerative parenchymatous changes in the kidneys, liver, heart, muscle, spleen, etc. (Busse and Merian, 1912; Tomaszewski, 1913; Corlett, 1913).

Laredde and Jamlin, 1914, attribute most cerebral accidents to Herxheimer reaction. Others, however, assume direct toxic actions. This is favored by their relation to the dosage.

Icterus.—Rather exceptionally, the syndrome of jaundice, generally accompanied by fever, may appear from 3 days to several weeks after
treatment. It occurs usually only after several intravenous injections (one or two courses). The symptoms start with sudden intense jaundice. Some recover, others run rapidly to a fatal ending, with vomiting hemorrhagic phenomena in the viscera, tubular nephritis, and the general typical symptoms and autopsy findings of acute yellow atrophy (Severin and Heinrichsdorf, 1912).

Fischer, 1915, attributes this to the syphils and not to the drug. However, the liver changes might also be due to the direct effects of arsphenamin, or to Herzheimer reactions.

**Group E: Neuro-recurrences.**—Sometimes arsphenamin injections are followed, after an interval of weeks or months, by severe nervous manifestations—epileptiform convulsions, acoustic, more rarely optic, facial, and other neurites. These do not appear to be due to the arsenic, for similar effects may occur in mercurial treatment, and they cede on further salvarsan or mercury medication. Ehrlich, 1911, attempted to explain them by the incomplete destruction of the parasites, those which escape being then less exposed to the normal restraining influences, and assuming a greater virulence.

**Optic Neuritis.**—This is a rare sequel of arsphenamin and neoparaphenamin. It is generally classed with the neuro-recurrences; but Arganaaz, 1914, reports a series of cases which he attributes directly to the drug, and not to the spirochetes.

**Absorption, Fate and Excretion.**

These are essentially alike for arsphenamin and neoparaphenamin.

**Absorption.**—This is slow, even from intramuscular injections, some arsenic generally remaining at the site of injection for months (Schuebel, 1914). Neoparaphenamin is absorbed more rapidly (Ullmann, 1912, 75 to 85 per cent. within a week; Swift, 1913). Very little is absorbed from the rectum.

**Fate and Excretion.**—Arsphenamin is decomposed in the body, and is excreted mainly in the form of ionized arsenic, by the urine and feces. Only a small fraction is excreted unchanged.

The arsenic appears promptly in the urine, but the excretion proceeds rather slowly, especially after muscular, but even after intravenous injection; unknown compounds being present, especially in the parenchymatous organs, for weeks (Valenti, 1912; Usuelli, 1912).

**Fate.**—The nature of the arsphenamin compounds appearing in the urine after arsphenamin and other organic arsenic compounds has been studied by C. Voegt and Burchhardt, 1916.

**Condition in Blood.**—After intravenous injection of arsphenamin or atoxyl into goats, the corpuscles and plasma contains the arsenic in a form that can not be separated from proteins by dialysis, differing in this respect from the administration of inorganic arsenicals (W. J. Young, 1915).

**Course of Excretion.**—This is essentially similar in luetic patients and in healthy rabbits (Barnasheim, 1912).

Arsenic may be demonstrated in the urine within a few minutes to two hours after administration (Abelin, 1911).

With intravenous injections it remains in the blood plasma for 1 to 2 hours (Bocker, 1918). The excretion begins within two or three hours (Usuelli, 1910); is maximal on the first day (J. Webster, 1910); and is practically completed in four days (Hoppe, 1910); but traces may be found up to three months (Heuser, 1911).

After intramuscular injection, the excretion is much slower (Greven, 1910; Fischer and Hoppe, 1910; Irokawa, 1914), but varies with the absorption. In man it begins in six hours; the maximum excretion occurs in four to six days; in eight days two-thirds have been excreted by the urine. Traces were found in twenty to forty days (Muto and Shin-no, 1911; Usuelli, 1912; by Heuser up to nine months). The course of excretion
has also been studied by Escallon, 1912. The excretion is said to be hastened by Potassium iodid (Greven, 1910).

Homeopathic injections are eliminated more rapidly than the intramuscular (Greven). Relatively large quantities are excreted by the gastro-intestinal canal (Ullmann, 1912; Stechmer, 1912); two to ten times as much as by the urine (Frenkel-Heldin and Navasart, 1914). The milk also contains arsenic (Caffarella, 1912).

Total Excretion.—There are few reliable data. Duret, 1918, examined the urine of the series of patients receiving weekly intravenous injections of neocarphamin. The total dose in 4 weeks corresponded to 0.2 gm. of arsenic. The urine during this period yielded a total of 0.1 gm. of arsenic, i.e., 1/2 of the quantity administered.

Excretion in the Cerebro-spinal Fluid.—This often (but not always) contains traces of arsenic within an hour after the intravenous injection of arsphenamin.

Mebths and McArthur, 1919, demonstrated the arsenic in about half of the patients. It averaged 0.00036 mg. of arsenic per c.c. of fluid. Further data are given by Camp, 1912; Hald, 1912; Stillman and Swift, 1915; Barbat, 1918; Rieger, 1918.

Distribution of Arsenic.—After intravenous injection, the arsphenamin does not remain free in the blood, which contains only traces after twenty-four hours; but is promptly deposited in the spleen, kidneys, bones, muscles, and especially in the liver (Borstein, 1911). It may be demonstrated in these organs for months, as inorganic and organic arsenic (Stuemke and Siegfried, 1911; Ritter, 1912; Ullmann, 1912). Arsenic also passes into the placenta (Burnasheff, 1912).

The central nervous system contains none or almost none (McIntosh and Filer, 1916; J. Webster, 1916).

ADMINISTRATION AND DOSAGE

Arsphenamin is now usually administered intravenously, repeated in "courses," in conjunction with vigorous mercurial treatment. Intravenous injections are sometimes used in neuro-syphilis, if ordinary treatment has failed.

Courses.—The ordinary "course" consists of 6 to 8 intravenous injections of arsphenamin or neocarphamin, given 5 to 7 days apart. With very early cases, the first two or three injections may be three days apart. Mercurial treatment is given at the same time (see Mercury). The kidneys must be watched.

Arsphenamin is usually allowed to rest for 4 to 6 weeks, when another course is given. This may be sufficient if the treatment has been started very early, while the Wassermann reaction is still negative. It is advisable, however, to administer six injections of mercury salicylate, after three months and another series half a year later.

With fairly early cases, but with positive Wassermann reaction, the semi-annual mercury courses are kept up for three years.

Dosage of Arsenophanin.—This should be varied with the strength and condition of the patient. For men, arsphenamin is usually started intravenously (or intramuscularly) with 0.3 Gm., and increased in successive injections by 0.1 Gm. to a total of 0.5 Gm. For women, the starting dose is 0.2 Gm., the full dose 0.4 Gm. For children, the full dose in 0.1 to 0.3 Gm.; for infants, 0.02 to 0.1 Gm.; for nurslings, 0.01 to 0.015 Gm.

Dosage of Neo-arsphenamin.—This is usually taken as 1/2 to 2 times that of arsphenamin.

Solution of Arsenophanin for Intravenous Injection.—The drug is used as arsphenamin 1/2 per cent. solution in an excess of alkali.

The ampul, containing the desired dosage, is laid in 15 per cent. alcohol for 15 minutes, to detect leaks. The neck is then broken off with a file, and the contents emptied into a sterile glass-stoppered mixing cylinder. Sterile, freshly distilled water is added,
ARSIPHENAMINE GROUP

20 c.c. per 0.1 Gm. of drug, and the cylinder is shaken until a clear solution results. A clear normal solution of NaOH is now run in slowly, to 0.9 c.c. per 0.1 Gm. of drug. The alkali first causes precipitation, which redissolves in the excess of alkali. (Others use a 15 per cent. solution of NaOH, added drop by drop to the arsphenamin solution until the precipitate is dissolved. This required about 4 drops per 0.1 Gm). The solution is then diluted with sterile distilled water, to 30 c.c. per 0.1 Gm. (U.S.P.H.S. Circular, J.A.M.A. 1910, 72: 1386).

If the solution is not perfectly clear, it must be filtered through a sterile filter.

With some brands, hot water may be used; with others not. If possible the injection should be given by body temperature.

The solution should be used within half an hour after it is made. It is inadmissible to use the contents of damaged tubes, or remnants of powder from previously opened tubes.

Chemical Changes in Dissolving Arsphenamin.—Arsphenamin may act both as a base, through its amine, or as an acid, through this phenol radical. Commercial "arsphenamin" is a hydrochlorid. Its solution in water has an acid reaction (hydrolytic dissociation). If it is not precipitated by acids. The addition of sodium hydroxid at first precipitates the free base. The precipitation is complete when 2 molecules of NaOH have been added for each molecule of salvarsan. This precipitate, suspended in water, is the form used for intramuscular injection. The further addition of NaOH again forms a soluble salt, the solution being complete when 2 further molecules of NaOH have been added. This is the form used for intravenous injection. (By actual measurement, the reaction is not completed until 54 per cent. more than the theoretical amount of alkali has been added; Bongrand, 1913.) Sodium carbonate does not dissolve the precipitate.

Solution of Neo-arsphenamin.—This drug dissolves directly in water.

It is injected in about 7 per cent. solution. Only a single dose should be injected at a time, in 10 to 15 c.c. of cold sterile, recently distilled water (10 c.c. for 0.5 Gm. or less; 15 c.c. above 0.5 Gm.). The temperature should be kept below 22°C. (72°F.)

Administration.—The patient should have an empty stomach, and should lie down for a time after the injection. The skin over the vein should be painted with iodin. Arsphenamin in injected by gravity, at the rate of two minutes per 0.1 Gm.

Neoarsphenamin is injected by syringe, using a very small needle, and taking at least five minutes for the injections.

Danger of Cumulation.—Too frequent administrations of arsphenamin would be cumulative and dangerous, since even with intravenous injection, only about 50 per cent. is excreted within three days. Intramuscular Injections.—These have largely gone out of use. Arsphenamin was usually employed as a 10 per cent. neutral suspension; neoarsphenamin as a 1/4 solution. Intramuscular injections must not be made too near to the sciatic nerve, or they may cause neuritis (Kissmeyer, 1916).

Spinal Injections of Arsphenamin Serum.—Cerebro-spinal lues often resists the intravenous administration of arsphenamin, since but little of the drug passes into the central nervous system. In such cases, when the ordinary treatment has failed, arsphenamin serum may be injected directly into the spinal canal, as an auxiliary; meantime keeping up the systemic treatment. Good results have been obtained in various forms of cerebro-spinal syphilis, especially in early cases, and with the "lightning pains" of tabes. The pains, psychical disturbances and cell count are usually markedly improved. Spinal injection is said to be dangerous if the lower limbs or sphincters are paralyzed. Dementia paralytica is not improved.

The safest medium for subdural spinal injections is the serum of the patient who has recently received an arsphenamin injection, according to the Swift-Ellis (1912) method. However, water or serum solutions of arsphenamin have been injected directly into the subdural canal.
Swiff-Elis Method.—The patient receives the ordinary dose of arsenphenamin or neo-arsphenamin intravenously. Half an hour to an hour later, 40 c.c. of blood are withdrawn from a vein. The blood is permitted to clot and left on ice for 24 hours. Twelve to 15 c.c. of serum are then pipetted off, and centrifuged. It contains about 0.01 mg. of arsenphenamin per c.c. It is heated to 60°C. for half an hour, either undiluted, or after the addition of enough normal saline to make 30 c.c. and the total quantity is injected through lumbar puncture, after withdrawing an equal volume of cerebrospinal fluid.

The injections are safe, and may be repeated as often as needed (Draper, 1925), at intervals of 2 weeks. Exceptionally, severe pain may prevent their employment.

Spinal Injection of Arsenphenamin Dissolved Directly in Serum.—This was advocated by Marini and Minea, 1914; using not over 0.5 mg. of the drug. It is safer than the watery solutions, but not as safe as the Swift-Elis method, in which the arsenphenamin has been changed into a less diffusible colloidal form (Young, 1912). It would be unsafe to give more than two or three consecutive injections (Draper).

Spinal Injection of Watery Arsenphenamin Solution.—This causes severe irritation of the cord, and some writers advise that it should not be attempted in man (Elliis and Swift, 1913; Marini and Minea, 1913; Swift, 1916). Others consider it fairly safe when a careful technic is followed; either using a hypertonic (6 per cent.) solution (Reavut, 1914; Wile, 1914); or mixing the drug with cerebro-spinal fluid so as to give a concentration of 0.05 to 0.15 per cent., and a dosage of 15 to 12 mg. Neoarsphenamin is almost always preferred. The injections are generally repeated every week to three weeks, and combined with systemic administration (bibliography, Naudé, 1915).

Gennerich, 1913, dissolves 0.15 Gm. of neoarsphenamin in 300 c.c. of normal saline. He withdraws 60 c.c. of cerebro-spinal fluid, mixes this with 60 c.c. of the above solution, and reinjects it.

Schubert, 1914, withdraws 20 c.c. of cerebro-spinal fluid. In 1 c.c. of this he dissolves 0.045 Gm. of dry arsenphenamin. A reservoir is connected with the spinal puncture, and lowered so as to fill with at least 20 c.c. of spinal fluid. Into this he drops 1 to 2 c.c. of the arsenphenamin solution, and then raises the reservoir so as to make the fluid flow slowly through the canal. He cautions that everything must be absolutely dry.

Oral Administration.—This has been tried in man (0.6 Gm.) and in animals, but the therapeutic effects are very feeble (Schambur et al., 1916). Vomiting and diarrhea may result, but no serious intoxication (Kohler and Schambur, 1912).

Rectal Administration.—This has been recommended (J.M. Joseph, 1918); especially for children (Araujo, 1948). It is, however, too unreliable.

Gangrenous Balanitis and Vincent’s Angina.—The intravenous injections or local dusting with arsenphenamin or neoarsphenamin powder often arrests the progress of the ulceration and is followed by prompt healing (H. N. Cole).

Use against Cutaneous Tuberculids.—Arsphenamin, intravenously has been credited with good results. It is not advised in acute, febrile or progressive cases (Sker, 1919).

PREPARATIONS—ARSSENPHENAMINS

*Arsphenaminæ Hydrochloridum, N.N.R.—(Arsphenamin).—Diamino-dihydroxy-arsenobenzene hydrochlorid, marketed under various tradenames; for instance, Salvaran, arsaminol, arsenosanol, diarsenol, 500, etc. A yellow, crystalline powder, very unstable in the air. Soluble in water with acid reaction. Marketed in sealed tubes containing the ordinary doses.

*Neoarsphenamin, N.N.R.—A mixture of sodium arsenphenamin methanal sulphate, with inert inorganic salts, having an arsenic content of approximately 1/2 of that of arsenphenamin. It has similar physical properties, but forms neutral solutions with water. On standing, the aqueous solution decomposes rapidly, turning dark brown and depositing a brown precipitate. The commercial brands usually bear the name of the corresponding arsenphenamin, with the prefix “neo.”

Silver Arsenphenamin. (N.N.R.).—Sodium arsenphenamin in which silver has been substituted. It contains about 20 per cent. of arsenic and 15 per cent. of silver. In field of usefulness is the same as for the other arsenphenamins; but it is effective in smaller doses, and is therefore claimed to be safer. However, this remains to be demonstrated. At present, it is used with greater circumspection, and is not advised in the presence of non-syphilitic diseases. It has been claimed that it renders the use of mercury super-
ARSFENAMIN GROUP

fluorous; but this is not established. It is conceivable that it might sometimes produce argyrism.

Administration.—It is administered intravenously, the starting dose for adults, is 0.1 Gm., repeating at intervals of not less than 4 days, with the gradual increase to 0.2 Gm. for women, or 0.5 Gm. for men.

Phenylglycinamid-arsenic Acid.—This is being tried by the Rockefeller Institute.

\[
O = \text{As} / \text{OH} / \text{OH}
\]

\[
\text{NHCH}_{2}\text{CONH}_{4}
\]

Chemistry.—It has the structure

It is easily prepared and inexpensive. The sodium salt is extremely soluble in water (to 50 per cent.), forming neutral solutions on brief boiling (Jacobs and Heidelberger, 1919).

Toxicity.—It is practically non-irritant, even when concentrated solutions are injected. The toxicity is low, and sub-fatal doses do little permanent damage (Pearce and Brown, 1910).

Efficiency against Experimental Spirochete Infections.—Definite results have been obtained with the recurrens and pallida organisms. Relatively large doses are necessary to destroy the parasites directly; but much smaller doses (1% to 2% of the MFD) seem to weaken the parasites so that they are destroyed by the host, without, however, producing immunity. This leads to rapid healing and eventual cure (Pearce and Brown; Brown and Pearce, 1910).

Clinical Efficiency.—This remains to be determined.

TELLURIUM

General Statement.—Although tellurium and selenium are chemically related to sulphur, their pharmacologic properties are very similar to those of arsenic. They produce the same paralysis of the capillaries, also identical changes in the blood-forming organs. Tellurium is relatively non-toxic, being rapidly reduced to the metallic state. Its most conspicuous effects are suppression of sweat; and a very persistent garlic odor, especially of the breath, due to methyl telluride. These effects are noted in the industries dealing with tellurium. Sodium tellurate has been used to suppress the night-sweats of phthisis.

Compounds.—The more important are tellurous oxide, TeO; telluric oxide, TeO; Sodium tellurite Na2TeO3 and sodium tellurate, Na2TeO4; hydrogen tellurite H2Te; tellurous acid (H2TeO3) and tellurium tetratrate, TeO42-. Solubility.—The sodium salts are soluble in water; but the tellurite would be transformed into insoluble tellurous oxide by the acidity of the gastric juice. The alkalinity of the intestine, however, would restore the tellurite. Tellurous oxide itself would therefore be dissolved in the intestines.

Absorption.—This is very incomplete from the alimentary tract, since all the compounds are rapidly reduced to metallic tellurium, which is eliminated by the feces, imparting a blue or gray color to these. A small proportion, however, is easily absorbed; apparently even from the intact skin; for even a trace adhering to the skin leaves a garlic odor to the breath.

Reduction in Body.—All living cells rapidly reduce all tellurium compounds to the metallic state, recognized by the greenish, blue green, blue, or dark grey-blue color, according to the quantity (Kankel). After intravenous injection, this is found in all organs, particularly abundant in the liver and kidney, while the lungs, spleen and renal are relatively free. Hofmeister, 1894 points out that the distribution of this reduction is quite different from that of dyes. The reduced metal is in an ultra-microscopic state. Beyer claimed that it is in the cell-nuclei. The deposition of the reduced metal throughout the body occurs also with oral administration. It remains in the cells for a long time, but part is continuously transmelled into methyl telluride. This explains the persistence of the odor.

Reduction by Micro-organisms.—Gonis, 1902, showed that living bacteria and other micro-organisms reduce tellurite (also selenium). As dead organisms do not effect
this reduction, potassium tellurite may be used as an indicator of living bacteria, yeasts, molds, etc. When incubated for 24 hours with a concentration of about 17,000,000 living cultures of all the more common microorganisms reduce the tellurite, as indicated by the appearance of a black precipitate. This concentration is practically harmless when injected into animals (W. E. King and Davis, 1914).

**Excretion.**—With oral administration, the major part is reduced to the metallic state, and is excreted as such unabsorbed by the feces. That which is absorbed is excreted partly as methyl telluride by the breath, urine and feces; and partly as a soluble form in the urine and bile (Mead and Gies, 1901).

**Methyl Telluride.**—A very pronounced odor of garlic, due to methyl telluride (CH₃Te⁻), appears in the breath within 5 minutes after administration, by any channel and in all animals. It persists for several days up to 8 months after a single dose, according to the quantity taken. In man, it has been noted after as little as 0.005 mg. (Keisner). The odor was described by Gmelin, 1824, and by Hansen, 1853, who made the first pharmacologic investigations of tellurium.

The odor is also present, though less marked, in the urine, feces, epidermal excretions, blood and viscera.

Hofmeister found that this interesting methyl telluride is produced by all tissues, though to a varying degree; also when tellurite is digested with finely powdered organ in size; but that it is prevented by any agents that tend to disorganize protoplasm; even by water or normal saline. On the other hand, saponin has little effect, and quinin restrains only in fairly high concentrations. There is no parallelism between the formation of methyl telluride and the reduction to metallic tellurium.

Methyl telluride is also produced by cold blooded animals, and invertebrates (earthworms), not by the higher plants (Knop, Bokorny; quoted from Gies and Mead).

**"Bismuth Breath."**—This has been attributed to contamination of bismuth preparations with tellurium; the two substances often occurring in association.

**Toxicity.**—This is quite low for oral administration; higher for hypodermic injection. The tellurite is perhaps 10 times more toxic than the tellurate. Commercial tellurate, however, often contains tellurite. Colloidal tellurium is also much less toxic. Möttö, in 1914, has inclosed for 24 hours with a concentration of about 17,000,000 living cultures of all the more common microorganisms reduce the tellurite, as indicated by the appearance of a black precipitate. This concentration is practically harmless when injected into animals (W. E. King and Davis, 1914).

**Oral Administration.**—Telluric acid, 0.5 gm. has no apparent effect (1,2); 10 mg. to 1 gm. is fatal. (2)

**Hypodermic Administration.**—Rabbits Na₂TeO₃; 2 mg. per kg., M. F. D. (2). With coccidiosis, 5 mg. per kg. M. F. D. (3). Guinea pigs 2 mg. per kg. survived (3); 5 mg. per kg. M. F. D. (3). Mice, 1 mg. per 40 gm., paralyzed within 24 hours (3). Fogs, 2 mg., fatal in 24 hours (2); 4 mg., fatal in 8 hours (4).

**Metallic Tellurium.**—Hofmeister showed that this is gradually converted into the active form in the tissues; for the garlic odor occurred after intravenous injection of the finely powdered metal.

**Colloidal Tellurium.**—This was investigated by de Angelis. He found it much more toxic than the tellurate. Indeed, the effects were not proportional to the dose. He attributed this to limited power of the organism to transform it into hydrogen telluride, which he assumed to be the really active agent.

**Industrial Uses.**—These are not extensive. It is employed in the glass industry, in impart a blue, red or brown color to glass. It is being tried in steel-making as a reducing agent in place of coke (Shie, 1920).

**Industrial Exposure.**—Tellurium occurs as an impurity of lead and copper ores and is encountered industrially in the purification of these metals, especially in the electrolytic refining of lead. Here it occurs in the fumes as hydrogen telluride, and in dust as tellurous oxide and tellurites (Shie, 1920).
**Tonic Effect on Frogs.**—Capek and Weil interpret these mainly as paralysis of the central nervous system. Skeletal muscle shows fibrillary twitching, even at a distance from the site of injection. The heart becomes paralyzed late in the poisoning.

**General Symptoms in Mammals.**—The essential features were described by the earliest investigators, Gmelin, 1824 and Hansen, 1825. Capek and Weil, 1825, made a comprehensive study and point out the close resemblance to selenium and arsenic; the effect is due to the tellurium, however, being slower and less virulent. They start with somnolence; restlessness, tremors, vomiting and diarrhoea; asphyxial convulsions and death.

The muscles and nerves remain irritable to the end.

**Industrial Symptoms.**—Shi, 1920, examined 12 lead workers exposed to tellurium. Eight of these showed effects that might be attributable to tellurium, especially the garlic odor, dry mouth and dry skin. These were of about the same frequency and degree with those who had been exposed only 2 weeks, as with those who had worked for a year.

The frequency of the symptoms among these 8 affected workers was as follows: 7 showed garlic odor, metallic taste, dry mouth; 6 showed dry, itching skin and rashes; 5 showed suppression of sweat; 4 showed constipation; 3 showed poor appetite, nausea, vomiting, somnolence; 1 showed loss of hair. None showed albuminuria, or malnutrition.

**Effects on Digestive Tract.**—Capek and Weil found that dogs and cats respond to large doses by vomiting and diarrhea, the stools becoming of a rice-water and finally mucous character. The necropsy shows the mucosa of the duodenum and jejunum congested, swollen, with small hemorrhages, covered with a pseudo-membrane; the epithelium is desquamated. The ileum and colon are usually quite normal. Rabbits generally die without gastrointestinal symptoms. Sub-ectic doses do not interfere with digestion. Even fairly high concentrations do not affect gastric and pancreatic digestion.

**Auto-lysis.**—Passion found that salts of Te and Se activate ordinary autolysis, whilst they inhibit the autolysis of mouse-sarcoma. However, the results were too confusing for application.

**Circulation.**—Capek and Weil found the characteristic arsenic effects: Profound fall of blood pressure and dilatation of splanchic vessels with good response of the heart and vasomotor system. They, therefore, adopt the same explanation, i.e., paralysis of the capillaries.

**Secretions.**—In man, tellurium diminishes or suppresses perspiration. The statements as to saliva are contradictory. Only very little work has been done on animals; none on the saliva or mucus; very little on other parasympathetic innervation.

**Saliva.**—The workers of Shi's series complained of dry mouth. Hansen recorded abundant salivation.

**Mucous.**—Mead and Gies record this as markedly increased in the stomach and intestines. The response to nerve stimulation has not been investigated.

**Gastric Juice.**—Mead and Gies found the quantity and acidity markedly diminished in dogs, even by small doses. The vomitus was never acid. They suggest that this may be concerned in the indigestion; but evidently the odor itself is nauseating to dogs, for an unpoisoned dog vomited when brought near another tellurium dog.

**Bile.**—Frequently regurgitated into the stomach.

**Cardiac Vagus.**—Capek and Weil state that this responds late in the poisoning.

**Sweat.**—Neuner, 1850, apparently first observed that sodium tellurite; 20 to 60 mg. per day, suppresses the night sweats of phthisis patients. The observations were confirmed by others, and this application endorsed especially by Comenballe, 1891.

**These doses produced no notable bad effect, except slight dyspepsia, and the marked garlic odor. The latter was probably mainly responsible for the abandonment of the tellurium, for but little has been written about them since that time.
Dryness of the skin, and skin eruptions attributed thereto were noted by Shie amongst industrial workers. He points out how this may disperse toward heat-exhaustion, although he has not observed any cases.

Mechanism of Sweat-paralysis.—This was apparently demonstrated experimentally by Czapek and Weil (p. 453), but it would be desirable to repeat their experiments. They found that in kittens, subcutaneous doses suppressed spontaneous sweating of the paws and weakened or abolished response to sciotic stimulation. Filocarpin provoked a feeble secretion. The gland cells did not show anatomic changes. From this, they conclude that tellurium paralyzes the nerve endings, analogous to atropin. They further claimed that arsenic had a similar effect, selenium not.

This line of evidence is not conclusive. The failure of the sweat-formation might have been due to a shock-level of blood pressure, which was not measured.

Blood-picture.—This corresponds with that of arsenic. It was studied especially by Czapek and Weil (p. 454). It would be desirable to repeat their experiments. Moderate doses (340 mg. per kg. on alternate days) produce leucopenia. With rapidly fatal doses, the white increase; the red decrease, their resistance is lowered, and some hemolysis occurs spontaneously, for instance, in rabbits or guinea pigs by 1/4 to 1 mg. of sodium tellurite (De Angelis).

Hemolysis.—Luzzato found that sodium tellurite is hemolytic also in vitro. It is believed that the action is not due to the tellurite as such, nor to the metallic tellurium to which it is reduced, but to an intermediate product, perhaps H2Te. In confirmation, Brunti found that colloidal Te is not hemolytic in vitro.

Blood Forming Organs.—The changes in these are strictly analogous to arsenic. Martelli studied especially the bone-marrow in rabbits and guinea pigs. With small doses, there is hyperplasia. Moderate doses cause leucopenia and hypoplasia. The animals tend to put on fat and increase in weight.

With fatal doses, the bone-marrow appears red, with hyperplasia of the white and red cells. If the animal survives, the picture is as for moderate doses.

Metabolism.—Mead and Gies fed sub-toxic doses of various Te compounds to dogs, for one week, without notable effects. The urine became dark-colored from the reduced tellurium.

Glycosuria.—Brutti, 1910, found that 50 to 200 mg. of sodium tellurite per kg. of rat or guinea pig produced in about half of the animals glycosuria (10 to 15 per cent. of sugar); with decrease of blood sugar. Mead and Gies did not find any glycosuria after toxic oral doses.

Urine.—Intravenous injection of 25 to 50 mg. of colloidal tellurium into rabbits produced marked increase of uric acid in the blood and urine, which de Angelis attributed to the hemolysis.

Kidneys.—Czapek and Weil often observed casts, leukocytes and sometimes red cells in the urine. Mead and Gies also record albumen after hypodermic or toxic oral doses. De Angelis, on the other hand, claims absence of albumen, unless the urine contained hemoglobin.

SELENIUM

General Statement.—The actions of selenium are identical with those of tellurium and arsenic, but it is much more toxic than tellurium. It obtained some notoriety as a possible specific treatment for tumors. This has proven a disappointment.

General Actions.—These were studied by Czapek and Weil, 1893. They attributed its higher toxicity to slower reduction.

Lower Organisms.—Czapek and Weil found sodium selenite practically non-toxic for protozoa or ciliated cells. It checked alcoholic and bacterial fermentations, being reduced to the red metallic tellurium.

A more recent investigation of selenium was made by Woodruff and Gies, 1919.

Methyl Compound.—This is formed in much smaller quantity than with Tellurium. Fatal Dose.—Sodium selenite or selenate, oral, hypodermic or rectal, 4 mg. per Kg. of animal, is fatal in a few minutes. The powdered metal is much less toxic than the mouth. Even 4 gm. per dog are non-toxic, being mainly excreted by the feces.

Distribution and Excretion.—These are practically identical with tellurium.

Normal Occurrence of Selenium in Tissues.—This was affirmed by Gassmann, 1906, especially for teeth and bones. However, Britsch, 1918, by improved methods, found none in animal or vegetable tissues.
SELENIUM

887

VANADIUM

The pharmacology of this metal has been studied by Jackson, 1912. According to Luzzatto (1903) poisonous doses of VCl or VB3 cause the usual anatomic lesions of metals in the kidneys, liver, intestine, and stomach. No lesions are found in the central nervous system. The blood pressure is raised, and the excitability of the vagus is depressed. Death occurs through respiratory paralysis.

Circulatory Effects.—Jackson found, with intravenous sodium orthovanadate, that the rise of blood pressure is due to systemic vasoconstriction, by direct action on the arterial muscle or vasomotor endings. The heart is not strengthened. The pressure in the pulmonary artery also rises by the systemic and pulmonary vasoconstriction. Perfused lung vessels are strongly constricted (Bachr and Pick, 1913). Branchial muscle also shows moderate but prolonged constriction (confirmed by Bachr and Pick, 1913).

Chronic Vanadium Poisoning.—This occurs especially through its industrial use as a mordant, and by the wearing of dyed fabrics. The symptoms and lesions are those common to other chronic metallic intoxications. The lungs, kidneys and digestive canal are especially affected (Dutton, 1917).

Therapeutic Use.—The pharmacologic actions do not point to any definite therapeutic usefulness. Vanadium has been recommended as an alternative, similar to arsenic, in tuberculosis, diabetes, etc., but the evidence is not convincing.

PREPARATION

Sodi Metisvanadatis.—White, almost tasteless powder, sol. in water. Dose, 1 to 8 mg. (% to ½ gr.). According to Jardin (1903) it lessens assimilation and increases protein destruction.

TUNGSTEN

A brief discussion of its toxicity is given by Faintus, 1917. Very little is known about the subject.

ANTIMONY

Actions.—The actions of antimony resemble those of arsenic. The difference lies in a greater local irritation and a much less absorption. Consequently, when given by the mouth, doses can be chosen whose only action is that of producing nausea, or if somewhat larger, vomiting.

Toxicology.—If injected into the circulation, or if given in overdoses, it produces precisely the same effects as arsenic, but vomiting is always a prominent phenomenon, the poison being rapidly excreted into the alimentary canal. Small doses long continued lead to a train of symptoms of subacute poisoning, entirely analogous to those produced by arsenic in the same manner (Gaethgens, 1876; Solowjetschyk, 1880), also including the metabolic changes. Antimony has not been recorded as giving rise to industrial poisoning, except through contamination with arsenic. However, the pentasulphids that are used in the rubber industries are fairly soluble in human gastric juice (Carlson, 1915). Antimony is sometimes used in the glaze of cheap granite ware. This should be prohibited by law (as it is in some European countries), since some samples yield from 3 to 14 mg. of dissolved antimony in a single cooking test (E. W. Miller, 1915).

In distinction to arsenic, selenium and tellurium, antimony is not converted into volatile compounds by molds (Knafl-Lenz, 1915).

Treatment of Antimony Poisoning.—The chemic antidotes are eggs, milk and tannin (tea, etc.), or in its absence magnesia.

Potassium hexatantallate precipitates antimony compounds, even in the tissues; but it could be utilized only orally, since its hypodermic injection is too toxic (Rosenthal and Severin, 1912).
Habituation.—One difference from arsenic is that the continued administration of antimony to mammals does not lead to tolerance; nor does arsenic habituation confer tolerance to antimony. This difference is explained by the observation that the absorption of antimony is not diminished (Cleoet, 1912); on the contrary, it is rather increased (Brunner, 1912); he claims some tolerance for 3-valent but, not for 5-valent. Protozoa also do not become immune as readily as with arsenic (Rowntree and Abel, 1912). Antimony immunity can be induced in inusoria and does not extend to arsenic (Neunhaus, 1910). Bacteria immunized to arsenic are also resistant to antimony (Marks, 1910).

Local Action.—Applied to the skin, the chloride is a strong caustic. The double tartrate of antimony and potash (tartar emetic) when applied over long periods, produces a purpuric eruption. This is due to the decomposition of the double salt, which is but slightly irritant, by the acid, secretion of the follicles into more irritant antimonial oxide, Sb₂O₃, and other compounds. Such salves were formerly used for counterirritation, but have been abandoned as too destructive and toxic.

Differences in Antimony Compounds.—As with arsenic, the 3-valent is more toxic (to ten times) than the 5-valent. The organic derivatives show similar relations, the side-chains being relatively unimportant (Brunner, 1912). Cleoet found the pyrrolidine much less toxic than tartar emetic.

Mechanism of Emetic Effect.—This is produced by local action; for while it occurs both by gastric and venous administration, the latter requires much larger doses, vomiting occurs much more slowly, and only after the antimony has been excreted into the stomach, as shown by its presence in the vomitus (Kliemann and Simonovitsch, 1875). The nauseant action, and the increase of the salivary and bronchial secretions, are also reflex (V. E. Henderson and Taylor, 1910). Like other irritants, antimony is said to increase uric acid excretion (Abi, 1913).

Therapeutic Use as Nauseant and Emetic.—"Tartar Emetic," the tartrate of antimony and potassium, is the compound usually employed internally as a nauseant. It has fallen out of favor, its action being too slow and too depressing. As a nauseant it has advantages over all other metals, since the dose required for this is only about one-tenth of that which produces vomiting. Its continued use, however, is dangerous. It is employed mainly as a depressant expectorant in the first stages of acute bronchitis; often in the form of Wine of Antimony, 1 c.c. = 4 mg., ½ gr.; or smaller doses (1 mg.) may be repeated every hour with precaution against excessive depression. It also enters into a number of compound expectorants, such as Mistura Glycyrrhizae Co. (8 c.c. = 2 mg. of tartar emetic and 1 c.c. of paregoric); and Compound Syrup of Squill (2 c.c. = 4 mg. of tartar emetic).

Antimony has an interesting history. Paracelsus in the sixteenth century praised it as a panacea, and it was used against the plague, etc., perhaps a forecast of its most recent use in chemotherapy. However, numerous deaths caused its formal proscription.

Trypanocidal Action.—Antimony and bismuth, as well as arsenic, are highly toxic to trypanosomes, although not to all protozoa.

As with arsenic, the trivalent form of antimony, in inorganic or organic combination, is much more toxic to protozoa, bacteria and yeast, than is the pentavalent form (Friedberger and Joachimgu, 1917).

At the suggestion of Cushing, various investigators (Pflimmer and Thomson, 1907; Mennil and Brimont, 1908, Thomson and Cushing, 1910, Camac, 1911, and others) have successfully used injections of antimony-sodium tartrate in experimental and human trypanosome infections. The intravenous dose for man is 10 mg. in saline. Rowntree and Abel, 1910, advocate certain organic compounds, such as sodium-antimony thio-lycollate. They have the advantages over the organic arsenicals in that the parasites do not become immune as readily. They are also cheaper. The trypanocidal activity of tartar emetic is greater in the presence of serum; this does not hold for arsenic (Shilling and Coretti, 1914).

Jemna, 1910, states that tartar emetic is specific in the Leishmaniosis of children.

Malaria.—Tartar emetic has proven inefficient even in large intravenous doses (Law and Newham, 1917; E. W. W. Stephens et al., 1927).
ANTIMONY

PREPARATIONS—ANTIMONY

*Antimonii et Potassii Tartarum (Antim. et Pot. Tart.), U.S.P.; Antimonium Tartaricum (Antim. Tart.), B.P.; Tartarated Antimony (Tartar Emetic), 2 K (SO4)2H3O2 + H2O.—Colorless, transparent crystals or white granular powder. Sweet, then metallic taste. Efflorescent. Slightly acid to litmus. Incompatible with alkalies and tartaric acid. Sol. in water (1:20) or glyc. (1:15). Insol. in alc. Dilute, expectorant, 5 mg., 1/4 gr., U.S.P.; 2.5 to 8 mg., 1/8 to 1/4 gr., B.P.; emetic, 30 to 60 mg., 1/4 to 1 gr., B.P.

*Vinum Antimonii (Vin. Antim.), B.P.—Contains 0.4 per cent of Tartarated Antimony. Dilute, expectorant, 0.6 to 1.8 c.c., 10 to 50 minims; emetic, 8 to 16 c.c., 2 to 4 drams, B.P.

Antim. Oxid., B.P., Antimonious Oxid, Sb2O5.—Grayish powder, insol. in water. Dilute, 0.05 to 1.2 Grm., 1 to 2 gr., B.P.

Potis. Antim., B.P.—Antimonious oxide, 1 part; calcium phosphate, 2 parts. Dilute, 0.2 to 0.4 Grm., 1 to 6 gr., B.P.

Antim. Sulphur., B.P.; Sulphated Antimony.—A mixture of antimony sulphides and oxides and sulphur. Orange-red powder. Dilute, 0.06 to 0.12 Grm., 1 to 2 gr., B.P.

URANIUM

The salts are very corrosive, consequently readily absorbed, and highly toxic. Their systemic actions are similar to those of other metals, with a special paralytic effect on respiration; this resembles cyanide poisoning superficially. They produce a characteristic nephritis; glycosuria; and a unique edema.

Systemic Actions.—These have been studied especially by Woronchikovsky, 1890, and D. E. Jackson, 1910. In acute poisoning, the respiration is peculiarly affected, first increased, then paralyzed. This results in the usual asphyxial phenomena, stimulation of the vasomotor center and rise of blood pressure. The respiratory paralysis is the cause of death. The blood is rendered non-coagulable by an unknown mechanism. The kidneys are involved in a few days by albuminuria and glycosuria; parenchymatous degenerations, gastrointestinal disturbances; paralytic symptoms; and changes in the blood vessels.

Excretion of Uranium.—This occurs mainly by the kidneys, which may be a factor in the nephritis (Karsner, Reimann and Brooks, 1918).

Anatomic Changes in Uranium Nephritis.—These affect both the tubular epithelium and the glomeruli, one or the other predominating according to conditions (Fleckseder, 1907; Hesseke and Myerstein, 1907; Dickson, 1909). The vascular mechanism is involved first, but the tubular changes progress longer and finally predominate (MacNider, 1912). The anatomic and functional changes are more severe in old animals, and are increased by anesthetics, especially chloroform (MacNider, 1913, 1914). Dogs are more resistant than rabbits (O'Hare, 1912). The epithelium shows fatty changes; the glomeruli are congested; or the glomeruli shrink, with enlargement of the glomerular space (Tribe et al., 1918).

Christian, 1911, describes characteristic hyaline droplets in the vessel-walls of the glomerular tufts. These do not occur in other vessels of the kidneys or in other organs. (The histology of uranium nephritis is also described by J. Oliver, 1916; and by Tribe et al., 1916.)

Repeated injections of small doses produce a chronic interstitial nephritis with fibrous changes. (These are not as severe as with chromates; arsenic did not produce interstitial changes; R. M. Smith, 1911.) The histologic lesions are similar to human chronic diffuse nephritis, but not quite identical. They are not associated with arterial lesions (Dickson, 1912).

Urinal Changes.—In the early (vascular) stages, the quantity and specific gravity of the urine are increased. Albumen, glucose, and acetone substances appear, especially in older dogs (MacNider, 1914). A further increase of urine flow may be secured by caffine or salines, although the response is slower than normal (Toshorn and Guren, 1910; Boycott and Koffel, 1913; Mosenthal and Schayer, 1913). With the appearance of the epithelial changes, the urine decreases, the tubules being obstructed by the swelling and desquamation of the cells. This is not relieved by diuretics, although the vascular response to the diuretics may be preserved (MacNider, 1912, 1914, 1915). The
excretion of chlorides and urates is diminished in acute, somewhat increased in the subacute nephritis; i.e., it varies in the same direction as the urine flow.

Pohl described a subacute nephritis in rabbits, with polyuria until death, and with increased excretion of nitrogen and diminished chlorid excretion, for up to 14 days. This is inconstant. The intravenous injection of calcium or of hypotonic NaCl converted this subacute nephritis into an acute form. Isotonic saline had no effect.

The excretion of creatinin in the urine is diminished in both stages; but injected creatinin is completely excreted in the subacute, retained in the acute (Kraus, 1918). The phenol-p-phenylalein excretion also varies in the same direction as the urine flow (Eisenbrey, 1953). It bears no definite relation to the histologic lesions (Smith, 1911).

The most marked effect of uranium nephritis is a depression of the factor: urine-urea divided by plasma-urea. This is fairly parallel to the anatomic injury (Watanabe et al., 1917).

The non-protein nitrogen retention in the blood goes parallel to the phthalein retention; both increase and recover together, except that the phthalein responds more promptly (Frothingham, Fitz, Polin and Denis, 1913; Kasner and Denis, 1914). However, Moensthal, 1914, points out that the increase of non-protein nitrogen in the blood is not necessarily proof of retention, but could be explained by increased protein destruction or by insipidness of the blood through polyuria.

Acidosis.—MacNider, 1916, finds the toxicity of uranium associated with acidosis, sodium carbonate having a distinct saving effect. It also protects the uranium kidneys against anesthetics, so that these produce much less epithelial degeneration.

These findings are confirmed by Goto, 1917.

Kasner, Reimann and Brooks, 1918, also constate that uranium poisoning is almost always accompanied by acidosis and that this is more severe in older animals. The albuminuria always precedes the acidosis; so that the acidosis is not the cause of the nephritis.

Hepatic Degeneration.—This has been studied on dogs by MacNider, 1919. It is similar to that seen after mercury, and is parallel to the acidosis, rather than to the dose.

Uranium Glycosuria.—This develops on the first or second day. The action consists in causing the kidneys to give sugar, for it may occur without hyperglycemia (Franck, 1912), and may even relieve hyperglycemia when this is due to decreased permeability of the kidney cells (Pollak, 1911). The sugar does not bear any definite relation to the other urinary constituents, except albumin, which goes fairly parallel (Wallace and Myers, 1914). However, uranium may itself cause hyperglycemia, even when the kidneys are excised, so that part of its action must be extrarenal (Flecker, 1906).

Nephritic Glycosuria.—Glycosuria without hyperglycemia occurs with many nephritic poisons. With cantharides, it is attributed to increased permeability of the vessels; with uranium, chromium, tellurium, mercury and aloes, to lesions of the tubular epithelium (Luzzato, 1914).

Uranium Hydros.—The hypodermic administration of uranium salts produces gaseous anuria and anuresis (Leconte, 1854; Richter, 1904), a highly albuminous fluid transuding mainly into the serous cavities, but also into the other tissues, and extending even to the fetus in utero (Billergell, 1905).

It seemed natural to explain this by nephritis and anuria, but this explanation does not correspond to the facts. Nephrectomy alone does not produce hydros, so that the anuria does not furnish the explanation. On the other hand, the uranium-hydros occurs in nephrectomized animals, so that the kidneys are not concerned in its production (Flecker, 1904). The injection of the blood of uranium animals into chromate animals also produces edema (Heinecke, 1905; Bianch, 1908). Edema, however, occurs only in animals which are freely supplied with water; otherwise the uranium causes anuria without hydros (Flecker, 1904). Recovery of salts is not connected with its production (Richter, 1905). In acute uranium poisoning, the lymph flow is not increased (Jackson, 1910).

Uranium poisoning interferes with the restoration of the blood-volume after saline infusion (Bogert, Underhill and Mendel, 1916).

Oral intoxication by insoluble uranium compounds.—Although uranium oxyd and uranyl nitrate are nearly insoluble in water, they are highly toxic when given by mouth (to guinea pigs), since they are fairly soluble in dilute hydrochloric acid (Kasner et al., 1918).
Therapeutic Uses.—The soluble uranium nitrate has been used in diabetes mellitus and in phthisis in doses of 75 mg. (1 gr.); largely diluted. The results are too indefinite to justify the further employment of so dangerous an agent.

PREPARATION—URANIUM

Uranii Nitras (Uran. Nitr.), U.S.P., UO₄(NO₃)₂, + 6H₂O.—Light yellow prisms; bitter, astringent taste. Freely sol. in water (1:2:2) or in alc. Dose, 0.01 Gm., 3⁄4 gr., U.S.P.; diluted. Use with caution.

BISMUTH

The insoluble basic bismuth salts are used on inflamed surfaces. They act largely mechanically, as protective and drying dusting powders. The use of soluble bismuth preparations is therefore irrational. The insoluble bismuth compounds are also employed in X-ray diagnosis. Even large doses are ordinarily harmless, but may become poisonous under special conditions. The medicinal use of bismuth is said to date from Dr. Odier of Geneva, 1785.

Local Actions of Insoluble Basic (oxy) Bismuth Salts.—These form fine adhesive powders. The subcarbonate, subsalicylate and magna are insoluble in water. The subnitrate and subgallate are somewhat hydrolyzed and therefore very slightly soluble (Bonček, 1910; Stingel, 1911). Their solubility in the body-fluids is only very slight.

They have a marked healing effect when dusted on wounds and on inflamed mucous surfaces. Applied to wounds, they dry the secretions and form a protective covering, so that the wound heals as under an asceptic scab. This action is partly mechanical, due to the stoppage of the lymph and blood capillaries by the fine particles of the powder (H. H. Meyer, 1885). Other indifferent substances in an equally fine state of subdivision have a similar action. However, a small amount of bismuth undoubtedly goes into solution, and aids by exerting an astringent and mild antiseptic action; indeed, the basic bismuth salts are among the most effective of the non-irritant intestinal antiseptics (Solmann, 1906).

In the alimentary canal, the basic bismuth salts act not only in the manner indicated, but also by precipitating hydrogen sulphid (Stingel, 1911). Bismuth stools are therefore black. The subcarbonate (not the subnitrate) is a slowly acting antacid (J.A.M.A., 60:1175).

Therapeutic Use in Digestive Disorders.—The combination of these actions render the subnitrate or subcarbonate (0.5 to 2 Gm., 8 to 30 gr., every two to four hours) very useful for allaying diarrhea (X-ray observations, Hess, 1913) and gastritis, and sometimes against vomiting. They may be combined with other intestinal antiseptics, such as salol. The bismuth powders are similarly useful in gastric ulcers (1 to 2 Gm. suspended in fluid, before each meal). They lessen gastric secretion and acidity (Bastedo). In normal individuals, bismuth is not constipating, even with the large doses used in X-ray work (Cannon, 1911). This indicates that the effects are on the inflammation, and not on the peristalsis.

Hulse, 1910, claimed that “bismuth-milk” (a suspension of the hydroxid) does not check diarrhea, the stools remaining light-colored. However, Stingel found that these preparations also bind sulphids.

Like other intestinal sedatives, bismuth subnitrate is said to diminish uric acid excretion (Abl. 1913).

Use in X-ray Diagnosis.—The opacity of the bismuth salts to X-rays makes them very suitable for outlining the shape and movements of the alimentary canal. About
30 Gm. (2 ounces) of the subcarbonate (not the subnitrate) are administered, suspended in buttermilk, thick soup, etc. Heat and Colnhelm, 1917, believe that the bismuth meal delays the emptying of the stomach by an hour. The use of other substances for radiographic purposes is discussed in Merck's Report, 27:45, 1914.

Other Uses.—Bismuth is used as dusting powder or ointment (30 per cent.) on ulcers and other open surfaces and mucous membranes. Suspensions containing 10 per cent. of bismuth subnitrate may be injected in sredhritis. Bismuth poisoning may arise if it is applied too extensively, or if it is confined, as in the injection of bismuth paste into sinuses.

Bismuth Paste.—E. Beck introduced a paste of 1 part of bismuth subnitrate and 2 parts of petrolatum, in chronic suppurative abscesses and sinuses, often with curative results. The injections are made at first every three or four days, then not oftener than once a week. Acute abscesses do not respond. Stomatitis has followed its use after three weeks; on its occurrence the remaining paste should be washed away with warm oil. Jensen, 1919, also reports nitrite poisoning from fistule infected with B. coli.

The technic and precautions for the use of bismuth paste are described by E. G. Beck, 1916.

Differences Between Bismuth Salts.—The subnitrate and subcarbonate, the oldest of the insoluble bismuth compounds, answer every purpose.

Various organic salts have been introduced as substitutes, such as the subgalate (Dermatol), especially for dusting powders; but it is difficult to see how they can be superior to the much more economical older products. In other substitutes, antiseptic aromatic radicals have been introduced, but the same or better results can be secured by mixing the ordinary bismuth salts with other insoluble antiseptics, such as salol or betanaphthol; in fact, however, the bismuth alone is sufficiently antiseptic for all purposes for which it is used.

There is little difference between the actions of the subcarbonate and subnitrate; but on the whole, the subcarbonate deserves the preference, since it can not give rise to nitrites. The subnitrate has also been said to be irritant, since it consists of sharp-pointed microscopic crystals, whereas the subcarbonate is amorphous. This supposed irritant action is wholly imaginary, as can be shown by dusting the subnitrate on the conjunctiva.

The use of soluble bismuth salts is irrational, since they lack the soothing qualities which constitute the main value of the insoluble products. The double citrates are indeed partly precipitated in the acidity of the stomach; but the quantity of the precipitate is too small to be effective (Sollmann). Their introduction was due mainly to the extravagant desire for "elegant pharmacy" which was responsible for the oil-free colly or oil preparations.

Absorption and Excretion.—A small amount of the basic bismuth salts is dissolved by the acid gastric juice, is absorbed, and excreted by the urine (Dorner and Weingaertner, 1909), mouth and large intestines. The quantity is not sufficient to produce any systemic effects. The corrosive soluble salts are absorbed more extensively, and even the insoluble salt may be absorbed sufficiently from extensive burns to produce poisoning (T. Kocher, 1882). In human poisoning the bismuth was found mainly in the stomach and kidneys, and a little in the liver (Barthe, 1913).

Poisonous Effects of Bismuth Compounds.—Even very large doses of insoluble bismuth salts do not ordinarily produce any harmful effects when taken by mouth. Under other conditions, toxic symptoms may arise.

The phenomena may take several forms: nitrite effects from the reduction of bismuth subnitrate; capillary thrombosis from precipitation of bismuth sulphid in the intestinal vessels; chronic bismuth poisoning; and the acute effects of soluble corrosive bismuth salts.
Cabot, 1912, has collected thirty-three human cases, of which thirty-one were from bismuth introduced into sinuses or wound dressings in extensive burns. He also reviews the experimental work.

The literature of bismuth poisoning is also reviewed by W. H. Higgins, 1916; and J. Phillips, 1917.

Nitrite Poisoning.—The use of the relatively enormous doses of bismuth subnitrate for radiodiagnostic purposes has caused several intoxications, with methemoglobinemia, intense cyanosis, diarrhea, dyspnea and death by arrest of respiration. These effects are not due to the bismuth, but to the production of nitrite by the reducing action of putrefactive fecal bacteria, especially in the large intestines and rectum (Bennike and Hoffman, 1906; Boehrne, 1907; E. G. Beck, 1909; Zollinger, 1917; Zadek, 1914).

Precipitation of Bismuth Sulphid.—Bismuth forms a black and very insoluble sulphid. Since H2S is always present in the large intestine, the feces are always colored black. When the bismuth is in the blood, the precipitation may occur in the vessels of the large intestine, and lead to capillary embolism, and this is ulceration, with the clinical symptoms of vomiting, diarrhea, cramps, colic, and colitis—the latter very rarely as severe as with mercury. The autopsy in bismuth poisoning shows the staining of the cecum, adjoining colon and appendix; less in the descending colon; and none in the small intestines (Cabot, 1912).

Bismuth sulphid is also precipitated in the mouth, and forms a “lead-line” at the junction of the gums and teeth; then patchy discoloration of the adjacent mucosa and tongue, and general stomatitis. These are prominent symptoms in chronic bismuth poisoning (Warfield, 1912).

Direct Systemic Actions.—These can be elicited by intravenous injection of the non-precipitant salts. They may also occur from relatively small doses of the soluble bismuth salts when taken by mouth, since these are strongly corrosive. If a soluble bismuth salt is injected directly into the blood, it produces the arsenic phenomena on blood vessels. There is perhaps also a direct involvement of the central nervous system and depression of the vasomotor center. The heart muscle is also depressed. The blood pressure sinks therefore very rapidly (Meyer and Steinfield, 1883).

Chemical Bismuth Poisoning.—This is characterized by fever, headache, stomatitis, lead-line, gastro-intestinal irritation, colic, and albuminuria. It differs from lead poisoning by the absence of paralytic, circulatory, blood and respiratory changes. Fatal cases may show convulsions and lock-jaw (Zollinger, 1912).

If bismuth symptoms develop with Beck’s paste, this should be removed with warm olive oil, curdeting if necessary. Oxygen and saline may be administered for methemoglobinemia (Zollinger, 1912).

PREPARATIONS—BISMUTH

Bismuth Betanaphthol (Bism. Betanaph.). U.S.P. (Orphol).—A compound of bismuth and betanaphthol of somewhat varying composition, yielding not less than 73 per cent. of Bi2O3. Decomposed into its constituents in the intestine. A buff-colored to grayish-brown, amorphous powder; odorless, tasteless, nearly insol. in water and alc. Dose, 0.5 Gm., 8 gr., U.S.P.

Bism. et Ammon. Cit., U.S.P.—Of somewhat varying chemical composition; yields not less than 45 per cent. of Bi2O3. Very sol. in water and sparingly sol. in alc. Used for making bismuth solutions and elixirs. Dose, 0.125 Gm., 2 gr., U.S.P.

Liq. Bism. et Ammon. Cit., B.P. Dose, 2 to 4 c.c., ½ to 1 dram, B.P.

Magma Bismuthi (Magma Bism.), U.S.P. (Milk of Bismuth).—A thick, white, opaque liquid, containing bismuth hydroxide and bismuth subcarbonate in suspension in water. Prepared by precipitating a solution of Bismuth nitrate with Ammonia; corresponding to about 6 per cent. of Bi2O3. Dose, 4 c.c. (½ dram), U.S.P.

*Bismuth Subcarbonas (Bism. Subcarb.), U.S.P.; Bism. Carb., B.P. (Bismuth Oxy-carbonate).—Of varying chemical composition; yields not less than 90 per cent. of Bi2O3. White powder; odorless and tasteless. Insol. in water or alc. Incompatible with acids, sulphur, sulphides, and iodides. Dose, 0.5 Gm., 8 gr., U.S.P.; 0.3 to 1.2 Gm., 5 to 20 gr., B.P., in powders or suspension.

Trock. Bism. Co., B.P.—Each contains 0.15 Gm. of Bism. Subcarb., 0.15 of Magn. Carb., and 0.5 of Calc. Carb.
IRON

General Statement.—Iron occurs widely distributed in the body, in several more or less firm and non-ionizable combinations. It is found in all chromatin and therefore in all cells; in the hemoglobin of the blood; and in granular form as "reserve iron" in the blood-forming and destroying organs. It is also a necessary constituent of the oxidases.

Iron is therefore of great importance in metabolism. When administered to normal animals, it has no systemic action, but increases the "reserve iron." In most anemias, the administration of iron tends to restore the hemoglobin to the normal and therefore improves nutrition. The soluble ionizable salts exert local astringent effects.

Direct systemic actions may be secured by the intravenous or hypodermic injection of non-precipitating salts, or by the absorption of corrosive preparations. The effects resemble those of arsenic (H. Meyer and Williams, 1881; Jacob, 1887). Toxic effects occur with 60 mg. per kilogram, hypodermic or by vein; but not with therapeutic hypodermic doses (Lépine, 1897).

Astringent Action and Uses.—The soluble salts, especially the ferric, precipitate proteins readily and are therefore stptic, astringent, irritant and even corrosive. Their internal administration is apt to produce some gastric irritation and constipation. The tincture of ferric chloride is employed as an astringent, especially in gargles (1:10); this, and other iron salts, particularly the Liq. Ferris Sulph., are also used as local stpits.

In hemorrhage, the efficiency of coagulant astringents is low; even under favorable experimental conditions (Hanžlik, 1918).

The administration of iron does not cause renal irritation. Ringworm.—Garrett, 1913, recommends painting the scalp with undiluted Liq. Ferri Chlor. Fortis.

Income and Output of Iron.—The body of an adult man contains about 3.0 to 3.5 Gm. of iron, of which about 2.4 to 2.7 Gm. are in the form of hemoglobin. On a normal diet, he excretes daily about 20 mg. of iron; even in starvation the excretion averages about 8 mg. (F. Mueller). This is normally replaced by the absorption of iron from the food. A daily minimum income of 6 to 12 mg. is required to maintain the equilibrium. The iron content of the ordinary daily diet may vary between 7 and 35 mg., generally between 11 and 19 mg., 16 mg. being the mean value (Sherman, 1907; extensive bibliography). The iron income is therefore ordinarily more than sufficient for the needs; this even in other- wise poorly nourished individuals, since a vegetable diet is relatively rich in iron.

1 A. P. Matthews states that recent work throws doubt on the presence of iron in all nucle
Iron Content of Foods.—This varies considerably, a fact which may be utilised in the treatment of anemias. It suffices to remember that blood, meat, yolk of eggs, and the green portions of vegetables, carrots, fruits, etc., are especially rich in iron (17 to 50 mg. per 100 gm. of substance); while egg-white, milk, and the cereals (especially white flour) are poor in iron. Whole wheat, potatoes and the legumes are intermediate.

Dock (Rumex crispus), according to Sachet, has the highest iron content of any plant, and has therefore been recommended for anemia (Yanoeur, 1902). It is claimed (Gilbert and Lereboullet, 1906) that this content of organic iron can be considerably raised by cultivating the plant on a soil artificially enriched with ferrous carbonate.

Metabolism of Iron.—The increase of the iron content of the body in growing animals, and the equilibrium in adults, are sufficient evidence that food-iron is normally absorbed, metabolized and excreted. The controversy, whether inorganic iron compounds can also be metabolized, may now be considered settled in the affirmative: their fate is identical.

All compounds of iron undergo some preliminary and probably unimportant changes during digestion. They are then absorbed, mainly from the duodenum, but also in decreasing order from the succeeding portions of the intestine. A part generally escapes absorption and is eliminated by the feces. The part which is absorbed passes into the intestinal epithelium in a dissolved condition, the organic compounds being at the same time changed into looser combinations. The absorbed iron may then pass directly into the capillaries; or through the stroma into the lymph, reaching the blood via the thoracic duct. The relative role of the blood and lymph absorption is not yet clear, but it seems that normally the main absorption is directly into the blood.

From the blood, the iron is deposited as granules in an easily decomposed organic form (ferritin) in the cells of the hematopoietic organs, in the liver and red marrow, and particularly in the spleen, to a less extent in the kidneys. In this form it remains until it is used or excreted. The spleen seems to be important in maintaining the iron reserve and in preventing excessive excretion.

The excretion occurs mainly by the large intestines with traces in the urine, bile and gastric juice. The excreted iron is in firm organic combination.

The utilization of the iron, its transformation into hemoglobin, occurs only as needed; so that the total quantity of hemoglobin does not rise above normal. The same is probably true of its utilization by other cells. An excessive absorption of iron results merely in an increase of the reserve stock.

The administration of iron is therefore useful only in those conditions in which the normal income or the assimilation of iron is deficient.

Organic and Inorganic Iron.—To understand the following discussions, it is necessary to have a clear conception of the terms "inorganic" and "organic" iron. Inorganic iron preparations contain the metal in ion-form; i.e., the iron can be separated from them by electrolysis; and they give the ordinary iron reactions (with ammonium sulphide, ferrocyanide, or hematoxylin) without preliminary treatment of any kind. It is immaterial whether the iron is combined with an organic or inorganic anion. Even the albuminate of iron is considered as "inorganic" in this sense.

Organic iron ("masked" or "non-donic") preparations, on the other hand, contain the metal as a constituent part of the molecule, in a non-dissociable condition, so that they do not give the iron tests until the metal has been liberated by the decomposition of this molecule. There are all degrees in the firmness of the organic combination; some are decomposed by dilute acids (ferritin, the granules in which the iron reserve is stored in the spleen, liver, etc.); in others (hemoglobin, and the iron of food) nothing short of
combustion or heating with concentrated acids will liberate the iron. In certain organic compounds, e.g., the various double salts containing citric and tartaric acid, the iron is also largely non-ionic, but can be easily liberated. In molecular compounds, such as ferrocyanides, the iron is very firmly combined.

Hematoxylin (fresh 1% per cent. solution in water) is one of the best reagents, since it retains its yellow color with masked iron, but is blackened by inorganic (Macallum, 1897). However, acids interfere with the reaction, so that "dialysed iron," although inorganic, does not react until it is made alkaline. Ammonium sulphide is also a good reagent; but its prolonged contact liberates iron from the less firmly masked compound.

**Nature of Food-iron.**—Iron occurs in food exclusively in organic form, more or less firmly masked, generally in combination with nucleo-proteins. The first natural iron nucleo-protein was prepared by Bunge, 1885, from egg-yolk and named Hemoglobin. Zaleski also found an iron nucleo-protein in the liver. This was later isolated by Marfori and Schmiedeberg, 1894, and named Ferritin. These products are probably not uniform substances, since they contain varying proportions of iron (Salkowski, 1906). Schmiedeberg and Marfori also prepared what they considered an Artificial Ferritin, by the interaction of iron and alkaline egg-albumins. It has been shown, however, that this has absolutely no relation to the natural substance, being simply a rather firm ferric-aluminate (De Groote, 1895; Battistini, 1895). While true ferritin is not attacked by digestion, the artificial is converted into ferric chloride. It has therefore no advantage over the ordinary mild iron salts.

**Hemoglobin** holds the iron much more firmly than most other compounds. It is converted into hematin in the stomach (Rep. Coun. Pharm. Chem., 1903; 64). Its further fate is not known, but at least a part of its iron is evidently absorbed, since its administration can satisfy the iron requirements of the body. It has no serious therapeutic advantage.

**Outline of the Iron Controversy.**—Even the ancients employed iron in the treatment of anemia; drinking water in which swords had been allowed to rust. Perhaps they were led to do so by an obscure idea that the strength of the steel would in some way pass into the patient. With the discovery of the presence of iron in the blood (Menghinis, 1740), the therapeutic results seemed to be easily explained on the assumption that the iron is absorbed and converted into blood, much as the nitrogen of food is converted into muscle. The earlier experiments, however, failed to show any absorption of the medicinal iron preparations. This led some writers to consider the clinical results obtained with iron as largely imaginary; while others (especially Bunge, 1885) were inclined to ascribe them to the local actions of iron in the alimentary canal.

There could never be any question as to the absorption of food-iron, for the hemoglobin increases with the growth of the animal. The same holds true for certain organic iron, and of course for Macallum (1884) and Hall (1896) studied this absorption by microchemic methods. The absorption of inorganic iron was also proven, but the latter result was criticized, the objection being made that the iron had produced corrosion. This was finally withdrawn, but it was now claimed that inorganic iron, while it is absorbed, can not be converted into hemoglobin (Abderhalden, 1897; Hoffmann, 1900); but that it is nevertheless beneficial in anemia, by stimulating the blood-producing organs to a better use of the organic iron. This objection was also found untenable and abandoned (Abderhalden, 1906). It appears therefore that inorganic iron is absorbed assimilated and converted into hemoglobin, precisely like food-iron.

The long resistance to the acceptance of this explanation was due largely to the fact that the conversion of iron into hemoglobin would have been an unique instance of the synthesis, in the animal organism, of a protein from an inorganic compound. It is now probable that the phosphorus of nucleo-protein, and probably other proteins, may also be derived from inorganic sources.

However, even without prejudice, the problems of iron metabolism presented some peculiar difficulties, which could be only gradually overcome (critical bibliography. Erich Meyer, 1906).
Evidence from Excreta.—If one wishes to show the absorption of nitrogen or of chlorides, it suffices to estimate the quantity of these substances in the food, and in the feces and urine. The same method was applied to iron. The results seemed to show that the iron is absorbed, but the feces gave a smaller amount of iron than the food (Kletzing, 1854) and the iron in the urine is not at all increased. It was soon shown, however, that the intestines are the principal channel for the excretion of the iron. As the feces contain this metal in about the same amount as the food (Gottlieb, 1852), we conclude that most of the iron is excreted subcutaneously very much more was excreted by the feces than by the urine. It was therefore evidently impossible to decide whether the fecal iron was unabsorbed or excreted. Absorption could be proven, by this method, only if it predominated greatly over the excretion. The estimation of the iron in the bile and in the intestinal juice gave similarly inconclusive results.

Iron Excretion by Urine.—This always contains traces of iron (in man, normally 1 to 2 mg. daily), partly in rather loose, partly in very firm combinations (Welcher, 1912). There is practically no increase if iron is administered by mouth (E. W. Hamburger, 1875; Korbelt, 1891), even when organic iron is continued for weeks (Gottlieb, 1860). Nor is there any increase on intravenous injection of ferratin (Glotzka, 1899). Some increase occurs in fever, nephritis, hepatic disease, leucemia, and especially in diabetes. This indicates that the iron of the urine comes from tissue destruction, and not from the iron of the food or drugs (Tartakovsky, 1904).

Intestinal Excretion.—The iron leaves the body mainly by the feces. This is true for starvation (Bidder and Schmidt, 1852; F. Mueller), and for the normal iron income; or when iron is administered orally, hypodermically or intravenously. However, the total excretion of the iron is not increased. For several weeks (Gottlieb, 1861). It was at first assumed that the excretion occurred mainly by the bile, but actual observation showed that the quantity of iron in the bile is small (mean, about 40 mg. per liter); and that it is not materially increased by the administration of iron (E. W. Hamburger, 1880; Anselm, 1894, 1916). The iron must therefore be excreted through the intestinal epithelium. This is confirmed directly by fistula experiments, in which the access of food to isolated parts of the intestine is prevented (Korbelt; Gottlieb, 1892; Hensingmann, 1896). These show that the excretion occurs mainly in the large intestine; the excreted iron being very firmly combined, so that it gives the iron reactions only after inunction (Tartakovsky). In rabbits, after hypodermic or peritoneal injections of iron salts, the hemoglobin, the main excretion is through the epithelium of the upper duodenum (Chevalier, 1914). As with metals in general, the excretion is a slow process; requiring several weeks for the complete elimination of a hypodermic injection (Gottlieb).

Chemic Evidence of Absorption in Small Intestine.—A fistula in the lower ileum would separate fairly sharply the place of the principal absorption, the small intestine, from the principal excretion, the large intestine. Rabe, 1912, found in this way that about 80 per cent. of citrated iron was absorbed in the small intestine. By using fistula dogs, found that the greatest absorption of saccharated iron occurs in the duodenum, although the larger portions playing a progressively smaller role.

Iron Content of Organs.—Changes in the iron content of individual organs, or of the entire body, also give evidence of the absorption of iron. We have seen that injected iron, aside from the alimentary canal, must therefore be temporarily stored in the body. Jahn, 1888 and 1890, found that iron preparations, injected into a vein, had disappeared from the blood in two to three hours. At this time, only 10 per cent. had passed into the excrement; about 40 per cent. was deposited in the liver, and the remainder in other organs (spleen, kidney, intestines). The Liver is also normally very rich in iron (this is true likewise of animals which do not form hemoglobin—molluscs, crayfish, lobsters, etc.). The liver iron decreases with iron-poor food, or when there are extra demands for iron, as in pregnancy or after hemorrhage. The iron content of the liver may thus be taken as an index of the iron stock of the body, and therefore of absorption. With small animals, the iron content of the entire body can be estimated.

Since the animals must be killed to estimate the iron, control experiments are necessary. These would be impossible if the animals were chosen at random, for the individual differences of iron content are often greater than the quantities which could be absorbed. Bunge found, however, that the proportion of iron in new-born animals is very high (increasing very rapidly in the last three months of fetal life; Huguenenon, 1890); and that it decreases steadily during the period of lactation (because milk is very poor in iron) until it has reached a practically constant quantity—about the seventeenth day in guinea pigs or rabbits, and the twenty-third or twenty-fourth day in dogs. The animals of the same litter can therefore be used for controls, some being fed, at the end of the lactation period, with iron-poor food, others with the same food to which the iron Preparation is added. Rice and milk, which contain a very small proportion of iron,
are commonly employed. The animals which do not receive the iron thrive very poorly, remaining small and pale. Those which receive iron, in some cases, undergo a remarkable increase in the total iron content of the body, especially of the liver, spleen and bone-marrow (Hall, 1894; Kunkel, 1895; Oerum, 1906).

After the administration of iron preparations, iron is found in the liver, spleen and bone-marrow (Hall, 1894; Kunkel, 1895; Oerum, 1906), object.ected to the experiments of Hall that the iron administered is absorbed as inorganic iron, and that plasma, white corpuscles and bone-marrow are quite free from iron. The experiments of Kunkel, however, who worked with larger doses, were not confirmed. The large doses did not produce any effect. These experiments therefore prove that inorganic iron is absorbed and deposited in the liver and other organs.

Microscopic Evidence.—Important information is obtained by applying the color reactions for iron directly to the tissues. The macroscopic examination of the depth of stain gives a general idea of the quantity of iron present, the details being revealed by microscopic study. Since, however, the iron compounds are apt to dissolve in the fixing solutions, many of the earlier experiments gave fallacious results. The best method consists in hardening the tissues in alkaline ammonium sulphate and converting the ferrous sulphide into the more stable Berlin blue, by treatment with potassic ferrocyanide and dilute hydrochloric acid. Only the inorganic and the loosely combined iron is revealed. The experiments are made on animals with different diets, or fed on iron for varying periods. The method is of value especially for showing the place and manner of absorption, and the course of iron through the system.

Course of Absorption.—Macalpin, 1894; Quincke, and Hochhaus, 1894; and Abderhalden, 1906, after the administration of iron preparations, found the reaction especially strong in the epithelial cells of the duodenum. The results below the duodenum were inconstant, depending upon the quantity administered. The gastric epithelium gives no reaction.

The large intestines show a diffused iron reaction of the epithelium, and granules in the submucous leucocytes. It was generally assumed that this iron was the course of excretion. However, Tartakowsky found that the large intestine shows no sulphid reaction in starvation or with iron-poor food, although the chemic examination of the intestinal contents proves the continued excretion of free iron. It would therefore seem that the excreted iron is too firmly combined to give the sulphid reaction; and that the sulphid reaction of the large intestine is also due to iron in the course of absorption. Hence, the amount absorbed here must be small.

The absorption of iron must therefore take place mainly through the cells of the duodenum. This differs from other metals, which are absorbed between the cells (Hopfer, 1907). The iron reaction is essentially identical, whether organic or inorganic iron is used. Since food-iron does not give the sulphid reaction, even in the intestinal contents, it must be broken down into ionic iron within the epithelium. This does not exclude the possibility that a part of the organic iron may be absorbed unchanged; for this would not be revealed by the microscopic reaction.

Further Course of the Absorbed Iron.—The iron reaction is also seen in the strata of the duodenal villi; in the central lacteal, and sometimes in the mesenteric lymph glands, partly dissolved in the lymph plasma, often as granules in the lymph corpuscles (ferrocytes) (Quincke; Gaule; Abderhalden). Gaule, 1896, also found that iron absorption does not increase the iron content of the spleen, if the liver is prevented from reaching the circulation, by a fistula of the thoracic duct. These observations would indicate that the iron reaches the blood through the lymph. Franz Muehr observed opposite results: The lymph of the thoracic duct contained no iron; and the fistula did not prevent the accumulation of iron in the organs. The difference is perhaps explained by the dosage: Gaule worked with large doses and his histologic results at least could be referred to corrosion; while Mueller used smaller doses. It is therefore probable that the iron normally passes directly into the intestinal capillaries. It is then rapidly deposited in the organs.

Reserve Stock of Iron.—Animals on an ordinary diet lay up a considerable reserve stock of iron, as loose protein compounds, especially in the liver and spleen. The reserve disappears ("asleronie" of Quincke) gradually when a diet poor in iron is given, or if there is an extraordinary use of iron, as after hemorrhages, or during pregnancy (when considerable iron is transferred to the fetus). In acute hemorrhagic anemia of rabbits, the reserve iron largely disappears, especially from the liver cells, when the blood is replaced. The smaller amounts are still present in the endothelium of the hepatic capillaries, in the spleen and in the renal cortex (Muir and Dunn, 1915). The deposits increase, on the other hand, when the iron of the food is increased.

The liver of fish and lobsters is also rich in iron, although these animals do not form hemoglobin. It is therefore probable that the storage of iron in the liver ...
originally for the purpose of excretion, rather than as a reserve depot for the reformation of hemoglobin.

Relation of Spleen to Iron Metabolism.—The constant occurrence of loosely bound iron granules in the spleen, varying in quantity with the iron in the blood and diet for a time, shows that it is one of the important depots for reserve iron (Chevalier, 1914). Even animals fed on iron-free food from birth, and whose liver is free from reserve iron, contain some in the spleen (Schmidt, 1914). However, this function is shared by many other organs, so that splenectomy does not entail any constant or important changes in normal iron metabolism (Austin and Pearce, 1914). When the iron income is inadequate, the loss of the spleen may perhaps lead to a less effective retention of iron, as is believed by Asher and his pupils, 1909 and 1914. On the other hand, excision of the spleen has real, if not very conspicuous effects on the red blood corpuscles.

Effects of Splenectomy.—These have been investigated especially by Pearce and pupils, 1912 to 1915. They find that excision of the spleen from normal dogs is followed by moderate anemia, with very slow recovery. The decrease is greater for the hemoglobin than for the blood count. The mechanism of this anemia is not clear. Subsequently, as the anemia recovers, the red cells become abnormally resistant to hemolytic agents and the fatty bone-marrow becomes cellular. The cells of the lymph nodes and perhaps of the liver show a compensatory increase of phagocytic function toward the red cells.

Splenectomy does not modify the bile-pigment excretion, with or without hemoglobin injection (Hooper and Walpole, 1917).

Injection of Spleen Extracts.—Intraperitoneal injection produces for one or two days a distinct increase of hemoglobin in corpuscles in normal, not in spleenectomized animals, apparently by stimulating the bone-marrow. Feeding of spleen is ineffective (Krumbhaar and Muser, 1914).

Splenic extract has no hemolytic action in vitro; nor does the blood of the splenic vein contain more free hemoglobin than the splenic artery (ibid).

Assimilation of Iron.—It would be quite conceivable that the absorbed iron, particularly the inorganic preparations, were of as little use to the organism as the particles of solid carbon which are absorbed by the lungs. It had to be shown therefore that the iron can be actually assimilated and converted into hemoglobin. This could not be done by the method of the blood, because the normal supply is simply sufficient for all the needs of the organism; an excess has no effect whatever on the hemoglobin. The animals must be reduced to a condition in which the needs exceed the ordinary income. In young and actively growing animals, this may be secured by a diet poor in iron (milk and rice). This produces a progressive fall of the percentage of hemoglobin, and the animals become emaciated and do not develop. As soon as iron, in any form, is added to the diet these animals recover very rapidly (Hosslin, 1896; Chodda; Tartakowsky; Abderhalden). It must therefore be concluded that all forms of iron can be assimilated. The same result is obtained with adult animals. These can not be rendered markedly anemic by an iron-poor diet; by drawing on their reserve stock, and possibly utilizing the iron several times, they can keep up an almost normal percentage of hemoglobin for a considerable period. They can, however, be rendered anemic by hemorrhage. Even a rather severe simple hemorrhage is rapidly recovered from on a milk and rice diet; but this is hastened by the administration of organic or inorganic iron (Eger; Mueller, 1900). When several hemorrhages have been made and the iron reserve has become exhausted recovery occurs only when iron (in any form) is added to this diet. (Kunkel, 1895; Tartakowsky, 1903 and 1904).

Abderhalden at first contended that even these experiments did not prove the assimilation of inorganic iron: He concluded from his data that the undernourished animals did not improve as rapidly by the simple addition of inorganic iron, as did the animals which were placed on a normal (iron-containing) diet plus inorganic iron; but that the improvement was more rapid on a full diet plus inorganic iron than on a full diet alone. He interpreted these observations to the effect that inorganic iron was not assimilated at all, but that it increased the assimilation of organic iron, perhaps by stimulating the bone marrow. Jacquet, however, pointed out that the slower improvement, when the iron was added to the restricted diet, would be explained by the lower content of this diet; and Tartakowsky showed that inorganic iron added to a rich iron does not hasten the improvement, as it should if it stimulated the bone marrow. Abderhalden seems to have dropped his objection.

Changes in Bone-marrow.—When iron is administered in anemia, the marrow cells show greater activity, more nuclear erythrocytes and mitotic cells; but this is a natural accompaniment of the increase of hemoglobin. The observation of Mincze, 1913, with iron administration in human anemia, that the increase of
erythrocytes considerably precedes the increase of hemoglobin, is also not convincing proof of direct bone-marrow stimulation, until we know more about the normal and pathologic sequence of blood regeneration.

A. B. Macalanni, 1890, found in frogs that the hemoglobin arises from the transformation of the iron-containing nuclear chromatin of the hemeblobin.

Disassimilation of Iron.—A part of the reserve iron is doubtless derived from the destruction of the red corpuscles and their hemoglobin; for the injection of hemoglobin or hematin increases markedly the iron content of the liver, spleen and marrow. The transformation of hemoglobin into the less firmly marked iron may be seen in extravasations of blood, and takes place there in gradual stages. The improbability of producing severe anemia in adult animals by limiting the iron of the food, indicates that the iron-stock may be used several times. But a portion is undoubtedly lost by the feces and urine.

 Fate of Hemoglobin.—If free hemoglobin occurs in the plasma, as a result of injection or hemolysis, in concentrations above about 0.12 per cent., the excess is mainly filtered through the kidney and produces hemoglobinuria. A part, however, and with lower concentrations all of the dissolved hemoglobin is taken up and destroyed by the liver, spleen, kidney, etc. In the liver, the hemoglobin is converted into bile-pigment. If the amount of this exceeds the excretory capacity of the bile, it results in icterus (Peurs, Austin and Eisenbery, 1912).

With hemolysis so severe as to destroy nearly half of the blood in three days, Mair and Dunn, 1915, found nearly all of the iron of the destroyed hemoglobin deposited in the liver, spleen and kidneys. A third of the total iron of the blood may be thus deposited in twenty-four hours.

The conversion of hemoglobin into bile-pigment is not quantitative on intravenous injection, and the feeding of blood does not modify the bile flow, or the secretion of bile-pigment (Whipple and Hooper, 1917).

Although it is practically certain that bilirubin is produced from hemoglobin, the steps of the process are unknown. From their formulas, it may be a rather simple oxidation (Kuester, 1916).

Injections on Alimentary Canal.—These were advanced in explanation of the therapeutic effects when the assimilation of inorganic iron preparations was still in doubt. The inorganic salts of iron produce an astringent effect, which may conceivably support the other actions, by improving digestion (Koebert, 1882). There is always danger, however, that the useful action passes into irritation, and, in fact, iron causes digestive disturbance (especially constipation) more often than improvement.

Effects on General Nutrition.—While these are doubtless mainly the indirect result of the increase of hemoglobin, it must not be overlooked that iron forms a constituent of all cells, and some of its effects may be direct; but its importance in this connection is difficult to estimate. The majority of organisms require some iron, even those which do not form hemoglobin. (The blood of some invertebrate animals contains copper or manganese in place of iron.)

Therapeutic Use in Anemias.—The administration of iron would be useful in all conditions in which the need for iron exceeds its income; conditions which are characterized by a low percentage of hemoglobin, and by the general clinical picture of anemia.

The plainest indication for iron is furnished by the anemia produced by severe or repeated hemorrhage. Infantsile anemia are often traceable to a deficient iron content of the food, and would be greatly benefited by iron. Some cases of simple anemia in adults may also be due to this cause. It is conceivable that deficiencies in the iron income are concerned in the etiology of rickets and the other nutritive diseases of infants.

Iron Content of Milk.—Anemia is very apt to occur if the infant is kept too long on an exclusive milk diet. It may also be favored by an inferior quality of milk. The normal human milk contains about 0.6 mg. of iron per liter (0.7 mg.), but the unhealthy mothers is poorer in iron; and artificial infant foods generally contain only
1.4 to 2.6 mg. Cow’s milk is even poorer in iron than is generally believed. It contains 0.4 to 0.7 mg., mean 0.5 mg. per liter; the higher figures of older determinations were due to contamination from metallic containers (Edelstein and Csonka, 1921).

Pernicious Anemia.—Iron is useless in those cases of anemia in which there is no deficiency in the income or store of iron; but in which the fault concerns the formation or destruction of the corpuscles. In pernicious anemia, a most severe destruction of the corpuscles (probably through an unknown hemolytic agent) is accompanied by a very considerable increase of the reserve iron of the liver and spleen (Rumpf, 1901) and of the dissolved iron of the spleen (Erben, 1900). The urinary excretion of iron remains normal (Queckenstedt, 1911). Clinical experience has confirmed that the administration of iron is useless in this condition.

Most instances of anemia, and especially chlorosis, can not be attributed directly to deficient iron income; but nevertheless, the administration of iron often secures brilliant results. It must therefore be supposed that conditions exist in these diseases, which demand an extraordinary income of iron to keep the hemoglobin normal.

Iron in Chlorosis.—A complete explanation of the action of iron in chlorosis can be furnished only when the pathology is understood. This is not the case at present; little is known beyond the fact that the hemoglobin is decreased (Fördisch, 1832) much more than the number of corpuscles (several authors, 1842), and that the excretion of iron by the urine is nearly normal. Even the question, whether the reserve stock of iron is altered, does not seem to be decided. Digestive disturbances are often present, but they may be secondary or accidental; indeed, they disappear spontaneously with the iron treatment.

Our knowledge of the etiology is equally unsatisfactory. It has indeed been shown by Stockmann that the diet of chlorotic girls is often very poor in iron (containing 2.8 to 3.2 mg. per day, instead of the normal, 6 to 14 mg.). But this, as well as other unhygienic conditions, can be considered only as contributory factors, since many persons are subject to these conditions, while chlorosis is confined to females about the age of puberty. There is no evidence of defective absorption of iron.

The treatment is much more successful than might be expected. The administration of iron holds the first place. This should be supplemented by proper hygiene—good air, rest, suitable diet, stomachics, attention to the bowels (aenes), etc. Arsenic, phosphorus or manganese are often used in addition to the iron: it is difficult to judge of their value.

Administration.—Although both organic and inorganic iron are absorbed and produce therapeutic effects, the ionized iron appears to be more active therapeutically, for reasons not fully understood. On the other hand, inorganic-iron preparations are more apt to set up digestive distress, which may interfere with the prolonged administration that is ordinarily needed. In such cases, it is necessary to begin with the milder organic or insoluble preparations; and to induce a tolerance to the local effects by progressing slowly to the stronger compounds. The ferrous carbonate can be given to most patients without difficulty, and is sufficiently effective. The most suitable form and dosage are governed by individual experience. The daily dose should correspond to about 0.1 gm. of iron. This would be contained in about 5 or 6 Blaud pills, but should require 30 to 250 Gm. of the organic preparations (Morawitz, 1914).

The order of irritation and efficiency is about as follows (in ascending order): food-iron; other organic irons; reduced iron (in powder or pills); ferrous carbonate (saccharated; Blaud’s pill); the double “scale” salts; ferrous sulphate; ferric chlorid.
Reduced iron should be given just before meals, to permit the solvent action of the gastric juice. All other inorganic iron preparations should be taken just after meals, taking care to protect the teeth. The incompatibilities of iron must be remembered. The tendency to constipation may be met by aloe or other laxatives.

Hydropenic Administration of Iron.—Iron ammonium citrate has been used clinically; 1 c.c. of 10 per cent. solution daily. It is efficient, but has no advantage over oral administration; and is rather painful, and sometimes produces severe local and systemic reaction, gastritis etc. These accidents have not been observed in animals even with much larger doses (L. W. Rowe; 1917).

IRON PREPARATIONS

Only the most important preparations need to be studied. It may be remembered that ferric salts have a reddish, the ferrous a greenish color. The most important incompatibilities are; alkalies, salicylates, phenol.

Organic iron preparations had a brief popularity when it was believed that inorganic preparations were not absorbed. The modern conceptions have caused them to be practically abandoned, except in so far as iron foods are emphasized in the diet in anemia.

PREPARATIONS—INSOLUBLE IRONS

Ferrum, U.S.P.; B.P.; Iron.—Metallic iron in the form of fine, bright, and non-elastic wire. Used only for preparing the salts.

*Ferrum Reduciun (Ferr. Reduct.) U.S.P.; Ferrum Reductum (Ferr. Reduct.), B.P.; Reduced Iron (Iron by Hydrogen; Quev enne’s Iron)—Iron reduced to the metallic state by the action of hydrogen upon ferric oxide. Very fine, grayish-black, hollow powder, without odor or taste. *Dose, 0.06 Gm., 1 gr., U.S.P.; 0.05 to 0.03 Gm., 1 to 1 gr., B.P., as powder.

*Trachel ferr. Reduct., B.P.—0.06 Gm., 1 gr.

*Ferrum Carbonas Saccularis (Ferr. Carb. Sacch.), U.S.P.—Contains not less than 15 per cent. of FeCO₃. Made by precipitating ferrous sulphate with sodium bicarbonate, and diluting with milk-sugar. A greenish-brown powder, gradually becoming oxidized by contact with air; odorless, and having at first a sweetish afterward slightly ferruginous, taste. Only partially sol. in water. *Dose, 0.25 Gm., 4 gr., U.S.P., suspended in water.

Ferrous Carbonate tends to give off CO₂ and absorb oxygen, changing rapidly into a basic carbonate and finally into ferric hydroxide. The change may be retarded by the addition of sugar, as in the pharmacoeutic forms; but these should always be prepared as freshly as possible.

*Ferr. Carb. Sacch., B.P.—Not less than 50 per cent. of Ferrous Carbonate, preserved by Glucose. *Dose, 0.6 to 2 Gm., 10 to 30 gr., B.P.

*Ferr. Carbonicum Compositum (Ferr. Carb. Compositum).—About 0.7 per cent. of Ferrous Carbonate in suspension in flavored water. Must be freshly prepared. *Dose, 15 to 30 c.c., ½ to 1 ounce, B.P.

*Magna Ferri Carbonatis (Mass. Ferr. Carb.), U.S.P.; (Vallet’s Mass.).—A pill-mass with not less than 41.5 per cent. of FeCO₃. *Dose, 0.25 Gm., 4 gr., U.S.P.

*Pill, Ferr. B.P.—Pill-mass with 22.5 per cent. of FeCO₃. *Dose, 0.5 to 1 Gm., 5 to 15 gr., B.P.

*Pill, Ferr. Carb., U.S.P. (Blaud’s, Chalybeate, or Ferruginous Pills)—0.06 Gm., 1 gr., of FeCO₃, made from ferrous sulphate and pot. carb. *Dose, 2 pills, U.S.P.

Contrary to the prevailing impression, the U.S.P. Blaud’s pills are quite stable, and preferable to the proprietary substitutes (Warren, 1025).

Ferris Hydroxidum Com Magnesii Oxide (Ferr. Hydrox. cum Mag. Oxid)., U.S.P. (Arsenic Antidote; Ferric Hydrate with Magnesia).—40 c.c. of Solution of Ferric Sulphate are diluted with 125 c.c. of water. This is added, when needed, to 10 Gm. of Magnesium Oxide or 500 c.c. of Magna Magnesia diluted with water to about 250 c.c.

Always keep the diluted solution of ferric sulphate and magnesium mixture on hand in separate bottles, ready for immediate use, so that this antidote to arsenical poisons may be quickly prepared.

*Dose, 120 c.c., 4 ounces, U.S.P.
PREPARATIONS—COLOIDAL IRON AND "SCALE SALTS"

Liq. Ferri Oxycloridi.—A colloidal solution of ferric hydroxyd in ferric chloride; approximately FeCl₃ + 8Fe(OH)₃, containing the equivalent of about 3.7 per cent. of metallic iron. It is only mildly astringent. Dose, 0.5 to 2 c.c., 8 to 30 minims.

Liq. Ferri Dihysulates (Dialyzed Iron).—This is a similar solution from which the excess of acid and chlorid has been removed by dialysis. It has the same iron content and is less astringent. Dose, ½ to 2 c.c., 8 to 30 minims.

*Ferri et Ammonii Cibars (Ferr. et Ammon. Cibis), U.S.P. (Soluble Ferric Citrate, Ammonio-ferric Citrate).—A mixture of iron citrate and ammonium citrate containing about 17 per cent. of Fe. Thin, transparent, garnet-red scales, without odor and having a saline, mildly ferruginous taste; deliquescent in moist air. Readily and completely sol. in water; insol. in alc. Dose, 0.25 Gm., 4 gr., U.S.P.; 0.5 to 0.6 Gm., 5 to 10 gr., B.P.

Vin. Ferr. Citr., B.P.—1.8 per cent. of Ferr. et Ammon. Cit. Dose, 4 to 16 c.c. 1 to 4 drams, B.P.

Vin. Ferr., B.P.—Prepared by macerating iron in Sherry Wine; Contains the equivalent of 0.525 to 0.54 per cent. of Fe. Dose, 4 to 15 c.c., 1 to 4 drams, B.P.

Ferr. et Pot. Tar., B.P. (Ferrum Tartaratum).—Garnet scales. Dose, 0.5 to 0.6 Gm., 5 to 10 gr., B.P.

Ferr. et Quin. Cit., U.S.P., B.P.—Contains about 13.5 per cent. of quinine and 13.5 per cent. of Fe. Dose, 0.25 Gm., 4 gr., U.S.P.; 0.3 to 0.6 Gm., 5 to 10 gr., B.P.

*Ferr. Phos., U.S.F.—Ferric phosphate, made soluble by the presence of Sed. Cit.; corresponding to not less than 12 per cent. of Fe. Bright green scales. Freely sol. in water, insol. in alc. Dose, 0.25 Gm., 4 gr., U.S.P. (El. Ferr. Quin. et Strychn. Phos.—See Index.)

(Syr. Ferr. Phos. Quin. et Strychn.—See Index.)

PREPARATIONS—SOLUBLE FERRIC SALTS

Fil. Ferr. Iod., U.S.P.—Each pill contains FeI₃ corresponding to not less than 0.04 Gm. of ferrous Fe. Dose, 2 pills, U.S.P., contain about 0.1 Gm. of iodin.

*Syrius Ferr. Iodidi (Syr. Ferr. Iod.), U.S.P.—5 per cent. of ferrous iodid, FeI₃. Pale green acid liquid of strong iron taste. Very susceptible to oxidation, turning brownish. It combines the therapeutic properties of iron and iodids, and is often prescribed in goiter (2 drops, twice daily, gradually increased to 15 drops three times daily; Marine and Lenhart, 1913) and as a general tonic in "serous" conditions. Average dose, 1 c.c., 5 minims. U.S.P., contains about 52 mg., 0.85 gr., of iodid.

*Syrr. Ferr. Iod., B.P.—7 per cent. of Fil. Ferr. (i.e., 7 to 14 c.c. 1/4 to 1 dram, B.P. Ferr. Phosph. Sacci, B.P.—60 per cent. of ferrous phosphate, Fe₃(PO₄)₂·8H₂O, preserved with glucose. Partially sol. in water; sol. in HCl. Dose, 0.3 to 0.6 Gm., 5 to 10 gr., B.P.

Syr. Ferr. Phosph. B.P.—1.7 per cent. of ferrous phosphate. Dose, 2 to 4 c.c., ½ to 1 dram, B.P.

Ferr. Sulphus (Ferr. Sulph., U.S.P., B.P.; Ferrous Sulphate (Green Vitriol); Iron Protosulphate, FeSO₄ + 7H₂O.—Large, pale green crystals; odorless, saline, styptic taste; effloresces in dry air. Freely sol. in water (1:1:4). Practically insol. in alc. Dose, 0.1 Gm., 1/2 gr., U.S.P.; 0.06 to 0.3 Gm., 1 to 10 gr., B.P.—The crude salt is employed as a desodorisant for fecal matter, but is not germicidal.

*Ferr. Sulphatis Excitatorius (Ferr. Sulph. Exciti., U.S.P., B.P.—50 per cent. of anhydrous FeSO₄, 1 part being equivalent to about 1.5 parts of the crystalline salt. Grayish-white powder; astringent taste. Dose, 0.06 Gm., 1 gr., U.S.P.; 0.03 to 0.2 Gm., ½ to 3 gr., B.P.; in pills, often with aloes.

Fil. Alces & Ferr., B.P.—10 per cent. of Ferr. Sulph. Excr.; 20 per cent. of Aloes. Dose, 0.25 to 0.5 Gm., 4 to 8 gr., B.P.

PREPARATIONS—SOLUBLE FERRIC SALTS

Ferr. Chlor., U.S.P.; Ferric Chlorid (Iron Perchlorid).—Contains FeCl₃ equivalent to 20 per cent. of Fe. Very sol. in water (1:0:2) or alc.; sol. in glye. Dose, 0.06 Gm., 1 gr., U.S.P.
MANGANESE

Occurrence.—Traces of manganese occur naturally in all organisms, in man and various animals, its presence being fairly constant in the same species (Bertrand and Medigue, 1912). The amount in wheat, for instance, is about equal to the iron, and is independent of the manganese percentage of the soil (Headon, 1912). The manganese of a plant is derived partly from vegetable, but mainly from animal food; but does not disappear from the body even on manganese-free food.

Actions.—When administered by mouth, the salts of this metal (but this does not apply to the phytates) produce no noticeable effect. Manganese is absorbed to a slight degree from the alimentary canal, being deposited mainly in the liver and kidneys, and passing also to the fetus in utero. Its excretion begins within three hours, mainly by the intestine (as sulphate in the feces), and the bile, but the urine participates (Barbero, 1906; dog; Piccinini, 1915). It appears to take about the same course as iron (Harnack and Schleicher, 1907). Benedetti, 1906, and Piccinini, 1915, 1917, claim that it increases the reserve iron. Benedetti has investigated its fate by subcutaneous injection (citrate, dog). It is toxic by vein (Barbero), and also causes fatty degeneration of the liver.

Manganese chlorid accelerates autolysis when added to excised liver; perhaps by converting indigestible proteins into forms that can be attacked by the liver enzymes (Bradley and Morse, 1917).

Manganese Toxicosis.—Chronic poisoning results from exposure to the dust of any of its compounds in the industries, in zinc mines, grinding, etc. (Emden, Casamajor, 1913; Jakuch, 1913). The symptoms are nervous, with mental and ataxic disturbances. The prognosis is good as to life, bad as to recovery. The condition has not been produced in animals.

PREPARATIONS—MANGANESE

Mangani Disodium Precipitatum (Mangan. Dis. Pre. ). U.S.P.—Consists chiefly of manganese dioxide (MnO)). Prepared by precipitating Manganese Sulphate by Ammonia in the presence of Hydrogen Dioxide. Heavy, fine, black powder, without taste or odor; insol. in water or alcohol. Dose, 0.55 Grm., 4 grs., U.S.P.

CHROMATES

Uses.—Chromium trioxide (chromic acid) is used externally as a caustic. It and the chromates have some toxicologic importance, the dichromate being used in dyeing and in “battery fluids.” They are also interesting by producing a characteristic nephritis and glycosuria.
Kolipinski, 1901 and 1908, reported favorable results from chromium sulphate (5 gr., three to four times daily) in neurasthenia, tabes and other nervous conditions. They have not been adequately confirmed.

Acute chromate poisoning exhibits corrosive effects and necrosis with death in one to forty-eight hours. The fatal dose of potassium dichromate is below 8 Gm.; of chromic acid, 6 Gm. The treatment is by evacuation and demulcients. Chronic poisoning produces local irritation (severe dermatitis, ulcers, etc.) and necrosis.

Ulcers are produced by chromate dust, especially where the skin is already injured. They develop slowly, but are very penetrating and heal with difficulty. It also causes ulceration and perforation of the nose.

Fate.—When bichromates are given by the mouth, they are reduced to chromous and partly deposited as such in numerous organs, the rest being excreted by the urine (Kappeler, 1896).

Chromate Nephritis.—This is produced experimentally by hypodermic injection of the chromates. It is mainly tubular, but the glomeruli are involved first. All the phenomena are similar to uranium (including retention, glycosuria, chronic nephritis, etc.); except that edema is not common (Gergens, 1876; Hellm and Spiro, 1897; Schleyer and Hedingor, 1907; Ophuls, 1908; Austin and Eisenbrey, 1911; R. H. Smith, 1912; Folin, Karasev and Denis, 1913; MacNider, 1917; Eisenbrey, 1917; E. Fraseck, 1913; glycosuria, Mosenthal and Schlayor, 1913; diuretics, etc.).

PREPARATIONS—CHROMATES

Chromii Triiodidum (Chrom. Trios.), U.S.P.; Acidum Chromicum (Acid. Chrom.), B.P.; Chromium Trioxide, Chromic Acid (Chronic Anhydrid), CrO₃.—Dark red, needle-shaped crystals, very deliquescent and very sol. in water (1:60). Explosive with all organic matters. Used as a caustic, solid or in solution (1:2); as an astringent (2 to 5 per cent.); for urethral injections (1:20,000 to 4,000); and against sweating feet (5 per cent.).

Potassium Bichromate, B.P., K₂Cr₂O₇.—Large orange-red crystals. Sol. in water (1:50). Incompatible with alcohol and all reducing agents. Dose, 6 to 12 mg. 3/4 to 3/4 gr. B.P., diluted (against gastric ulcer); locally, 1:10 solution against rectum ulcer and cancer.

ALUMINUM

General Statement.—The soluble salts are strongly precipitants to proteins, and therefore astringent and antiseptic. They are used externally, and sometimes against diarrhea. They are not readily absorbed from the alimentary canal, so that even very large doses cause only local exudative inflammation (vomiting and diarrhea). The precipitates redisolve in an excess of protein.

The quantities which may be dissolved from aluminum cooking vessels, even by dilute acids, are too small to be of any importance. Alum baking powders are perhaps more seriously objectionable.

Absorption and Distribution.—It was formerly stated that aluminum salts are not absorbed (Hagge and Lebbin, 1890). Gies, 1912, Steel, 1911, and Kahn, 1913, however, showed that considerable absorption occurs even from biscuits baked with alum baking powder, and this tends to accumulate in the body. The bile is especially rich; the parenchymatous organs retain considerable; the brain and heart but little.

On the other hand, the Referee Board, 1914, found no aluminum in the blood after administering to men 1 Gm. per day for four days.

Aluminum occurs naturally in the ash of bird feathers (Gonnermann, 1918).

Excretion.—Schmidt and Hoagland, 1910, administered soluble and insoluble aluminum compounds, over long periods. They recovered the entire ingested aluminum (within limits of error) from the feces; none from the urine. Steel, 1912, also found it mainly in the feces even after intravenous injection. Kahn, 1913, claims that it is excreted partly by the urine, after oral administration.

Effects on Metabolism.—Schmidt and Hoagland, 1910, administered to men over extended periods about 0.5 Gm. per day of aluminum, as potassium or sodium alum, and as alumina. They found that the metal is excreted in the feces partly as phosphate;
thus detecting the phosphates from the urine, or preventing their absorption and utilization. This is practically unimportant, unless the income of phosphorus is deficient.

They also give the bibliography since the Reference Board report. Delayed Symptoms.—The aluminum compounds spread very slowly even when injected subcutaneously, and appear to penetrate cells with great difficulty; for the symptoms appear only several days or weeks after the injection (Simm, 1886), at a time when the metal has entirely disappeared from the blood, and has become fixed in the cells. The symptoms then resemble those of subacute arsenic poisoning. They never occur when aluminum salts are given by mouth, no matter in what doses, nor how long continued. Roth and Voegtlin, 1916, found that prolonged feeding of aluminum salts to animals produced mainly gastro-intestinal irritation.

Astringent Action.—This has been studied by Barnetti, 1914.

PREPARATIONS—ALUMINUM

Alumens (Alum., U.S.P.; Alumen Purificatum (Alum. Pur.), B.P.; Potassium Alum (Aluminum Potassium Sulphate), AlK(SO4)2+12H2O; or Ammonium Alum, AlNH4(SO4)2+12H2O.—Large colorless crystals; strongly astringent taste; without odor. Freely soluble in water (1:1), practically insol. in alc.; freely sol. in glye. Incompatibility with alkalies, carbonates and lead salts. Dose: 0.5 g.; 8 g., U.S.P.; 0.3 to 0.6 g.; 5 to 10 gr., B.P. Used as gargle (1 to 5 per cent.; somewhat injurious to teeth); as urethral injection (0.5 to 1 per cent.); and as skin lotion (1 per cent.).

*Alumens Enecratica (Alum. Esen.), U.S.P., B.P. (Burnt Alum.)—Alum with 45 per cent. of water of crystallization (expelled). It is used as a mild astringent.

Glycerium Alumini (Glycer. Alum.), B.P.—20 per cent. of Alum.

*Laqua Aluminii Acetatis (Liq. Alum. Acet.), N.F., (Barrow's Solution)—A dest colorless solution containing about 5 per cent. of neutral aluminum acetate, Al(C2H3O2)3. Used as a mild astringent and antiseptic. A 1 per cent. dilution is said to be antiseptic and 5 per cent. germicidal (Kaeble, 1932). For application to the skin it should be diluted five to fifteen times. 

Liq. Alum. Subacet., N.F.—Contains nearly 8 per cent. of basic aluminum acetate, Al(OH)(C2H3O2). It is practically equivalent to the preceding and is used in the same dilutions.

Alunimi Chloridum (Alum. chlor.), N.F.—AlCl3+6H2O. Freely soluble in water (1:1), and in alc. (1:2). It has no special advantage over alum as a general astringent and antiseptic. Stillians, 1916, recommended it in hyperhidrosis (painting of the skin with 25 per cent., at first every 2 to 3 days; later once a week).

BAKING POWDERS—These are chemicals which serve as substitutes for yeast-fermentation, rendering bread and pastry dough by evolving carbonic acid. They are of course altered in the process. The decomposition products are partly expelled by the heat of baking. The fixed residue is the part which could conceivably produce pharmacologic action. The baking powders belong to four chemical types (Crampton, 1869):

2. Phosphate Powders.—Calcium super-phosphate and sodium bicarbonate. Reaction: CaH2PO4 + NaHCO3 = CaHPO4 + NaH2PO4 + CO2 + H2O. Soluble residuum: 3.6 g. sodium phosphate per lb. of bread. Innocuous.

3. Alum Powders.—Alum (usual ammoniacal) and sodium bicarbonate. Reaction: (NH4)2Al(SO4)3 + 6NaHCO3 = Al(OH)3 + 3Na2SO4 + (NH4)2SO4 + 8CO2 + 4H2O. Residuum, per lb. of bread: 1.5 g. aluminum hydrate; 2.62 g. sodium sulphate; 2.1 g. ammonium sulphate. The aluminum hydrate is insoluble in water; in the stomach, some is dissolved by the hydrochloric acid, and perhaps by the proteins. Gies, 1911, considers this seriously objectionable. The sulphates are practically without action. The action of alum whitens pastry baked from inferior flour. This fraudulent use is prohibited in several countries.

4. Ammonium Carbonate.—Decomposed and volatilized as NH3 + CO2. Expelled so completely that it is inactive. Some baking powders are mixtures of several of the above. They are often differced with indifferent substances (starch, etc.).
CERIUM

Cerium resembles aluminum. The insoluble Cerium Oxalate is employed against vomiting, especially in pregnancy (Simpson, 1854; Mills, 1879), but it is probably useless. It is non-toxic even in large doses.

Since cerium oxalate is not absorbed (Bachem, 1907), its action must be entirely local and analogous to that of bismuth. This has been demonstrated experimentally by Baehr and Wessler, 1909: They found that it had no effect on central vomiting (aphorosis), but that large doses delayed vomiting from local gastric irritation (epi-cac). They also showed that central vomiting was not affected even by the soluble and absorbable cerium nitrate. The systemic effects corresponded to those of Thorium, but the metal is excreted exclusively by the feces.

Injection of neutral solution of cerium tartrate injures the heart, lowers the blood pressure, and arrests respiration. Death occurs by pulmonary edema. Repeated sub-lethal doses do not seem to produce nephritis (Ozaki, 1919).

PREPARATIONS—CERIUM

Cerii Oxalati (Cerii Oxal.), U.S.P.—A mixture of the oxalates of cerium (about 40 per cent.; Coblenz, 1920), didymium, lanthanum, and other associated elements. Fine white or slightly pink powder, without odor or taste. In sol. in water, aq. or eth. Dosage: 0.5 Gm., 3 gr., U.S.P.; 0.05 to 0.5 Gm., 1 to 8 gr., as powder.

Cerium Nitrate (soluble) has been substituted, in doses of 0.05 Gm. or less, but is irrational.

YTTRIUM AND ZIRCONIUM

Neodymium, Praseodymium, Lanthanum, Yttrium and Zirconium (as the chlorides) also precipitate proteins, and the observed effects can be attributed to this reaction (antiseptic, paralysis of muscle, etc.) (Dreyfuss and Wolf, 1903; Bachem; Hüber, 1907; Hoebcr and Spagbth, 1914). Their oxalates are all practically non-toxic by mouth, even in enormous doses (50 Gm. per dog).

BERYLLIUM SULPHATE

Seaman, 1912, found that this salt, when administered to dogs with food, resulted especially in nutritional disturbances: emaciation, with loss of N, S, and P. Large doses produced vomiting without acute toxic symptoms. Hydrodynamically, it caused local edema and necrosis. Intravenous injections were markedly toxic, with disturbances of circulation, respiration and temperature; diuresis, bloody diarrhea and vomiting. It inhibits the action of digestive ferments.

THORIUM

The chemic effects resemble those of aluminum. The nitrate of thorium is markedly astringent, precipitating proteins and coagulating blood. Injected hypodermically, it causes ulceration. The toxicity is slight. It is fairly well tolerated by the stomach, very large doses being required to produce vomiting. It is not absorbed from the alimentary canal. The addition of sodium citrate prevents the coagulant action. When this solution is injected intravenously, it has absolutely no effect on the circulation, or any other function, even when 0.25 Gm. are injected per kilogram of dog. However, the animal remains emaciated, and shows ulcers of the gums. When killed, after some weeks, an extensive calcification of connective tissue is noticed. The thorium is excreted by the kidneys. The solutions have no effect on the excised muscle or heart of frogs (Chace and Gies, Brown and Sellmann, 1903). The nitrate was tried for stimulating ulcers, but did not prove superior to alum. The oxalate and oxir are practically insoluble.

The thorium-sodium citrate solution is impervious to X-rays, and has been suggested for radiographic work (Burns, 1915).
RADIO-ACTIVE METALS

General Statement.—Thorium, radium, uranium, etc., undergo atomic decay into a series of new elements (emanation, etc.). This decay is accompanied by the generation of rays which produce irritant or destructive effects. Radium itself is thus used to irrigate or destroy pathologic tissues. The milder emanations are employed especially against chronic joint and rheumatic diseases. Their therapeutic status is still uncertain, but the original expectations were probably too optimistic.

Nature of Radio-activity.—Radio-activity is defined as “the property of spontaneously emitting radiations capable of passing through plates of metal and other substances opaque to ordinary light and having the power of discharging electrically charged bodies.” The rays may be of several kinds:

Cathode rays are produced when an electric discharge is passed through a high-vacuum tube. They are interpreted as negatively charged particles (corpuscles or electrons) sent off from the cathode with very high velocity.

X-rays (Köntgen, 1896) are produced when the cathode rays strike the wall of the tube. They are believed to consist of a series of pulses in the ether, somewhat analogous to light, but sent out at irregular intervals.

Radio-active Metals.—Active rays are also emitted by a number of metals of high atomic weight, and by their compounds, presumably in the course of the disintegration of their atoms.

The discovery of radio-activity started with the observations of Becquerel, 1896, that uranium salts act on photographic plates through black paper. Similar rays were discovered in thorium in 1898 by Schmidt and Mme. Curie; and in the same year the Curies discovered polonium and radium.

The principal radio-active metals are: thorium, radium, uranium, and some others (ionium, polonium, etc.), and their disintegration products. Four kinds of rays are distinguished:

The alpha-rays have low penetrating power, but are most efficient in ionizing gases. They consist probably of positively charged helium atoms. They represent the main energy of radiation.

The beta-rays are more penetrating, with less ionizing action. They are considered as negative electrons, and therefore identical with the cathode rays, except in their velocity. They are also identical with the more slowly moving delta-rays, which are produced when alpha-rays strike solids.

The gamma-rays have the highest penetrating and the lowest ionizing power. They are identical with the X-rays, i.e., they consist of ether vibrations, produced by the impact of the beta particles.

The ratio of these rays varies for the different metals, but is constant for the same metal, independent of its combination or other conditions.

Disintegration of the Radio-active Metals.—A spontaneous disintegration of the atoms characterizes all the radio-active elements, and is the cause of the discharge of the rays. This transmutation is also independent of external conditions. The probable course of the atomic decay for thorium, uranium and radium is as follows:

Uranium minus α = Ur. X; β = and γ = long-lived isotope; β = and γ = Radium; β = and γ = T. Atoms; β = and γ = short-lived isotope.

Radium B; little radiation = Radium C; α = and γ = Radium D; no radiation = Radium E; β = and γ = Radium F; α = (7 Lead).

Thorium α = Mesothorium; β = and γ = Radiothorium; α = Thorium X; β = and γ = Emanation; α = Thor. A; β = and γ = Thor. B; α = Thor. C; α = Emanation; α = Thor. D; β = and γ = Thor. E; α = and γ = Thor. F; α = (7 Lead).

Emanation.—This is the first product of the disintegration of radium. It has the properties of a colorless indifferent gas. It diffuses through porous, but not through tight containers; can be condensed into a liquid by low temperature and volatilized by heat, etc. Its chemical properties resemble the argon group. A similar gaseous emanation is produced by thorium X. When the metals are subjected to high temperature, the gas is driven off and their emanating power is lost; but they recover on resting, as their deterioration proceeds.

Radium Emanation.—“Radium emanation is continuously given off from aqueous solutions of radium salts. It can be collected as it escapes from the solution, drawn off through the use of the mercury pump, or by other suitable means, quantitatively deter-

minded by either the alpha- or gamma-ray electroscope, brought into solution in water for internal or external use or be set free in an emanatorium for inhalation treatment.
It may be collected into small glass containers and this used in place of the applicators described under "N.R. surgical use." (N.N.R.).

Decay of Emanation.—The emanations lose their activity rapidly. That of thorium falls to one-half in one minute and to almost nothing in a very few minutes. That from radium persists for some days. The decay is due to the change of the emanation into radium A (induced radio-activity) or thorium A, with the production of alpha-rays (charged helium). The rate of decay is independent of external conditions, such as temperature.

Induced Radio-activity.—Any substance, liquid, or solid, when left in the presence of radium, acquires radio-activity. This is due to the deposition of a radio-active substance, produced by "emanation X", on the surface. This substance is formed by the decay of the emanation. Its quantity is extremely small. The deposit can be removed chemically or mechanically, f/4, by sandpaper. It also decays similarly to the extrinsically induced radium A, etc.

Properties of Radium.—Radium is a bivalent element, closely related to barium. Because of its chemic reactivity, it cannot be kept in the metallic state and is therefore marketed in the form of its salts, especially the soluble bromide or chloride, and the insoluble sulphate and carbonate. It is generally mixed with more or less of the corresponding barium salts and is sold on the basis of its radium content, as determined by the radio-activity.

Determination of Radio-activity.—This is accomplished by measuring the ionization of gases. Thus when radium is allowed to act on the air in a charged gold-leaf electrometer the air becomes ionized and therefore a conductor of electricity and allows the charge to leak out, causing the leaf in the electrometer to move. By observing the rate of movement of the leaf in a calibrated apparatus the radio-activity can be determined" (N.N.R.).

Units.—"Quantities and concentrations of radium emanation are expressed in terms of "curie" and Mache units. A "curie" is the amount of emanation in equilibrium with one gram of radium; a micromicron, one millionth of a "curie," is the amount of emanation in equilibrium with 0.001 mg radium and is equivalent to about 2,500 Mache units (N.N.R.). A more detailed description of the measurement of radium emanations is given by Stratton, 1915.

Radio-active Thorium Compounds.—Ordinary thorium gives off alpha-rays and changes into mesothorium (discovered by O. Hahn, 1907). Its chemic properties resemble those of radium and barium, differing in the intensity and power of radiation. It gives off beta-rays and changes into Radiothorium, and this, by giving off alpha-rays, passes successively into Thorium X and Emanation. The thorium X is therefore the principal radio-active product. The distribution, excretion and effects are described by Flesch, Karzaz and Kettman, 1912. The actions and therapeutic uses are in all respects similar to radium. It is less efficient, but much cheaper (Schwarz and Zehner, 1912; Fals and Zehner, 1912; Gedzert, 1912). Leducx and Lehard, 1913, consider mesothorium even better than radium against malignant tumors, and believe that thorium X, because of its richness in alpha-rays, is especially suitable for internal medication.

Biologic Effects of Radium Rays.—Exposure to radium affects all living cells, similarly to X-rays. The tissues differ, however, in their relative susceptibility to the different radiations. According to the dosage, the results are irritant or destructive. In higher animals, the irradiation grades from hyperemia to destructive inflammation (Bibliography, Loewenthal, 1912; Hussakoff, 1907).

Intact Animals.—Continued exposure of mice (London) produces in three or four days, nervous depression terminating in coma. In rabbits, the symptoms begin in two weeks and last many months. They consist in loss of hair, ulceration of the skin, nervous changes similar to those in mice, and sexual impotence. In man, exposure has produced persistent diarrhea, vomiting, general weakness and coma.

The susceptibility of the individual organs, according to Horowitz, is greatest in the central nervous system, lymphatic tissues, sexual glands and liver. It is less in the kidneys, spleen, cartilage, muscle, and vessels; least in salivary glands, pancreas and mucous membranes.

Central Nervous System.—Obersteiner found the following symptoms in mice which died after 13 months' exposure: convulsions; forced movement; motor restlessness; paralysis of individual extremities; ataxia; paralysis of sphincters;
trophic disturbances. The autopsy showed inflammatory changes of the entire nervous axis with the degenerative lesions in the nerve cells.

Sexual Organs.—The spermatozoa of guinea pigs, when exposed to radium in vitro, soon lose their motility (London and Goldberg). The testes of exposed guinea pigs show atrophy; degeneration of the epithelium, and absence of sperm (Schoenberg; London; Frieden). The ovaries exhibit analogous changes (Halber- stadtter; London).

Lymphatic Tissue.—This reacts especially strongly. Inflammatory changes are found in the spleen, intestinal follicles, mesenteric glands, etc. (Heinicke; London). Smaller doses destroy the follicles and increase the connective tissue. The leucocytes are diminished by emaciation and by X-rays. It is not known whether there is increased destruction or lessened production.

Blood.—The hypodermatic injection of soluble radium salts produced rapid increase of the red cells, persisting for several weeks. The hemoglobin did not rise as much. The leucocytes were also increased by small doses but diminished by large (Brill and Zehner, 1912). In vitro, sheep corpuscles are hemolyzed, and methemoglobin is formed (thorium X, Schwartz and Ehren, 1912).

Sailer, 1916, reports good results from the radium treatment of polylykemia. Leukemia.—Treatment with X-rays, radium and thorium X causes a temporary decrease of the leucocytes and the size of the spleen, and delays the progress of the disease. The clinical improvement is often even better than the blood-picture. However, the results are not permanent. Repeated treatment may again be effective, keeping the cells about 20,000 to 30,000; but eventually the patients succumb (Stengel, 1917; Griffin, 1917; Peabody, 1917).

Radium is sometimes effective when X-rays or benzoil fail (Ordway, 1916). It is applied over the spleen; or first over the bones.

The serum of X-rayed patients caused immediate and marked reaction on injection into lymphocytic patients (Capps, 1917). However, thorium X also decreases the red corpuscles and produces parenchymatous changes. It should not be used where such lesions exist (Hahn, 1914).

Rosed Heart.—Zweigerman and Feenstra, 1916, 1918, claim that the potas- sium of Ringer’s fluid may be replaced by equiradioactive quantities of any of the radio- active metals; and that therefore the action of potassium in aiding automatic con- tractions is due to its radioactivity. Further work is needed to confirm this theory.

Glucose Permeability of Kidneys.—H. J. Hamberger and Brinkman, 1917, claim that this is also affected by potassium, uranium and radium in equiradioactive doses.

The Blood Vessels of the Skin show dilatation, emigration of leucocytes; later swelling of endothelium and extravasations (Thieff).

The effects of mesothorium on the vessels of the rabbit’s ear were studied by Riker, 1914.

Embyrional Development.—This is hindered in the ova of lower animals, as also in chicken eggs.

Radium radiations thicken the fertilization membrane of Nereis ova (Redfield and Bright, 1918).

Plants.—The leaves and seeds are killed.

Bacteria.—The rays are more feebly bactericidal, the alpha-rays being most effective. Toxicity is probably not injurious (Goldberg).

Ferments.—Autoysis is increased (Neuberg). Other ferments differ in suscepti- bility.

Decomposition of Lecithin.—Schwartz, 1904, observed discoloration and odor in the yolk of hen’s eggs, suggesting decomposition of lecithin. This occurred also in vitro. Wohlgemuth attributed this to stimulation of autolytic ferments; but Menemitz, observed the decomposition even in boiled yolk. Werner and Ascher, 1912, confirmed the decomposition, and showed that the injection of decomposed lecithin or cholin into animals produced degenerative changes analogous to the rays, in the blood, taste,
skin, etc. Promising results were also obtained with tumors. The same effects are produced by thorium X. This also decomposes proteins and reacts with many other organic substances (Knoess and Zezne, 1912). Ferranti and Peabody, 1911, found that the changes by proteins by radium rays resemble those of heat coagulation.

Vitamins.—These are not affected by radium rays or emanation (Funk, 1916).

Surgical Uses of Radium.—These are employed for producing inflammatory reaction or destruction of tissue in skin lesions, birth-marks, scars, epithelioma and other accessible tumors, malignant or benign (pelvic, breast, neck, etc.). Deeper structures may be reached by filtering the gamma-rays through at least 3 mm. of lead. Nearly all pathologic tissues are more sensitive than normal tissue.

Sarcoma is generally more amenable to ray treatment than is carcinoma (Pancoast, 1917). The efficiency is due to the beta- and gamma-rays, which are proportional to the radium content of the salt.

Surgical Application.—The dosage, etc., is still in an experimental stage. Heavy doses are usually employed for epithelioma and deep work (always filtered); and lighter doses for the other conditions.

Roentgen-rays in Cancer.—They are said to be useful in cutaneous epithelioma and localized, superficial, inoperable cancers; but useless in deep-seated or widely disseminated forms (Pusey, 1911; Pflüger, 1912). The use of merthiolate in cancer is discussed by Bumm, 1913 (J. Ewing, 1917, is rather optimistic as to the local treatment of cancer).

Pate Radium.—After oral administration of insoluble radium salts (sulphates) to mice, the digestive tract is strongly radio-active; the other organs and the urine contain mere traces. With soluble preparations, orally or hypodermically, the excreta also occurs mainly by the small and large intestines, and by the lungs; little by the urine, and none by the liver and skin. The excretion of the soluble preparations is prompt; it is very slow after the injection of the insoluble salts (E. Smith and Bellingham, 1912; Brill and Zezne, 1912). The emanation has a high lipid coefficient, and is distributed in the organs in proportion to its solubility (Knafl-Lens, 1912). With inhalation, the amount in the blood increased with the time of exposure. The excretion is rapid, especially by the expired air, and partly by the urine.

Biologic Effects of Radium Emanation.—Large doses produce toxic effects essentially identical with those of radium. The toxic dose for man has not been determined. The actions are greater by inhalation than by hypodermic administration. With the smaller (therapeutic) doses, the effects are somewhat different.

Inhalation of Large Doses.—This leads to dyspnea and depression (but no true narcosis), terminating in death. The autopsy shows widespread hyperemia, with histologic changes in the brain cells, and to a less degree in other central nerve cells. The emanation hemolyzes the blood of guinea pigs, but not of rabbits. It decomposes lecithin (Knafl-Lens, 1912; Poulsson, 1908).

Effects of Therapeutic Doses.—The activity of autolytic fermentes is increased; diastase is first hindered, then augmented; peptin and trypsin are augmented. There is little bactericidal action. The embryonal development of lower animals and the growth of plants is hastened. In healthy man, the leukocytes are first increased, then diminished. The coagulability of the blood is promptly and markedly raised. The blood pressure is generally lowered 20 to 25 mm. (Loewy and Plesch), so that the work of the heart is diminished. This is attributed to vasomotor changes. The hypnotic action which is often observed may be due to modifications in the cerebral circulation. The frog's heart, perfused with activated Ringer's solution, is slowed with increased diastole and irregularities; small doses are sometimes stimulant (Maas).

In rheumatic, gouty and chronic inflammatory conditions the emanation treatment often causes a "reaction," consisting in an exacerbation of the inflammatory symptoms. This occurs after a few days of treatment, and subsides spontaneously if the treatment is continued.

Urate Metabolism.—Investigations with modern methods have failed to show any effect on the uric acid of the blood, by radium, intravenously or by inhalation (Fine
and Cheve, 1912). Less perfect methods led to the general belief that the inhalation of emanation leads to increased elimination of uric acid and purin bases, endogenous as well as exogenous; that this is followed by the disappearance of urate deposits, topik or artificial (Fodanow); and that in gout, the uric acid disappears from the blood, often with subjective improvement. Abl, 1912, also claims increased elimination of endogenous uric acid by thorium X. The mechanism of these effects (if they occur) is not established.

Gudziel claimed that radium D (formed from the emanation but not from the rays), converts in the test-tube the lactim urate into the soluble isomeric lactam, and then into NH₃ and CO₂. Falk and Zeher, 1912, claimed that thorium X also increases the solubility of urates and destroys uric acid. Other observers (Lazarus; Knafl-Leutz and Wiechowski, 1912) have been unable to confirm the destruction. Lazarus attributes Gudziel's results to mould fungi.

Kaplan, 1912, claims that alkaline radium water decreases the uric acid and increases the purin bases: Stechelin and Maase, 1912, affirm that these alkaline waters diminish the gas metabolism in health, but not in gout.

Therapeutic Use in Gout.—Favorable effects are claimed. In most cases the treatment brings on an acute attack, generally mild, in the first six to fourteen days of treatment. Improvement sets in after three to four weeks, parallel to the disappearance of urates from the blood. Cases with anatomic lesions are not so favorable.

Therapeutic Use in Arthritis.—Emanation treatment is said to be markedly successful in chronic joint and "rheumatic" lesions, sciatica, tuberc, pain, etc. The main effect is on the pain but the inflammatory phenomena are also decreased. The improvement is often, but not always, preceded by the "reaction" a flare-up of the inflammatory symptoms (Loewenthal; Fuerstenberg). The late fibrous and anatomic changes are not removed. The results are therefore better in early cases and in young subjects. Acute arthritis, arthritis deformans, and luetic or tubercular lesions are not affected. Progressive polyarthritis and chronic myalga react well.

This was the first, and is probably the most successful use of the emanation (Loewenthal; Laquerre). The mechanism of the action is not explained. It may be mainly anaphoretic. It certainly assumes a direct effect on the inflammation, activation of autolytic fermenters, and general increase of metabolic processes.

Administration of the Emanation.—This can be carried out properly only in specially equipped hospitals. "It may be administered as baths, by subcutaneous injection in the neighborhood of an involved joint (0.05 to 0.5 microcurie in 1 oz or 2 c.c. distilled water), by local application as compresses (5 to 10 microcuries), by mouth as a dusk curie (increasing doses of from 1 to 10 microcuries three or more times a day), or by inhalation, the patient for two hours daily remaining in the emanatorium which contains 0.0053 to 0.25 (average 0.1) microcurie per liter of air" (N.N.R.).

SILVER

General Statement.—The inorganic silver salts, especially the nitrate, are used to produce astringent, caustic and antiseptic effects. They form resistant precipitates with proteins, so that their local action is easily controlled. The toxicity for higher animals is very low, and the antiseptic efficiency is high. In the presence of the tissues, silver surpasses mercury, since the protein compounds of silver are also antiseptic. These may be used directly when antiseptic action without irritation is desired.

Silver is not absorbed in sufficient quantity from the alimentary canal to produce systemic actions. Because of its precipitation by protein and chlorid, even large doses of silver nitrate rarely produce serious poisoning. Long-continued use results in blackish discoloration of the skin (argyrosis) by the deposition of silver particles, probably organic, Tzanos must therefore be absorbed.

Argyrosis.—This develops gradually after prolonged internal or external use of silver when the total dose has reached 15 to 30 Gm. Since silver is now rarely used in this way the condition is infrequent. It has been produced by the application of silver-containing hair dyes. It may also occur locally from the use of organic silver preparations of lacerated tissue (Olson, 1917).
Argyrism consists in a bluish-black discoloration of the skin, especially where exposed to friction of lateral organs and mucous membranes (Frommman, 1877; Rieger, 1876). The black granules do not consist of metallic silver, for they are easily soluble in KCN, and difficulty in concentrated nitric acid. In the skin, they are situated in the lower layers of the corium in the dermal papillae. They remain indefinitely. No silver can be demonstrated in the urine. The argyrism does not give rise to other symptoms. In animals, silver deposition has also been produced in internal organs, but not in the skin.

Argyrism persists indefinitely or disappears very slowly. Crippin, 1914, and Olson, 1916, believe that recovery is hastened by hexamethylenamin. (Mercuric chloride decolorizes the granules in silver, but not in zinc).

Silver Stains.—The stains following shortly after the application of silver salts are quite distinct from argyrism. They are easily removed by 10 per cent. potassium iodid or cyanid; or by 10 per cent. mercuric chloride in 10 per cent. ammonium chloride (Mankiewicz, 1916).

Systemic Actions.—These are never seen in man but may be produced in animals by the injection of non-precipitant silver solutions (AgCl in sodium thiosulphate, Gachgens, 1892; colloidal AgCl or AgI, Gros, 1912). The actions are mainly on the central nervous system, consisting of paralyses and spasms, beginning in the lower extremities; disturbances of respiration; and fall of blood pressure (paralysis of vasomotor center); sometimes diarrhea. The secretion of bronchial mucus is greatly increased, probably by injury to the epithelium, and may lead to asphyxia. Death occurs usually promptly, by paralysis of respiration; the diaphragm being paralyzed before the other respiratory muscles. The heart is but little affected and may beat after death. In frogs, the paralysis is preceded by convulsions (Ball, 1862; Jacob, 1877; Gachgens).

Chronic systemic poisoning shows changes in the blood corpuscles; disturbances of metabolism; cloudy swelling of the heart and skeletal muscle; and fatty degeneration of the liver and kidney (Bogosloowsky).

Therapeutic Use of Silver in Nervous Diseases.—Insanity, Epilepsy, Etc.—This was a survival of the fantastic teaching of the middle ages, when it was based on its dedication to the moon, and the supposed connection of the latter with lunacy. Although it is absolutely proved that silver can not be absorbed in amounts sufficient to have any action whatsoever, it has been tried again and again against all forms of nervous disease, with uniformly negative results.

Local Astringent and Caustic Action.—Silver nitrate acts as astringent, irritant or caustic, according to the strength and duration of its application. The surface first turns white, then gradually gray and black by the reduction to metallic silver and oxide. The nitrate, fused into pencils (“Lunar caustic”) is used in substance for the removal of warts, etc., and the stimulation of ulcers and granulations. The pencils should be moistened before use. Solutions are employed for their astringent and antiseptic action in acute and chronic cutaneous inflammations of mucous membranes, in the following concentrations:

- Ordinary conjunctivitis, 0.2 to 3 per cent.
- Disinfection of conjunctiva (prevention of opthalmia neonatorum), a drop of 2 per cent., followed in a few minutes by normal saline to arrest the action. Larynx, 2 to 10 per cent.
- Urethritis (gonorrheal or other), irrigation with 1:10,000 to 1:20,000. Cystitis, irrigation with 1:5,000. Gastric douche (hyperchlorhydria and ulcer), 1:2,000 to 1:1,000, followed after two minutes by sodium chloride solution.

Penetration of Silver Nitrate.—Contrary to the prevalent opinion, the action of silver nitrate extends quite deeply, since it forms easily soluble double salts of silver and chlorides in the tissues (Unna, Schumacher, 1912).

Antiseptic Concentration.—1:1,000 is fatal to bacterial cultures in five minutes; 1:10,000 in blood serum has a distinct inhibitory effect.

A watery solution of silver phosphate with ethylalcohol is said to be more penetrating, which would be an advantage especially in urology; but it seems to be too irritant (Frenkel). The mucous membranes should always be cleansed before the silver is applied. The solutions must be made with distilled water. The action may be stopped with sodium chloride.
Silver Pills.—Pills of silver nitrate, 10 to 20 mg., $\frac{1}{4}$ to $\frac{1}{2}$ gr. (made with kaolin and petrolatum), are sometimes used in gastric ulcer, etc. There is probably a slight local action before the silver is precipitated, and after it is dissolved by protein. The esid, 0.01 to 0.1 Grm., $\frac{1}{4}$ to $\frac{1}{2}$ gr., may be similarly employed.

Silver-protein Compounds.—These are practically non-precipitant and therefore non-astrangent and non-irritant; but they possess a limited degree of antiseptic and germicidal effects when in the presence of proteins (Culver, 1912; Dakin and Danham). The most important may be arranged under 3 types (Sollmann, 1918):

They are used in gonorrhea (0.1 to 2 per cent.); conjunctivitis (0.5 to 5 per cent.); nose and throat infections (2 to 10 per cent.); etc.

The products usually dissolve slowly in cold water. The solutions decompose on exposure to light.

Germicidal Efficiency.—Pitman, 1912, claims that their germicidal action depends entirely on their uncombined silver, and is therefore inseparable from irritation. Verhoeft, 1906, charts that the germicidal properties of argyrol and protargol are completely destroyed by serum. Others attribute the effects purely to the physical (demulcent) characters.

Dakin and Danham found that a 5 per cent. solution of argyrol in a blood-serum and muscle extract mixture infected with staph, aur. required more than 6 hours for complete sterilization. This would be practically useless.

On the other hand, Young et al., 1910, state that 20 per cent. argyrol kills B. coli and auresus within 5 minutes; and that 1 per cent. protargol also kills coli within 5 minutes, but auresus not in an hour.

Gonococci are apparently much more sensitive, for Culver, 1918, reports hydrocele-broth cultures killed by momentary exposure to $\frac{1}{2}$ per cent. argyrol or 0.4 per cent. protargentum.

(Early Preventive) Treatment of Venereal Diseases.—The ordinary routine consists in washing the parts thoroughly with soap and water; followed by the method of injection of 2 per cent. protargol-strong solution which is held in the urethra for 5 minutes. The glans is then inunctioned with 30 per cent. calomel ointment for 5 minutes.

The efficiency is high if the treatment is applied thoroughly within an hour after exposure, and is fair up to three hours. It is practically useless after five hours (see Young, 1915).

Freshly precipitated silver iodid was recommended by Siter and Uhle, 1908; but has not been shown generally. Thum, 1915, gives a formula for concentrated solutions of silver iodid. Colloid silver was discussed under "Colloid Metals."

Toxic Actions.—Silver nitrate to 0.05 or 0.1 Grm. by mouth produces no symptoms. Swallowing pieces of the pencils up to $\frac{1}{2}$ Grm., is also often harmless. Larger quantities cause acute gastritis. The fatal dose would be above 10 Grm. (Levin); even 30 Grm. have been survived. The treatment would be by sodium chlorid and demulcents.

PREPARATIONS—SILVER

Argentum Nitricum (Arg. Nit.), U.S.P.; Argent. Nit., B.P.; Silver Nitrate (Lunar Cautel); AgNO₃.—Colorless crystalline tables, becoming gray to black on exposure to light in the presence of organic matter. Odorless; metallic taste. Very sol. in water (1:4); sol. in alc. (1:3). Incompatible with chlorids, bromids, iodids; carbonates and hydr- ids; organic drugs and reducing agents. Dose, 10 mg., $\frac{1}{4}$ gr., U.S.P.; 16 to 30 mg. $\frac{1}{4}$ to $\frac{1}{2}$ gr., B.P. Maximum dose, 30 mg., $\frac{1}{4}$ gr.

Argentum Nitricum Paste (Arg. Nit. Fus.), U.S.P.; Milled Silver Nitrate (Stick Cautel).—AgNO₃, fused and molded into pencils. A small quantity of AgCl is added to toughen the mass.

Argentii Oxidum, Arg. Oxid., U.S.P.; Ag. O.—Heavy, dark brownish-black powder; odorless; metallic taste. Very slightly sol. in water. Dose, 0.06 Grm., 1 gr., U.S.P.

"Argentum Collodial, Collodial Silver (Collargol, etc.).—Colloidal silver and silver oxid, with sufficient protein to stabilize the solution. Commercial brands contain various amount of silver, up to 78 per cent. (Collargol). Occurs as black scales, easily soluble in water. Not precipitated by chlorids; non-astringent. Used mainly for intravenous injection. In case of collargol, the intravenous dosage is 10 to 20 c.c. of 2 per cent. As it contains eggs-albumen, it should not be employed with patients having idiosyncrasies toward this protein.

"Protagrin Müll, N.N.R.; Mild Protargin (Argyrol, etc.).—Colloidal reduction products of silver, stabilized by protein; entirely non-irritant and non-astringent; 20 to 25 per cent. of silver. The commercial brands differ as to protein base, and probably also in the proportion of the various silver reduction products; but these differences appear to be therapeutically unimportant. They occur generally as black scales, readily soluble in water; not precipitated by chlorids. Applied as to 10 per cent. solutions in water,

"Protargol Fortius, N.N.R.; Strong Protargin (Protargol, etc.).—Colloidal reduction products, probably largely silver proteinate; slightly but distinctly irritant; 7 to 8.5 per cent. of silver. Commercial brands differ in details of composition, but are practically equivalent therapeutically. Occur usually as brown powders, slowly soluble in water; not precipitated by chlorids. Applied as 0.1 to 10 per cent. solutions. Solutions are best made by sprinking the powder on cold water, without stirring.

GOLD AND PLATINUM

Gold and Platinum are still more easily reduced to the metallic state than is silver, and are therefore devoid of general action when taken by the mouth. When injected into the circulation they produce an arsenic action. (Gold, Schults, 1892; Platinum, Kohler, 1878; Cohnheim, 1892).

Gold cyanid was advised against tuberculosis and scrofula by Chrestien 1853. It fell into disuse, but has again been resuscitated, with doubtful justification. Bruck and Glièreck, 1913, claim successful results from intravenous injection of gold-potassic cyanid (especially when combined with tuberculin!) in lepus; also in syphilis, though inferior to salvarsan. Hauck, 1913, however, reports a fatal result.

DeWitt, 1912, found gold salts unsuccessful in experimental tuberculosis of guinea pigs. Indeed, they tended to shorten life, through hemorrhage and hyperemia. Further references in Merck's Report, Vol. XXVII.

PREPARATIONS—GOLD

Auri et Solvi Chloridum (Aur. et Sod. Chlor.), U.S.P.; Gold and Sodium Chlorid.—A mixture of equal parts of anhydrous gold chlorid (AuCl3) and anhydrous sodium chlorid. Orange-yellow powder, odorless, saline and metallic taste; deliqueissant. Very sol. in water. Dose, 5 mg. 1/4 gr., U.S.P.

TIN

Actions.—This metal is absorbed in part even from non-corrosive preparations. However, poisoning is rare, the metal not passing very easily into soluble form, and having no pronounced tendency to cumulative action. The symptoms on injection develop to some extent on the central nervous system, as stimulation and subsequent paralysis. The arsenic action and paresis of the heart are also prominent. With more chronic poisoning the gastroenteritis is most marked, but there is also an ataxia and motor paralysis, resembling chronic lead-poisoning (White, 1850). Saltzer, 1912, reports chronic poisoning resulting from a dental plate of "Watt's metal."

There were nervous symptoms and anemia.

Absorption and Fate.—When soluble salts of tin are fed, a small quantity is absorbed and accumulates in the tissues, traces appearing also in the urine. When soluble salts are injected hypodermically elimination occurs slowly, mainly by the alimentary tract, but some appearing in the urine, producing marked injury of the kidneys. Considerable quantities are retained; 20 to 25 per cent. in the skin, 5 per cent. in the liver (Saltzer and co-workers, 1912).
COPPER

General Statement.—Cupric sulphate irritates the nerve endings in the stomach which give rise to the vomiting reflex, and thus has a rather specific emetic action. It is also used on mucous membranes as an astringent and caustic. It has a relatively high toxicity for fungi, protozoa and algae, and has been employed for the purification of water, etc. It is not a reliable bactericide. Its absorption is limited and its toxicity to animals is therefore low. Its use for brightening the green color of vegetables is innocuous under proper conditions, but under others it may be somewhat harmful.

Emetic Action.—Copper sulphate is effective and prompt, with short nausea. However, it is irritating; and should not be effective, there is some danger of poisoning, and it must be removed by lavage. It is therefore not recommended, except in phosphorus poisoning, in which it oxidizes the phosphorus and coats the globules with a layer of metallic copper. The emetic dose is 0.5 Gm., 8 gr. in a single dose; or three doses (if necessary) of 0.25 Gm., 4 gr. each, fifteen minutes apart. It should be dissolved in a glass of water.

Astringent and Caustic Action.—Solid copper sulphate is used as a mild escharotic against granulations and trachoma. The everted lid should be lightly touched with the copper crystal or pencil, and then rinsed with water. The pencils are made by fusing 1 part of potassium alum with 2 parts of copper sulphate. Solutions of 0.1 to 3 per cent. may be employed as stimulant astringents in conjunctivitis, urethritis and vaginitis, but have no particular advantage over silver. Copper sulphate would probably be effective against aphthous stomatitis and other fungous diseases. It has been used internally against chronic diarrhea, 10 mg., 3/4 gr.

Antiseptic Action and Use in Water Purification.—Copper is markedly germicidal for fungi and algae, and fairly effective against bacteria of the coli group. It may be used to purify water from algoid contamination. The traces of copper remaining in the water are probably harmless. Its use against typhoid contamination seems to be unreliable (Clarke and Gage, 1906). Thomas, 1915, describes its use for the disinfection of swimming pools.

The mechanism of the action of copper on lower plants is discussed by Spiro, 1915.

Copper-Alum.—Shaw-Mackenzie, 1916, claims that this is not precipitant, and of very low toxicity to higher animals, but that it kills protozoa in dilutions of 1:20,000.

Copper Salts of Amino-acids.—H. C. Huber, 1919, reports that these act locally and systemically almost quantitatively like copper sulphate.

Toxic Actions.—Large doses of soluble copper salts produce mainly gastroenteritis, and characteristic lesions of the spleen, kidneys and other organs. The toxicity is low. The absorption is very limited.

Even on continued use, quantities of the copper sulphate up to 0.5 Gm. per day have been shown to be devoid of bad effects (Du Moulin). It is true that these were not continued indefinitely.

Absorption from Skin.—C. L. Vogt and Burckhardt report that copper oleate is absorbable.

Use of Copper in Foods.—Copper is sometimes used to give a bright green color to preserved vegetables, especially peas and beans. These contain 25 to 120 mg. per kilogram. The copper enters into a very firm compound with the chlorophyll. Other vegetables, which are not so rich in chlorophyll, contain it in much looser combinations with proteins. The chlorophyll compound produces no effects of any kind, even when continued for long periods in quantities corresponding to 12 to 15 mg. Cu per day, the maximum amount which would be taken in food. However, the same question, when more loosely combined, produce some digestive and metabolic disturbances.
The use of copper with young green vegetables would therefore be harmless; but with older vegetables it could become harmful, and its use would better be prohibited (J. H. Long, 1912).

**Occurrence of Copper in Tissues.**—Copper is not usually present in mammalian tissues; but after its administration, it occurs in the liver mainly as cupric nucloinates, and in the blood and bile. Traces are also retained in the kidneys, spleen and lungs; none in tubercular lymph glands or pus. Colloid copper, injected intravenously, shows a similar distribution (Copner, 1914).

It is found naturally in organic combination in the liver and other organs of cephalopods (octopus), snails and mussels; and as a blue blood pigment, hemocyanin, in mollusks and crustaceans. This is somewhat analogous to hemoglobin and contains about 35 per cent. of Cu in masked form (Henze, 1902). Copper is also a constituent of the feather pigments of certain birds.

**Systemic Actions.**—Direct contact with copper salts depresses skeletal and cardiac muscle. Intravenous injections therefore lower blood pressure.

The effect of colloid copper on tumors was discussed in the general article on "Metals."

**Bibliography.**—An extensive list is given by Huber, 1918.

---

**PREPARATIONS—COPPER**

*Cupri Sulphate* (Cupr. Sulph.), U.S.P., B.P.; Copper Sulphate (Cupric Sulphate, Blue Vitriol, Bluestone); CuSO₄ + 5H₂O.—Large, deep blue crystals; odorless; metallic taste. Freely sol. in water (1:2.5); slightly sol. in alc. (1:500); freely sol. in glyc. (1:2.8). *Incompatible* with fixed alkalies and carbonates; iodides; tannins; lead salts. *Dose, Emetic, 0.25 Grm., 4 Gr., U.S.P.; 0.5 to 2.0 Grm., 5 to 10 Grs., B.P.; as Astringent, 0.06 to 0.12 Grm., 1/4 to 2 Grs., B.P., diluted.* Maximum dose, 1 Grm., 15 Gr.

---

**ZINC**

**General Statement.**—The actions of the soluble zinc salts resemble those of copper, but are milder. Zinc sulphate is employed as emetic, and locally as astringent and antiseptic. Other soluble zinc salts are also used locally. The acetate is milder; the chlorid is escharotic. The insoluble zinc oxide and stearate are used externally as protective, similarly to bismuth. There are no systemic effects under therapeutic conditions.

**Zinc Sulphate as Emetic.**—This acts like copper, and is generally preferred, being nearly as efficient and less irritating. The short nausea, slight depression and absence of harmful irritation makes it particularly suitable in gastric disturbance from overeating, etc. 1 to 2 Grms., 15 to 30 Grms. may be given in a glass of water.

**Astringent and Antiseptic Action.**—Zinc sulphate or acetate is used in conjunctivitis, particularly that caused by the Morax-Axenfeld bacillus; and in chronic gonorrhreal urethritis and other catarhal conditions. The strength of solution for collyria is 0.1 to 1 per cent.; for urethral injections, 0.5 to 4 per cent. The phenolsulphonate has no advantage.

**Zinc Chlorid as Escharotic.**—This is used as the Liq. Zinci Chlor. on granulations, ulcers, etc.

**Zinc Chlorid as Disinfectant.**—This has been extensively exploited and overestimated in proprietary preparations. MacClintic, 1905, finds 1:200 to 1:500 a very poor germicide and feeble antiseptic, though a fair deodorant.

**Insoluble Zinc Compounds.**—Zinc oxide is mildly antiseptic and astringent. It is extensively used as a local sedative application in inflammatory skin diseases and superficial wounds. It may be applied dry or as an ointment, alone or mixed with boric acid, bismuth subnitrate, starch or phenol. Zinc stearate is perhaps somewhat smoother as a dusting powder, but has no other advantage.
Zinc in Food.—Birckner, 1910 found that traces of zinc are common in many foods, including milk (about 4 mg. per quart) and eggs (1 mg. per hen-egg). Zinc is almost invariably present in oysters from the Atlantic ocean. It is probably always associated with copper, and the two metals do not occur in uniform ratio (Hiltnner and Wichmann, 1910).

Systemic Action.—The effects of intravenous injection are mainly paralytic. The brain is affected first—the, i.e., consciousness is lost—but the motor areas are not involved. The blood pressure falls rapidly, but this is mainly due to the cardiac depression. The skeletal muscles are but little affected. Zinc salts are not sufficiently absorbed to produce systemic effects on oral administration. Zinc oxid has been used as a nervous sedative, in epilepsy, etc., but is probably useless. The movements of excised intestines are depressed by very dilute solutions; abolished by medium concentrations (Salant and Mitchell, 1916).

Urine.—Rabbits develop glycosuria, and generally albuminuria after intravenous injection of zinc malate, also after larger doses hypodermically or by mouth. The quantity of urine is either diminished or unchanged; rarely increased. Rabbits fed on carrot urine are more resistant (Salant and Vibe, 1918).

Industrial Poisoning.—"Brass founders'ague" is produced by the inhalation of the finely divided zinc oxide formed in the combustion of the metal—even of pure zinc (Lehmann, 1910). It has not been observed in animals, but only in man. After exposure of several minutes or hours—depending on the susceptibility and ventilation—there is slight irritation of the throat; but the main symptoms occur later, often after the patient has been in the air for some hours. The attack resembles a malarial chill, which may last some hours, with ordinary febrile symptoms—lassitude, headache, nausea, muscle cramps and joint pains, constriction sensation over lungs, etc. The attack ends in perspiration and rapid recovery (W. G. Thompson, 1912; Hayhurst, 1913; Pfender, 1914). Lehmann attributes the symptoms to the absorption of the remains of the respiratory cells that were destroyed by the zinc. The hypodermic injection of zinc salts also produces fever (Kisskalt, 1913); but so do most irritants. Repeated exposure to zinc fumes may result in chronic lesions of the respiratory, digestive, excretory and nervous systems (Hayhurst, 1913).

PREPARATIONS—SOLUBLE ZINC SALTS.
Zinc Acetate (Zinc. Acet.), U.S.P., B.P.; Zn(C2H3O2)2 + H2O.—Soft, white plates; faintly acetic odor; astringent, metallic taste. Freely soluble in water (1:2.3); sol. is alcal. (1:1.7). Dose, 0.1 to 0.2 gm., 2 gr., U.S.P. 0.1 to 0.2 gm., 1 to 2 gr., B.P.
Zinc Chloride, U.S.P., B.P.; ZnCl2.—White granular powder or porcelaines-like masses or in pencil; odorless; highly caustic. Very sol. in water (1:0.25); freely sol. in alc. (1:1.3) or glyc.
Zinc Chloride, U.S.P., B.P.—An acid solution, containing about 50 per cent of ZnCl2.
Zinc Chlorid (Zinc. Chlorid), U.S.P.; (Zinc Phosphoroxyd); Zn(C2H3O2)2 + 2H2O.—Colorless, transparent prisms, or tabular crystals or in granular form; odorless; astringent metallic taste. Freely sol. in water (1:1.6). Dose, 0.15 to 0.2 gm., 2 gr., U.S.P. Locally, similar to Zinc Sulph.
Zinc Sulphate (Zinc. Sulphur), U.S.P., B.P.; Zinc Sulphate (White Vitriol); ZnSO4 + H2O.—Small colorless crystals odorless metallic taste. Very sol. in water (1:3.5); practically insol. in alc. Incompatible with alkalies, carbonates, sodium borate, tannins, lead salts. Dose, as Emetic, 1 gm., 1 to 2 gm.; U.S.P. 0.5 to 1 gm., 10 to 30 gr., B.P.; diluted; as Astringent, 0.05 to 0.2 gm., 1 to 3 gr., B.P. Maximum dose, 5 gm., 13 gr.
Zinc Valerian (Zinc. Valerian.), U.S.P.; Zinc Valeriana, B.P. (Zinc Valeriana); Zn(C2H3O2)2 + 4H2O.—White, nearly scales, or white powder; odor of valeric acid, sweetish, astringent, and metallic taste. Dose, 0.125 gm., 2 gr., U.S.P.; 0.05 to 0.5 Grm., 1 to 3 gr., B.P.

PREPARATIONS—INSOLUBLE ZINC COMPOUNDS.
Zinc Carbonate Precipitatus (Zinc. Carb. Precip.), U.S.P.; Zinc Carb., B.P.—Basic Zinc Carbonate is a compound of somewhat variable chemical composition, corresponding to not less than 65 per cent of ZnO, U.S.P. Impalpable, white powder without odor or taste. Insol. in water or in alc.
Zinc Oxidum (Zinc. Oxid), U.S.P., B.P.; ZnO.—Very fine amorphous, white or yellowish powder, with a metallic or sweet taste. Practically insol. in water or in alc. Incompatible with acids. Dose, 0.2 to 0.6 Grm., 3 to 10 gr., B.P.
*Zinc Oxide* (Zink Oxidum, U.S.P. (Zinc Oxide), 0.02 per cent in Benzo Lard.

*Zinc* (Zink), B.P.—1% per cent of ZnO in Benzo Lard.

Lassar’s Paste, white is used in eczema, contains Zinc Oxide 1 part, Starch 1 part, Petrolat., 2 parts.

Zinc Stearate (Zinc Stear.), U.S.P., Zink Oleoestear (Zinc Oleost), B.P.—A zinc soap, White amorphous, insoluble, bulky powder.

*Zinc Oleost*, B.P.—A zinc soap, incorporated with white soft petrolatum.

**CADMIUM**

This resembles zinc closely.

The chloride is a powerful emetic (15 to 25 mg. per cat). It produces nephritis. Hypodermic injections are followed by local necrosis. Intravenously, it kills by arrest of respiration. Small doses diminish the appetite and growth of rats. The action does not appear to be cumulative (Alsberg and Schwartze).

**NICKEL AND COBALT**

These metals are only absorbed when given in strongest solutions. The local action is that of metals in general, with nothing particularly characteristic. Nickel salts have been used as emetics, but are not to be recommended. Nickel cooking vessels give up a harmless trace of the metal to the food (Dzierzowski and Schumoff-Sieber, 1906 and 1908; Lehmann, 1900).

Nickel-platers are subject to eczema (see J.A.M.A. 12:783, 1919).

When injected intravenously or hypodermically, these metals affect the central nervous system directly, in addition to the usual metal action on capillaries, heart, and kidneys. There are tremors, chills, and convulsions, followed by paraly. In frogs the medulla is stimulated before the spinal cord (A. Stuart, 1884). Some habituation occurs.

The urine is increased, and always contains sugar, often proteins. Cobalt salts act as antidotes to HCN poisoning, through the formation of cobalt-cyanide. To be effective they must be introduced subcutaneously in doses which are not devoid of danger. They are therefore not to be used in man.

With *caecitis intestinalis*, dilute solutions of nickel salts produce primary depression, which may be followed by stimulation. Higher concentrations abolish the movements. Nickel is much less toxic than zinc (Salant and Mitchell, 1919).

**Nickel Carbonyl.**—This gas—Ni(CO)₄—is formed by passing CO over finely divided nickel, as in the Mond process of obtaining pure nickel. It decomposes at 150°C. into CO and metallic nickel. The toxic effects are probably due to the deposition of the metal in the respiratory tract, for the carbonyl is not absorbed as such. The phenomena following its inhalation are very serious. There is transient malaise, with quick recovery in fresh air; but after twelve to thirty-six hours the patient becomes dyspneic, cyanotic, febrile, and delirious, with a blood-stained cough. Death occurs in four to eleven days, with hemorrhages (due to fatty degeneration of the vessel walls) in the lungs and brain, and pulmonary edema (Mond, Langer and Quincke, 1890; Arnfitt, 1907, 1908).

**MERCURY**

**General Statement.**—Mercury, particularly in the mercurial salts, has a strongly toxic action on all protoplasm. In virtue of this action mercurial compounds are active germicides; but their usefulness is limited by precipitation, irritation and general toxic effects. Even the insoluble mercury compounds are rapidly absorbed, distributed through all the tissues, and excreted by all channels, but mainly by the urine and feces. Traces remain in the body for many months. Acute poisoning presents chiefly the phenomena of local corrosion. The characteristic features of systemic poisoning are stomatitis, dysentery, and nephritis. In chronic poisoning, nervous symptoms, and cachexia appear.
Mercury kills the parasites of syphilis, and therefore may have a curative effect when properly used. Calomel is relatively insoluble and mild, so that it may be employed as a cathartic and diuretic.

Antiseptic Actions.—Mercuric chloride is one of the most effective of the mercurial germicides, since it dissociates readily and therefore gives the maximum concentration of mercuric ions, which produce the antiseptic effect. In pure cultures it inhibits the growth of most microorganisms in dilutions of 1:30,000 to 1:20,000; it is germicidal in 1:2,000 to 1:1,000. Spores and tubercle bacilli are more resistant.

Application.—Corrosive sublimate is used outside of the body, on hands, etc., in concentrations of 1:1,000. On exposed tissues, as 1:5,000 to 1:2,000.

In wounds, however, mercuric salts are not so useful; their activity is greatly lessened by the proteins; and they cause much irritation and toxic effects. These last are particularly to be feared when large serous cavities are irrigated.

Mercury compounds produce rapid corrosion of metallic instruments and a more gradual destruction of rubber.

To hasten the solution, to prevent precipitation in the water and to lessen the irritation it is customary to add some sodium or ammonium chloride, as is done in the commercial bichlorid tablets. These form double salts which are less dissociated and therefore somewhat less active (Sabatani, 1906). Hydrochloric, tartaric and citric acids have similar effects.

Mercury compounds are used in various skin diseases, especially those of parasitic origin. The bichlorid in Pityriasis and Syphilis; Blu-Ointment against Pediculi; White Precipitate against Impetigo; etc.

Potassium-Mercuric Iodid.—This is at least an equally efficient antiseptic, and has the advantage of being much less precipitant or irritant. It may be used on catarrhal mucous membranes, boils, etc., in 1 per cent. solution (Macfarlan, 1914).

Constitution and Actions of Mercury Compounds.—This has been compared by Tuwatsangming, 1919. He found that the local action is strongest with inorganic mercuric compounds. The systemic toxicity is highest for inorganic mercuric salts; the came the organic compounds; inorganic mercurous salts being the weakest.

Mercuroprophene (Sodium oxymerycuri-orthonitrophenolate).—This was introduced by Schamberg et al., 1917, 1919 as a highly promising germicide. It was found at least as effective as mercuric chloride, and at the same time much less precipitant and corrosive, and also less toxic. Further reports are necessary.

"Mercurochrome 220": Chemistry.—This compound was developed by Young et al., 1919. It is dibrom-oxymerycuri fluorescein.
It contains 26 per cent. of mercury. This is non-ionized, so that it does not directly give the mercury tests, and does not readily precipitate protein. It is therefore practically non-irritant. The sodium salt is freely soluble. The free acid may be precipitated by strongly acid urine (pH = 3), but not by ordinary acidity (pH = 6.5). It stains the skin red; this is removable by 2 per cent. permanganate; followed by 2 per cent. oxalic acid.

Penetration.—The color of the substance easily shows its penetration. With urethral and vesical injection, microscopic sections show staining of the epithelium, most intense in the superficial layers, but extending somewhat into the submucous.

Irritation.—In the urethra, a 5 per cent. solution causes temporary burning; 1 per cent. produces at most slight smarting. One per cent. solutions have been injected into the human bladder and renal pelvis, without bad effects. Rabbits' conjunctiva is not noticeably irritated by 1 per cent.

Bactericidal Efficiency.—Bacteria in urine-cultures, are killed more promptly than by other antiseptics that are available for mucous membranes; a concentration of 1:1000 kills in one minute; 1:100 in 10 to 30 seconds.

Toxicity.—This is relatively low, but excessive absorption would doubtless produce nephritis, as with all other mercurials.

Clinical Efficiency.—Promising results are reported in old and refractory cystitis, pyelitis, gonorrhea and chancroid. Further experience is desirable. It is applied in concentrations of 1/4 to 2 per cent.

Chloro-mercur-fluorescin.—Davis, White and Rosen, 1919, find that this is partly decomposed, after intravenous injections; but that nevertheless, non-toxic doses render the urine antiseptic. It may have a field as urinary antiseptic, if it does not injure the kidneys. It has not been tried adequately.

Tetrahydroxy-mercury Phenol Sulphonphthalain on Kidneys.—This produces in dogs acute and chronic nephritis, resembling the human type, anatomically and in the urine and blood changes. No lesions were found in other organs (J. E. Burns et al., 1916).

Germicidal Efficiency of Calomel.—This is generally considered much inferior to mercuric chloride; but Schambeg and Kolmer, 1914, contend that it and other insoluble mercury salts are equally effective.

Local Irritation.—The soluble mercuric salts are strongly irritating. They coagulate proteoplasm and thus give an ashy color and cooked appearance to the tissues, which are slowly corroded. These local changes are especially important in acute poisoning. The intact skin is also irritated; 1 to 5 per cent. causes vesication and corrosion; and sensitive skins may become inflamed by the strengths used in operations.

Mercurials in Ophthalmology.—Mercury preparations are used in a number of inflammatory eye diseases; conjunctivitis, blepharitis and keratitis.

Hydargyrum Oxidum Flavum is employed most extensively as a 1/10 to 1/4 per cent. ointment (made by diluting the official 10 per cent. ointment—Pagenstecher's Salve). Hydargyrum Ammonium is somewhat less irritating and is used as 1 to 10 per cent. ointment.

Calomel is also used as a dusting powder, but especially on ulcers. Mercure Chlorid is antiseptic, but very irritating to the eye. It may be used as 1:5,000 to 1:20,000, with boric acid. Subconjunctival injections have also been employed, but their usefulness is doubtful (de Schweinitz, 1863).

Mercurials and Iodid on Eye.—Mercury compounds should not be applied to the eye when the patient is using iodids; the very irritant mercuric iodid is formed on the conjunctiva and causes severe injury. Iodin compounds that do not ionize readily (iodtripin) naturally produce but little reaction (Grunme-Fohrdre, 1914). Bromids behave like iodids, but chlorids are harmless (Schloms, 1913).

Absorption, Fate and Excretion.—Mercury compounds and metallic mercury are absorbed readily from all surfaces, even from the intact skin.
All of these channels are used therapeutically. After their absorption, the mercury disappears rapidly from the blood; being taken up partly by the lungs, the kidneys, and, in variable organs, especially the kidneys and liver. Here the mercury appears to be fairly firmly bound, forming "deposits" from which traces of the metal may be mobilized for six months or longer after discontinuing the administration.

The excretion occurs mainly by the urine and feces (Wellander, 1886). These take a variable, but on the whole about equal share. There are reasons to believe that the urine plays the main part in the excretion of the organic, the feces of the inorganic compounds (Müller, Schoeller and Schratt, 1911). The excretion begins in a few hours, and after a single dose lasts for perhaps eight days; after long-continued administration the excretion persists intermittently for many months.

**Form of Absorption.** — The compounds undergo complex changes in the course of their absorption. **Metallic mercury** is readily oxidized, and then behaves as the other forms. **Mercuric salts** form soluble organic compounds with the proteins, NaCl, and alkalies (Voit, 1857).

**Distribution in the Body.** — The proportion of mercury is greatest in the kidneys; then in descending order, come the liver, spleen, bile, intestinal wall (Ullmann, 1892; Abelin, 1912). Tutusseming, 1916, confirmed this distribution. He also found some in the heart, and a little in the brain. The concentration in the brain was greatest with mercuric salts, even though death occurred much more rapidly than with mercurous salts.

Mercury has been reported in the cerebrospinal fluid (Conti and Zufoli, 1906); but Lasarew, 1912, found it absent in mercurial treatment and poisoning. If mercurial vapor has been inhaled, the metal may be found in the lungs. The deposition in the liver is said to be lessened by potassium iodid (Blumenthal and Oppenheim, 1914). It is sometimes found in the placenta and in the embryo, but probably only after very long time. It may injure the sex organs of adults. It is claimed, however, that congenital syphilis may be treated by mercurial inunction of the mother (Jung, 1914).

The distribution of mercury in acute poisoning is discussed by Kahn, Andrews and Anderson, 1914.

In a case of death occurring 8 days after taking a large quantity of mercuric chloride, Rosenbloom found the largest amounts in the liver (40 mg.); blood (12 mg.); and muscles (46 mg.). The kidneys contained only 6 mg.

The distribution of aromatic mercury compounds is described by Blumenthal and Oppenheim, 1914.

**Metallic Mercury Globules in Tissues.** — These have been reported in necrotic bone, and in the tissue of an aortic aneurism, presumably after inunction treatment (Kolmer and Mastin, 1918).

**Minor Channels of Excretion.** — Variable traces are generally found in the bile, sweat (Tachau, 1911; Lambert and Paterson, 1915), gastric (Lieb and Goodwin, 1910) and intestinal juice and saliva (literature in Alsinqu, 1912).

**Rate of Excretion.** — Buchta, 1911, found that the excretion, after intramuscular injection of mercury salicylate, was greatest on the following day. With intravenous injection, the greatest excretion (often half) occurred within twenty-four hours.

Ramsey and Ziegler, 1918, observed the urinary excretion (on children) as follows: After a single inunction, the rate of excretion was usually greatest during the first day; but the excretion was not completed for some time.

With daily inunctions, the excretion was not continuous, but periodic; large quantities appearing at one time, mere traces at another.

With the following methods, the excretion continued beyond 8 or 9 days, so that daily administration would lead to cumulation.

**Mercuric salicylate in oil, hypodermic.**

**Mercuric chloride, intramuscular.**

**Calomel, 0.016 gm. for 4 doses, oral.**

**Gray Powder, 0.05 gm. for 4 doses, oral.**

Potassium iodid, diuretics and sweating are said to hasten excretion; but there is little evidence for this. Buchta, found that the iodid rather delayed the urinary elimination of mercury.

**Excretion of Metals in Cows’ Milk.** — Lead is excreted into the milk, but not mercury, antimony or zinc (Koldevijn, 1910).
Varieties of Mercury Poisoning.—These may be classed under three forms:

(a) Acute, occurring generally from the abuse of mercuric chloride, chiefly with local phenomena.
(b) Subacute, especially in the therapeutic use of excessive doses.
(c) Chronic.—This may also occur medicinally, but is seen especially in industrial poisoning (workers in mercury, manufacturers of thermometers, mirrors, electric lamp bulbs, felt hats, etc.). A large proportion of those exposed to mercury are affected, because the adherence of the metal to the skin, and the inhalation of its vapor, makes protection difficult.

Phenomena of Acute Poisoning with Mercuric Salts.—The immediate effects are due to coagulation, irritation and superficial corrosion, to which mucous membranes are highly susceptible. There is an astringent metallic taste, salivation; burning, swelling and ashy discoloration of the mouth and pharynx; thirst; abdominal distress and pain, at first epigastic, then diffused; vomiting with white or often bloody mucous shreds; sometimes edema of the glottis.

The primary symptoms generally yield to local treatment, including abstention of food for thirty-six hours; and the patient may be quite comfortable. Signs of mercurial stomatitis usually develop in twenty-four hours, but are not especially severe.

Somewhat later, after absorption, the large intestines and kidneys are chiefly involved. Within two or three days, the urine shows albumin and casts, and becomes scanty. Anuria may be complete, with death within a week, without uremic convulsions. If the nephritis is not extreme, a membranous colitis develops, with dysentery and tenesmus, ulcerations and hemorrhages and hepatic degenerations. These phenomena may only appear, and prove fatal, several weeks after taking the poison (Lambert and Patterson, 1913).

The circulation is affected only in the severest cases, with a fall of blood pressure, probably mainly cardiac (v. Mering, 1880), perhaps with some vasomotor involvement. The poisoning then ends with feeble pulse, insensibility of the skin, coma and collapse.

The course is therefore variable; death may occur in a few hours, but is generally postponed for several days.

In case of recovery, the phenomena of subacute poisoning set in: nephritis, stomatitis and colitis, as described.

If the poison has been taken otherwise than by mouth, the symptoms, except the local ones, are strictly similar.

Postmortem Changes.—The mucous membranes are of an ashy color, congested and corrodated. The kidneys show acute nephritis, often with calcification of the epithelium. The lesions in the colon are indistinguishable from those of dysentery: coagulation necrosis with hemorrhages and black ulcerations. In experimental poisoning, degenerative changes are found in the kidneys, much less in the liver (Morel, Mourgues and Policard, 1912).

The viscosity of the blood (not of the serum) is doubled in mercurial, lead, and phosphorus poisoning (Farmacidin, 1912). A neutrophile hypoplasmyosis is a constant phenomenon (Donzello, 1915).

Toxic Doses.—These may be stated as follows:

Mercuric chloride, for children 0.18 to 0.6 Gm.; for adults 0.8 Gm. Recovery, however, has occurred, under treatment, after 2.5 Gm. Opium is said to lessen the toxicity.

Mercuric cyanide, which produces the same phenomena, has caused severe poisoning with 0.12 Gm. and death with 0.6 to 1.2 Gm. A case is described by Gettlée, 1916.

Colored.—Even large doses ordinarily produce only diarrhea; exceptionally, more severe and even fatal effects are recorded; for children with 0.4 Gm., for adults with 2 to 3 Gm.
**Metallic mercury**, which was formerly given in doses of 100 to 500 Gm., usually passes off by the feces with very little effect; sometimes there is diarrhea and stomatitis and exceptionally, severe and even fatal poisoning.

**Relative Toxicity of Different Compounds.**—This is under dispute. It is generally believed that the toxicity is proportional to the ionization, and therefore greatest with the chlorid, succinimid, etc. The aromatic compounds are much less toxic (Abelin, 1912). With mercurial dyes, the toxicity, and the efficiency against syphilis, are not proportional to the mercury content or dissociation (Klages and Schreiber, 1914).

Schaumburg, Kolmer and Raides, 1915, state that the toxicity for hypodermic and intravenous injection depends practically on the mercury content; and is essentially alike for inorganic and the different types of organic compounds. They explain this by the ease with which ionized mercury is liberated from these compounds.

**Treatment of Acute Mercuric Poisoning.**—This is fairly successful when started whilst the mercury salt is in the stomach. After the poison has been absorbed, it is not affected by antidotes; and the treatment becomes essentially palliative, and not very successful.

Three raw eggs in a quart of milk are among the best antidotes, if the patient is seen early. They act as precipitants and demulcents. A hypophosphite-peroxid mixture is almost equally convenient and perhaps more effective.

Fantus, 1916, recommends sodium hypophosphite, 1 Gm.; water, 10 c.c. and hydrogen peroxid, 5 c.c., per 0.1 Gm., of mercuric chlorid. This should be followed by lavage with the diluted reagent.

Various other antidotes, precipitants and reducing agents, have been proposed; often with the claim that they would render the mercury harmless even after its absorption. This claim is certainly incorrect, and it is not clear that they have any advantage over albumen. They will be discussed below.

**Phosphide and Hypophosphite Reagents.**—Sodium phosphide reduces mercuric chlorid to calcesol. Its use with sodium bicarbonate as an antidote was proposed by Linhart, 1913, 1917; although it is better known as "Carver's antidote," a mixture of sodium phosphide and sodium acetate.

Fantus, 1917, proposed a similar hypophosphite peroxid mixture (see above).

The phosphide mixtures are quite successful if given within 5 minutes after the poison (Fantus and Ryatt, 1917). They are useless after it has been absorbed; this even if the antidote is injected into the blood (Sansum, 1918).

**Sulphides.**—Sabbatani, 1907, investigated the antidotal value of hydrogen sulphid. Wilms, 1915 to 1917, makes the very improbable claim that calcium sulphid is effective even when started 12 to 20 hours after the poisoning. He uses it by mouth (0.5 to 0.6 Gm. every hour) and intravenously (in quantity equal to that of the mercury) as a freshly made, boiled and filtered, 0.2 per cent. solution. This contains Ca(SH)2 and is supposed to form mercuric sulphid.

The advisability of the intravenous treatment is doubtful. Haskell and Courtney, 1917, found the benefits no greater than with simple saline.

**Iodid and Quinid.**—Hall, 1914, proposed potassium iodid and quinid (a reversal of Meyer's reagent). This might have some effect in the stomach, but naturally not in the blood or tissues (Barbour, 1915).

**Charcoal.**—Ferreira and MacBride, 1914, advocated animal charcoal, a tablespoon every 2 hours, together with lavage, etc.

The local antidotes should be followed by an emetic or repeated gastric and colon lavage to remove the unabsorbed or re-excreted mercury; and by alkali administration, milk diet, and hot packs, to protect the kidneys.

**Lavage.**—Lieb and Goodwin, 1915, emphasize repeated gastric lavage for removing mercury excreted into the stomach. Lambert and Patterson, 1917, combine this with continuous rectal irrigation. The success is only limited if the poison has already been absorbed (Sansum, 1918).
Saline Infusions, Alkalies, etc.—Sansum, 1918, determined the minimal fatal dose of mercuric chloride by intravenous injection for dogs as uniformly 4 mg. per kg. This was not modified by the infusion of plain saline, or by sugar solutions, alkalies, Fischer’s solution, etc. i.e., these were all unsuccessful against acute poisoning. This does not exclude the possibility of diminishing the nephritic changes of subacute poisoning, which may explain the results claimed for these treatments. However, their benefit is not firmly established; especially since they are generally combined with other measures.

Vomition and Transfusion.—Burmeister, 1917, claims that these diminish the renal changes.

Alkalies.—The use of these is justified by the observation of McNider that they protect the kidneys against metallic poisons. However, their success is probably quite limited.

D. J. Lewis and Rivers, 1916, aim to increase the elimination by frequent gastric lavage, colon irrigations and hot packs. They also give sodium bicarbonate and glucose by mouth and vein, to combat acidosis and guard against nephritis. W. B. Weiss, 1917, 1918, also advocates alkalies, on Fischer’s theory of nephritis. After the local antidoites, he administers sodium bicarbonate freely, so as to keep the urine alkaline to methyl red. Schiller, 1917, claims good results from MgO, 2 to 4 Gm., every 3 hours.

Subacute Poisoning.—This (as seen in sequence to acute poisoning or in the ordinary medicinal use) presents especially the phenomena of nephritis, stomatitis and colitis; more rarely skin eruptions. The stomach and small intestines usually escape.

Mercurial Nephritis.—Some degree of albuminuria is common even in the ordinary therapeutic use of mercury. It is attributed to the excretion of the mercury. After severe intoxication it may last for years.

The acute nephritis is primarily tubular. When severe, it may be accompanied by hemorrhagic glomerular nephritis. The lumen of the tubes, and sometimes the epithelium, may contain crystals of calcium carbonate (Salkowsky, 1866), the origin of which is not explained. These may occur as early as 48 hours after the administration (Schamberg et al., 1915).

In the milder or more gradual cases, the nephritis is mainly interstitial; although the glomeruli, and with large doses the epithelium, may be involved. Later the kidney becomes cirrhotic.

The anatomical and chemical changes in acute clinical mercury nephritis are further described by W. R. Campbell, 1917; those in the subacute form by Foster, 1913.

Functional Changes in Experimental Mercury Nephritis.—The acute form generally shows polyuria (Schayer and Heding, 1907) and often renal glycosuria (Franck, 1913). The blood of rabbits is hydremic (Bils, 1910).

McNider, 1918, found in subacute poisoning, accompanied by partial or complete suppression of urines, a diminished phenol and phthalin output, retention of urea, and rapid reduction of reserve alkali.

These changes may not have time to develop in animals that die very acutely. Otherwise, the degree of acidosis is parallel to the morphologic changes (McNider, 1917).

Hepatic Degeneration.—MacNider, 1910, found that dogs poisoned by mercuric chloride, 15 mg. per Kg., by mouth, react with severe gastro-enteritis, but usually recover. The liver of these animals shows degenerative changes, beginning with deposition of fat in the cells around the central veins, then cloudy swelling and necrosis, the process extending toward the periphery. The intensity is parallel to the nephritis, rather than to the gastroenteritis.

Stomatitis.—This is important as the earliest symptom of excessive therapeutic use or of chronic poisoning. It occurs about as readily when the mercury is administered otherwise than by mouth. It begins with fetor, then metallic taste, soreness of the gums and some salivation (ptyalism). This is as far as the therapeutic use should go. If it is pushed further, the teeth loosen, the edges of the gums blanch, and they, and later the tongue, become swollen and ulcerated. The irritation and infection cause very severe salivation and progressive exhaustion. In
very advanced poisoning there may be loss of the teeth and necrosis of the jaw.

The susceptibility to stomatitis varies greatly and is markedly influenced by the hygienic condition of the mouth and teeth.

**Treatment of Stomatitis.**—The stomatitis is most effectively prevented and treated by hygiene and care of the teeth. The mouth should be in the best possible condition before mercury is started. Hydrogen peroxide or potassium chlorate (a tablespoonful of the saturated solution to a glass of water) should be used as a mouth wash several times a day. The use of tobacco is said to be injurious.

**Cause of the Stomatitis and Collitis.**—These are generally attributed to irritation during the excretion of the metal. Almkvist, 1906 and 1916, however, points out that they have no relation to the excretion but depend upon the presence of hydrogen sulphide and the precipitation of mercuric sulphide which can be shown chemically in the capillary endothelium of these situations. Similar deposits and irritation can be produced experimentally elsewhere to exposure by hydrogen sulphide. He therefore explains the process as due to bacterial action causing injury and desquamation of the epithelium, and the production and absorption of H₂S which precipitates the mercury in the capillaries from where it is deposited in the endothelium. Here it acts as an irritant and disturbs the function and nutrition of the vessels, leading to necrosis. The explanation is somewhat hypothetical.

Bismuth also gives similar precipitates but they are much less toxic. Lead and copper are not so easily precipitated.

The salivation is perhaps partly due to direct irritation of the salivary mechanism by the mercury. Gian, 1913, reports degenerative histologic changes of the parotid gland in mercurial poisoning.

**Metabolism.**—The effects are imperfectly known but appear to resemble those of arsenic, lead and phosphorus. Small doses, therapeutically and in animals, often cause considerable increase of weight (lat.). The red corpuscles are also increased (Scheiring. 1884). In chronic cachexia they are diminished. In acute poisoning there is often glycogenuria and disappearance of glycogen. On the other hand, mercury is sometimes beneficial in diabetes, presumably of syphilitic origin.

**Chronic Mercury Poisoning.**—If this takes a slow course, there are, in addition to the subacute symptoms, nervous and nutritional phenomena. The most common are tremor; cerebroseism (psychic irritability and restlessness), and other psychoses; cachexia with anemia, malnutrition and muscular atrophy; bone changes (decalcification) and more rarely neuritis or pareses.

**Treatment of Chronic Poisoning.**—Prophylaxis is of the first importance; it is doubtful whether treatment materially influences the course after the appearance of symptoms. Potassium iodide and hot baths are generally tried, with the intention of hastening elimination.

**PECULIARITIES OF CALOMEL.**

The mercurous or "mild" chlorid, because of its insolubility in water and limited solubility in the alimentary canal, has very much weaker actions. It is therefore suitable for a cathartic and intestinal antiseptic. In cardiac dropsies it is often markedly diuretic. It may be employed as an antiyphilitic.

**Solubility of Calomel in the Alimentary Canal.**—Calomel is not dissolved in the gastric juice and none is absorbed from the stomach or rectum (Nemes, 1908); but it is attacked in the intestines, especially in the ileum, by the alkaline pancreatic and intestinal juice. These dissociate it into mercury (shown by immediate darkening), and yellow mercuric oxid; the latter dissolves slowly and incompletely in the alkaline intestinal fluid (T. W. Schaefer, 1910).

**Interaction of Calomel and Salt.**—Mialbe attributed the solution of calomel to interaction with sodium chlorid, forming mercury and mercuric chlorid, and complex double
MERCURY 927

salts. Similar reactions were claimed by Jody to occur with hydrochloric and citric acids, alkalies, carbonates and sugar. These reactions do occur in pure solutions, especially at high temperatures and with concentrated solutions; and to some extent even under conditions resembling those of the body. The amount dissolved would be very small (at most 1 to 4 mg. per 0.5 Gm. of Calomel). However, mercuric chloride could not exist as such in the alkaline intestine, and the chorid can therefore not be made responsible for the solution of calomel (as was suggested, J.F., by Carraccio, 1900). Iodids, bromids, sulfo cyanids, thiouphates, etc., dissolve larger quantities of calomel.

CATHARTIC ACTION OF CALOMEL

This may be referred to the irritant effects of the small quantities of mercury which are progressively dissolved. The irritation is generally so mild that it may be employed even in enteritis. Some patients, however, are hyper susceptible. Ordinarily it produces dark green, semisolid stools, with mild colic, in about ten to twelve hours. Laxative doses diminish intestinal putrefaction (diminished indoxyl in urine). Larger doses probably favor the bacteria by lessening the intestinal resistance.

Dosage.—This is relatively unimportant, because any excess is generally expelled before it is dissolved. It is customary to give either a single dose of 0.125 to 0.5 Gm. (2 to 7 gr.); or fractional doses of 15 mg. 1/4 (gr.) every hour until 0.15 Gm. (2 1/2 gr.) have been taken. The divided doses insure better solution. Formerly much larger doses were used but they are superfluous; and while usually harmless, they may become dangerous should conditions become exceptionally favorable to absorption.

Calomel is not suited for long continued use on account of systemic actions. These may also be produced by large single doses, if they are not expelled in the usual time. It is therefore advisable to follow the calomel in six hours by a saline; or it may be mixed with Resin of Podophyllum (5 mg.; 1/12 gr.).

Calomel should not be perscribed with iodids, alkaliaries or organic substances.

Other mercurial salts are sometimes used as cathartics but without advantage.

Bile-flow.—This is not affected by calomel. The older views of chologogue action were based merely on the color of the stools, which is due partly to mercury sulphid and partly to lessened decomposition of the ordinary bile.

The absence of chologaque action has been shown by biliary fistula experiments by numerous investigators (Okada, 1915). Doyon and Dufourt, 1897, also showed that the green calomel stools occur even if the bile is prevented from reaching the intestines. The role of the antiseptic effect is shown by incubating the bile with calomel, when the green color persists much longer than with pure bile. Jakob, however, claims that calomel stools do not contain biliverdin.

Mechanism of the Cathartic Action.—This is due to a local effect, but there are differences of opinion as to its mechanism. It is generally attributed simply to irritation, and X-ray work shows that peristalsis is increased in the small and large intestines (Meyer-Betz and Gebhardt, 1912); but Flechseider, 1912, believes that calomel also prevents the absorption of water in the small intestine, directly and by quickening the passage of the contents. The catharism is prevented by strepoin or opium. It is not influenced by the presence or absence of bile (Valerdi, 1909).

Calomel probably acts mainly on the duodenum, and much less on the colon. Small doses may therefore only sweep the duodenal contents into the colon, without producing a stool. Large doses produce gripping and tenesmus.

Calomel Diuresis.—Adequate doses are sometimes remarkably diuretic in cardiac dropsties. The effect is uncertain and does not usually occur in health or in other dropsties. The mechanism is not definitely explained.
MANUAL OF PHARMACOLOGY

It is a heroic remedy, requiring large doses and generally producing salivation and diarrhea. Caution should be used in nephritic or debilitated patients.

The diuretic effect of calomel in cardiac dropsy is said to have been well known to the physicians in the latter half of the eighteenth century. It was used, f.d., by Alex. Munro. However, it fell into neglect, and was practically rediscovered by Jendrassik in 1886. A small, 0.2 gm., was given from four to five times a day, until a slight mercurial stomatitis was produced. If this did not prove effective from the start, the remedy was discontinued; it also seems wise to intermit it occasionally. The bowels may be regulated by opium. Jendrassik remarks that the calomel appears relatively or quite ineffective when the heart disease is uncomplicated by dropsy; it was also ineffective in pleuritic exudates, in nephritic effusions, and in healthy individuals. This report gave rise to extensive trials of the drug. The results of these were summarized by Jendrassik in 1891, together with further observations and experiments of his own. His previous conclusions concerning the best method of administration, and the usefulness of calomel in cardiac dropsy seem to have been generally confirmed, as also the relative inefficiency in non-cardiac disease, in pleuritic exudates and in normal individuals. It seemed to be slightly diuretic in the latter but the action can never compare with that seen in cardiac dropsy. It was often found effective in hepatic ascites, but failed frequently. It gave good results in some cases of nephritic edema, but in most instances gave no result; it seemed impossible to predict what it would do.

The theoretical objections to the use of so powerful a renal irritant as mercury in nephritis, were early emphasized, especially by Koch, 1889, and supported by some clinical observations. It was claimed that there is a very marked tendency to mercurial symptoms, and that the nephritis is often made worse. The greater number of observers, however, hold the opposite view, viz., that calomel does not render the nephritis worse, whether it has a diuretic action or not. This is denied by Jendrassik, and by Heuck, 1886. Schidt, 1892, reported three cases, in which he claims that a diuretic effect was obtained, together with a lessened per cent. of albumin; the daily output of protein being unchanged.

Briefly, it seems certain that the doses of calomel which are advocated have never produced albuminuria in normal individuals, but the question of their effect in an existing nephritis is not sufficiently investigated to admit of a decisive answer. Great conservatism in its employment is therefore indicated.

The mechanism of this calomel diuresis is not understood, notwithstanding the investigation of Jendrassik, of Cohmnst, 1892, and of Vejvux-Tyrone and Nelson, 1903. Fleckeseder, 1912, finds that all mercury compounds, by all methods of administration, produce a diuretic effect in rabbits. He believes that mercury lessens absorption of food-water from the small intestines; the water would therefore reach the large intestines in excessive quantity; and when absorbed from this place would act as a diuretic. The explanation is not altogether satisfactory; f.d., it does not explain the absorption of exudates.

The diuretic action of mercuric chloride has been studied in rabbits by Ferron, 1917. If albuminuria is Colonel Diuresis. — Fleckeseder found the blood of rabbits hypertonic. This would speak against the diuresis being of renal origin. However, the result was probably accidental, for all other workers have found the blood, in man or mammals, either unaffected or rather concentrated by the diarrhea. The lymph-done is set increased (Yanagawa, 1916; Loria, 1917).

Influence of Other Drugs. — The diuresis is surpressed by atropin; this would favor Fleckeseder's explanation; but opium which also lessens persial shells increased the diuresis. Schargorodsky, 1911, found it surpressed by ether or morphin. Excessive doses of mercury also produce anuria.

The constituents of the urine after calomel has been studied by E. Frey, 1906.

MERCURY IN SYPHILIS

The antisypilistic effect of mercury was discovered about 1500, very soon after the discovery of the disease; according to Rhenenodean, it was first used by one Jacobus Carpensis, "whose use was so successful that he presently became rich thereby." Till the present century, little further
advance was made in its employment, which remained entirely empirical. It was not known whether it acts symptomatically, or as a general tonic; or whether it really affects the causative agent directly; whether it merely relieves or actually cures. Its effects had to be judged entirely by the symptoms, which in syphilis are extremely subject to spontaneous variations. The proper dose, as well as the time and continuance of its administration were therefore regulated only by caprice and prejudice. This empiricism was revolutionized by the three important discoveries: of the Treponema pallida as the causative agent; of its transmissibility to monkeys and rabbits; and of its more definite diagnosis by the Wassermann reaction. Through these discoveries, it was possible to establish that mercury acts directly on the Treponemas, and not merely on the symptoms; that like all chemo-therapeutic agents, it must be used as early as possible, energetically and persistently; and that if so used, it can effect a perfect cure.

**Antihetic Agents.**—Experiments on monkeys (Neisser, etc.) have shown that mercury eradicates the disease in the presymptomatic, in the active, and in the latent stages. Organic arsenic is similarly successful, and acts more rapidly. Iodids also have some effect, but are much weaker. Their clinical efficiency in tertiary syphilis must be by some other mechanism.

**Spirochete Cultures** are killed by dilute solutions of mercuric chloride (1:250,000). Continuous cultivation produces some tolerance ("fastness"), but this is lost in a few generations of the culture, and is therefore practically unimportant (Akatsu and Noguchi, 1917).

**Importance of Early Treatment.**—It was formerly taught that mercury should be postponed until the onset of the secondary symptoms, so as not to interfere with the clinical diagnosis. This consideration became superfluous with the introduction of the laboratory methods. It is now recognized that the chances of complete success are the greater, the earlier the treatment. This should be started as soon as the diagnosis is made. If the administration is delayed, or if it is not sufficiently energetic and relapses occur, treatment becomes much more difficult and requires larger doses. In syphilitic aortitis, mercury rarely gives more than temporary relief (Longcope, 1914).

**Abortive Treatment.**—If treatment can be started within 4 or at most 8 hours after exposure, the site of suspected infection should be disinfected and dressed with an ointment containing 33 per cent. of calomel or 0.3 per cent. of sublimate ("Neisser-Siebert Ointment"). This should be followed by systemic treatment. (See also under Organic Silver Preparations.)

Mercury should not be used locally, after 12 hours have elapsed, until a diagnosis has been made, for it makes it more difficult to find the spirochetes.

**Systematic Treatment.**—Formerly mercury was administered expectantly, intermittently or continuously. It is now recognized that the treatment should not depend on the symptoms, and the expectant treatment is therefore of no use. The *intermittent treatment* (Fournier's) was based on the premise that the syphilitic virus acquires an immunity to the continued administration of mercury, and that its susceptibility is re-established by occasional intermittence of the treatment. There is no proof for this assumption; but the method seems to give the best clinical
results (perhaps because it permits a higher temporary concentration of mercury than could be attained with continued administration; in chemotherapy, the concentration generally counts for more than the time of exposure). The interrupted method also lends itself better to combination with Arsenophenamin. The two metals probably attack the parasite in a different way; at least, they seem more effective together than separately.

In the intermittent method, the mercury is given to slight ptyalism, in courses of five to six weeks' duration, with intermissions of one to six months, for at least one and a half years; or longer if the disease is not eradicated (see under Arsenphenamin).

Whatever method is used, it should be aimed to introduce the maximum of mercury that the patient can tolerate; something like 2 Gm. of Hg during the first year, and 1 Gm. in the two succeeding years. The relative failure of the older methods may be attributed to insufficient dosage.

If metasplbaletic lesions have set in, mercury is of little use, but its early energetic use is the best preventative of these lesions.

**Oral Administration.**—This is probably the most congenial method to the patient; but it is difficult to introduce sufficient mercury on account of the local action on the digestive canal. The patient is also under less perfect control. It has therefore been largely superseded by the intramuscular method or inunction.

It is only advised in new-born infants. To these mercury with chalk may be given in doses of 0.015 to 0.03 Gm. three times per day.

For adults, the oral method was used continuously: Beginning with a small dose, this is increased daily by about 10 per cent., to tenderness of the gums. The dose is then reduced to one-third or one-half and continued at this point till the end of the treatment. The usual preparations are, in order of preference:

- Hydargyri iodidum Flavum ("Proto-iodid") 0.01 to 0.05 Gm. (¼ to ½ gr.)
- Hydargyrum cum Creta 0.05 to 0.1 Gm. (½ to 1 gr.)
- Hydargyri Chloridurn Corroivium 0.005 to 0.015 Gm. (¼₂ to ½₄ gr.)

(These doses three times daily).

**Inunction.**—Although effective quantities of mercury can be introduced by this method, the dosage is always uncertain. Inunction, moreover, is time-consuming, dirty and disagreeable, and difficult to keep secret.

However, it is effective, and has a special field in the secondary cutaneous lesions, where it must have a local parasiticide effect.

Inunction is performed by rubbing about 2 Gm. of Ung. Hydargyri into the skin, until it is entirely absorbed, i.e., for about half an hour. The skin may then be sponged with benzine, to remove the tell-tale exces. The "rubs" are usually repeated every night on a different skin-area, so as to increase the absorbing surface, and also to prevent excessive local irritation; making the tour of the body in six nights. The seventh night a hot bath is substituted, and so on. The course lasts for four to six weeks. Salivation usually starts after 10 to 20 rubs.

The absorption of the mercury occurs mainly from the hair follicles, into which it is forced by the rubbing, and where it is gradually converted into soluble compounds. The epidermis does not participate in the absorption (J. Neumann, 1871; Fuerbringer, 1880). In case of volatile preparations, such as metallic mercury, some absorption may also occur.
through inhalation (Wile and Elliott, 1917; Schambregg et al., 1918); but this is of very minor importance.

**Excretion of Mercury after Inunction.**—This was discussed under Excretion. Cole and Littman, 1919, found no salivation even after 40 rubs; nor was there any improvement in the secondary syphilides.

**Inhalations, fumigations and plasters are obsolete methods of introducing mercury.**

**Intramuscular Injections.**—These permit the introduction of the maximum of mercury, with relatively slight gastro-intestinal irritation (although it may be doubted whether the stomatitis, colitis and nephritis are less severe than with oral administration). One of the chief advantages of injections is that they keep the patient under more effective observation, and permit a better control of the quantity of mercury introduced. The disadvantages are that the absorption especially of the insoluble preparations is variable; and that the injections are more or less painful, often with destructive lesions in the muscles (Robertson, 1913). These are unimportant practically. With the soluble preparations the pain lasts some hours or longer; with the insoluble several days. Of these, calomel is the most, Oleum cinereum the least, painful. The immediate pain may be lessened by injecting 1 c.c. of 2 per cent. procain from the same syringe. The injections are made deep into the gluteal muscles.

**The preparations used for intramuscular injections fall into two classes; according to whether they are absorbed rapidly or slowly. These have distinctive uses.**

**The Easily Absorbable Injections.**—These include all the soluble salts; and the salicylate, which is insoluble in water but is dissolved by sodium chlorid or carbonate.

The soluble preparations act more promptly, the dosage is under better control, and there is less possibility for cumulative action. The effects are correspondingly less persistent, and the injections must be repeated at more frequent intervals—every day to every third day. They are usually employed in 1 per cent. solution. Mercurocholorid is quite irri tant. The bismuthid, dissolved in 3 per cent. NaI is a good form. The cyanid, oxy cyanid, oxybenzoate and succinimid are also relatively non-irritant. The average daily dose is about 1 c.c. of 1 per cent. (≈0.01 Gm., 1/6 gr.), in courses of five to six weeks' duration. The treatment may be intensified by beginning with 2 c.c., increasing slowly to 3 or 4 c.c. (0.03 to 0.04 Gm.), or until mild pylialism occurs, when the dosage is reduced so as to keep the patient just short of salivation.

**The Insoluble Injections.**—These are used with the purpose of establishing "deposits" from which the mercury may be gradually absorbed, so that injections need only be made at intervals of 3 to 7 days, in courses of about 15 injections.

Roentgenographs (Cole, Littman and Sollmann, 1920) show that salicylate injections are actually absorbed in this time. Calomel injections require about 15 days for absorption. "Gray oil" injections are absorbed very slowly, so that most of the metal is still present after 4 weeks. Repetition of such injections at weekly intervals leads to increasing deposits, and may give rise to severe poisoning if the conditions for absorption should suddenly become favorable.

**Mercuric salicylate is employed as 10 per cent. suspension in oil or better, in lanolin emulsion (Nitardy, 1919) in the dosage of 1 c.c.**

1 **Formula for Permanent and Anesthetic Mercurec Salicylate Suspension**

It causes
very little irritation since the mercury is not ionized (not precipitated by H₂S).

*Calomel,* 10 per cent. suspended in oil, 1 c.c. twice weekly; this is considered one of the most active, but a painful method.

*Oleum Cinerereum* (gray oil), a 40 per cent. suspension of metallic mercury in oil. This is the most slowly absorbed of the mercurials. The injections (0.5 c.c.) are therefore spaced a week apart, and after five injections an interim of five or six weeks is made to discount capricious absorption; five further weekly injections are then given. (Semiweekly injections of 0.4 c.c. may be substituted for the weekly injections.)

**Absorption from Intramuscular Injections.**—The mercury, in whatever form it is introduced, acts on the proteins to form albuminates of mercury. These are strongly chemostatic, and attract leucocytes. Some of these are killed, but others take up the mercury, especially in their nuclei, and are released as mercurial leucocytes being the same, as with other methods of administration (Conti and Žuicoš, 1906; Lombardo, 1912). The quantitative excretion, however, is very capricious. Wallisch, 1912, finds that the solubility of the preparations is of subordinate importance; but that all inorganic salts are absorbed and excreted much less readily than the organic salts.

Ramsay and Ziegler, 1918, showed mercury in the urine eight days after intramuscular injection of mercuric salicylate or chlorid.

Schamburg et al., 1915, found in animal experiments that after intramuscular injections of insoluble preparations, calomel and gray oil, 50 per cent. of the mercury was unabsorbed after 6 or 7 weeks. However, their conclusions could not be transferred to the clinic, since the doses would have corresponded to about 10 gm. in man.

**Quantity of Mercury Introduced by the Different Preparations.**—This may be seen from the following table (adapted from Neisser, 1911):

**Intravenous Injections.**—These were recommended by Bacelli, 1892, and are used in several clinics. However, they present some danger of intoxication and embolism, at least in inexperienced hands; and a large part of the mercury is excreted so promptly that it probably has little effect. Mercuric chloride, iodid, or cyanid is used, in 1 per cent. solution, 1 to 3 c.c. daily or every second day, injected into a superficial vein, with glass syringe and platinum-iridium needle (Crume, 1908). The vein, however, soon become fibrosed. Similar injections have been tried in puerperal infections, and other septicemias, influenza, etc. (Barsony, 1909; Ferrarini, 1918; Perez, 1918). Veckl, 1918, endorses this use, but reports severe poisoning, exceptionally from 3 mg.

**Spinal Injections of Mercurialized Serum.**—This was introduced by Byrnes, 1914, and is endorsed by Ireland and Wilson, 1915, against cerebro-spinal syphilis, as being about equally successful and safe as the Swift-Ellis serum. It has the advantage that the serum may be kept on hand. It is prepared by adding 1 c.c. of 0.15 per cent. mercuric chloride to 12 c.c. of normal human or horse serum, heating to 50°C. for one-half hour. This gives a clear solution. This dose (double would be safe) is injected by gravity, at body temperature, after withdrawing cerebro-spinal fluid till its pressure is 30 mm. E. L. Hunt, 1916, also reports encouraging results. Hall, Culberson and Slight, 1916, describe the reactions following the intraspinal injection. They are usually not serious.

Swift, 1916, however, believes that repeated injection of mercurialized horse serum renders the meninges hypersensitive, and tends to produce chronic meningitis. Pittenger, 1917, finds that mercuric chlorid when dissolved in serum produces the
same systemic effects as when dissolved in water, and is equally toxic, by any channel; but that it causes practically no local irritation.

Inhalation of Mercury or Calomel Vapor.—This has been abandoned, mainly because of the uncertain dosage. It also produces marked pulmonary hyperemia (Ricker and Hesse, 1914).

Mercury vapor is not absorbed as such. When it is inhaled, it condenses in the mouth and on the respiratory mucous membrane and undergoes slow oxidation and combination. The compounds are then absorbed. In other words, mercury inhalation amounts practically to the administration of gray powder, except that the dosage is much less definite, and there is a possibility of focal injury to the lungs (Cole and Sollmann).

Organic Mercury Compounds.—On intravenous injection these produce at first characteristic acute "molecular" actions, distinct from those of mercury; and which are absent when they are absorbed more gradually. The mercury effects set in as the mercury is split off; the intensity of action depending on the readiness of this liberation, and on the rapidity with which the molecular form is excreted (F. Mueller, Schoeller and Schraut, 1917).

The writers arrange the organic mercury compounds into the following groups:
1. Inorganic.—Precipitated by sodium hydroxid, precipitant for proteins.
2. Pseudocomplex.—Less ionized; not precipitated by proteins, but precipitated by sulphides.
3. Half-complex.—The mercury is more firmly attached, directly to the benzol carbon. (Dimroth, 1911). Not precipitated by cold sodium hydroxid or sulphid, but precipitated on heating with these reagents.
4. Full Complex.—Each mercury valence is bound so firmly to an organic radical that precipitation does not occur even on boiling with strong reagents. These compounds are practically inactive.

The chemotherapy of mercury is discussed, with a bibliography, by Schamb erg et al., 1917.

Contraindications to Mercury.—Caution should be exercised with weak or anemic individuals, with albuminuria, during digestive derangements, and with diseases of the mouth or teeth. Pregnancy is not considered a contraindication. It is safer to begin treatment with small doses, since some patients are hypersusceptible.

Vegetable Antisyphilitics.—The prejudice against mercury has led to the introduction of a number of vegetable "alternatives"—Echinacea, Phytolacca, Iris, Sarsaparilla, etc., but their usefulness is attested even by modern sceptics (Hillson, 1909).

**MERCURY IN TUBERCULOSIS**

This was advised by R. L. Wright, but Hartz, 1910, found the ultimate results detrimental and never beneficial.

**PREPARATIONS—METALLIC MERCURY**

*Hydrargyrum (Hydrarg.), U.S.P., B.P.; Mercury (Quicksilver); Hg.—A fluid, silver-white heavy metal. It is used only in finely divided form, as in the following preparations:

*Hydrargyrum cum Croce (Hydrarg. c. Cret.), U.S.P., B.P.; Mercury with Chalk (Gray Powder).—Contains 58 per cent of Hg., U.S.P.; 33 per cent, B.P., with honey and chalk. A light gray, rather damp, sweetish powder. Used especially to secure the constitutional effect of mercury in infantile syphilis. *Dos., 0.25 Gr., 4 gr., U.S.P. equivalent to about 0.1 Gm. of metallic mercury; 0.06 to 0.3 Gm., 1 to 5 gr., B.P.; dispensed in powders.

Emp. Hydrarg., B.P.—33 per cent of Hg. in lead plaster base. Used against glandular enlargements, etc.

Mass. Hydrargyri (Mass. Hydrarg.), U.S.P., Pill. Hydrarg., B.P. (Blue Mass, Blue Pill).—33 per cent. of Hg. *Dos., 0.25 Gr., 4 gr., U.S.P.; 0.12 to 0.5 Gm., 4 to 8 gr., B.P. Used similarly to Calomel.

PREPARATIONS—INSOLUBLE MERCURIC COMPOUNDS

Hydrargyrum Chloridum Mite (Hydrarg. Chlor. Mit.). U.S.P.; Hydrargyrum Subchloridum (Hydrarg. Subchlor.). B.P.; Mild, Mercuric Chloride (Calomel, Protocolhid of Mercury); HgCl₂. Fine white powder, odorless and tasteless. Practically insol. in water or alc. Incompatible with alkalies; oxidizing acids; iodides and bromides; and with a mixture of sodium bicarbonate and antipyrin (J.A.M.A., 56: 285, 1917). Dust, as laevigate, 0.15 Gm., 2.5 gr.; as alterative, 15 mg., 0.04 gr., U.S.P.; 0.03 to 0.06 Gm., 0.4 to 0.5 gr. B.P.; as powder or tablets. Maximum dose, 0.6 Gm., 10 gr.

Ro. Hydrarg. Subchlor., Co., B.P. (Plummer’s Pill)—25 per cent. of Hydrarg. Subchlor.; 25 per cent. of Antim. Sulphur; 43 per cent. of Guaicus Res. Dose, 0.25 to 0.5 Gm., 4 to 8 gr. B.P.

Hydrarg. Subchlor., B.P. (Calomel Ointment)—20 per cent., in Benz. Lard.

Preparations—INSOLUBLE MERCURIC COMPOUNDS

Hydrargyrum Ammoniatum (Hydrarg. Ammon., U.S.P., B.P.; Ammoniated Mercury (White Precipitate); NH₄HgCl. White, amorphous, insoluble powder, obtained by precipitating HgCl₂ with ammonia. Represents about 80 per cent. Hg. Irritating and not used internally. Employed externally against eczema and parasitic skin diseases, especially pediculosis, as dusting powder, but chiefly as :

*Ung. Hydrarg. Ammon., U.S.P., 10 per cent. in woolfat and white petroleum.

Papeetecher’s Ointment contains as a per cent.

*Ung. Hydrarg. Oxidum, B.P., 5 per cent. in Benz. Lard.

Hydrargyrum Oxidum Flavum (Hydrarg. Oxid. Flav., U.S.P., B.P.; Yellow Mercut Oxide; HgO). A yellow-orange amorphous powder, turning darker on exposure to light. Odorless; somewhat metallic taste. Nearly insol. in water or alc. Incompatible with acids. Maximum dose, 0.05 Gm., ½ gr. Applied chiefly as :

*Ung. Hydrarg. Oxidum, U.S.P., 10 per cent. B.P., 2 per cent.—It is used in ophthalmology against inflammations of the lids and conjunctiva, being diluted with petrolatum so as to contain ½ to 2 per cent. of the oxide. "Papeetecher’s Ointment contains as a per cent.

*Ung. Hydrarg. Planum (Lot. Hydrarg. Flav.), B.P.; Yellow Mercurial Lotion (Yellow Wash).—A suspension of mercuric oxide, obtained by mixing 0.4G HgCl₂ with 100 lime-water. Used as application to venereal sores.

Hydrargyrum Oxidum Rubrum (Hydrarg. Oxid. Rubr., U.S.P., B.P.; Red Mercut Oxid (Red Precipitate). HgO—Orange-red crystalline scales or powder. Because of its gritty character it can not be used on the eye, but its Ointment is employed in skin diseases, etc.

*Ung. Hydrarg. Oxidum Rubr., B.P., 5 per cent. of Mercut Oxid in Oleic Acid.

Oleatum Hydrargyri (Oleet. Hydrarg., U.S.P.)—Made by dissolving 0.25 per cent. of yellow mercuric oxide in oleic acid.

Hydrargyri Benzoas, N.N.R.—Slightly soluble in water. Used as urethral injection 1: 1000 to 1: 2000, against gonorrhœa, and hypodermically, 0.02 to 0.03 Gm. in 00 c.c. of normal saline.

*Hydrargyrum Chloridum Corrosivum (Hydrarg. Chlor. Corr.) U.S.P.; Hydrarg. Perchloridum (Hydrarg. Perchlor.). B.P.; Corrosive Mercut Chloride (Corrosive Sublimate; Bichlorid or Perchlorid of Mercury); HgCl₂. Heavy, colorless crystals or white
powder of acid metallic taste. Slowly sol. in water (1:135), freely sol. in alc. (1:135), sol. in glyc. (1:12) or eth. (1:22). Its solubility is increased by ammonium or sodium chlorid and tartaric or citric acid ("Sal Alembroth" = 2 parts HgCl₂, 1 part NaCl). Incompatible with alcohols and carbon bisulphide; many alkalis and other organic compounds and reducing agents. *Dose:* 3 mg., 1/20 gr. U.S.P.; 2 to 4 mg., 1/32 to 1/16 gr., B.P. Maximum dose, 30 mg., 1/5 gr.

**Liq. Hydrarg. Perchlor.** B.P.—0.3 per cent. *Dose:* 2 to 4 c.c., 1/2 to 1 dram, B.P.

*Toxicatabile Hydargyri Chloridi Corrosivi (Toxicatab. Hydarg. Chlor. Corr.) U.S.P.; Poison Tablets of Corrosive Mercure Chlorid (Corrosive Sublimate Tablets; Bichlorid Tablets).—In order to guard against accidents, the U.S.P. directs these tablets to be of an angular, not disk shape, each having the word "Poison" and the skull and cross bones design distinctly stamped upon it. Each tablet contains not less than 0.45 Grm. nor more than 0.55 Grm. of HgCl₂ and about 0.5 Grm. of NaCl, and is to be colored blue, preferably with sodium indigotindisulphonate. Poison Tablets of Corrosive Mercure Chlorid should be dispensed in securely stopped glass containers on the exterior of which is placed a red label bearing the word "Poison" and a statement of the amount of corrosive chlorid in each tablet. A tablet to a pint of water makes an approximately 1:1,000 solution.

**Hydarg. Oxyn.**, N.N.R.; Hg(CN)₂HgO—Sol. in water (1:12). Used like Hydarg. Chlor. Corr.; said to be less irritating and does not corrode metals. (The preparation first used as "oxycyanid" was a mixture of one part of the true oxycyanid with two parts of mercure cyanid.)

*Hydargyri Iodidi Rubrum (Hydargyrid. Rub. Rubr.), U.S.P., B.P.; Red Mercure Iodid (Iodiniodid); Hgl₁.—Scarlet red powder, odorless and tasteless. Nearly insol. in water, slightly sol. in alc. (1:183); rendered sol. in water by the presence of four-fifths its weight of KI or NaI. Incompatible with alkalis and carbonates and alkali carbonates. *Dose:* 3 mg., 1/32 gr., U.S.P.; 2 to 4 mg., 1/32 to 1/16 gr., B.P. Maximum dose, 20 mg., 1/5 gr.

**Ung. Hydarg. Iod. Rubr.,** B.P.—4 per cent.

*Potassium Mercure Iodid, N.N.R.; K₂Hgl₁.—This is usually made as extemporaous solution, by dissolving Hgl₁ in water in excess of KI (1:4). For intra-muscular injection, the corresponding sodium salt is preferred (Hgl₁ = 1; NaI = 3; Water = 100).***

**Lig. Aeream at Hydarg. Iod.**—See Index.

**Liq. Hydarg. Nitr. Acid.,** B.P.

**Ung. Hydarg. Nitr.,** U.S.P., B.P.; (Citrine Ointment).—7 per cent. of Mercury, dissolved in Nitric Acid, and diluted with Lard (and olive oil, B.P.). Used as antiseptic, irritant and caustic.

**Hydargyri Sulphid. (Hydargyrid. Sulph.),** U.S.P.—A compound of mercury and salicylic acid containing about 57 per cent. Hg. White, slightly yellowish or slightly pinkish powder; odorless and tasteless. Nearly insol. in water or alc.; sol. in alc., forming a dark-brown, Incompatible with alkalis. *Dose:* 4 mg., 1/15 gr. U.S.P.; intra-muscular, 0.6 c.c. of 10 per cent. suspension in oil every four days. Maximum dose, 20 mg., 1/6 gr.

**Hydargyri Succinim. (Hydargyrid. Succinim.),** N.N.R.—Sol. in water (1:7); slightly sol. in alc. (1:300). *Dose:* 10 to 15 mg., 1/6 to 1/4 gr.; Intramuscular, 0.5 to 1 c.c. of 8.5 per cent., daily. Relatively non-irritant.

**LEAD**

**General Statement.** —The lead salts precipitate proteins and therefore act as local astringents. Their acute toxicity, however, is low. They are fairly easily absorbed but very slowly excreted, so that they tend to produce cumulative effects and chronic poisoning. This is a common disease with characteristic symptoms: Nutritional and structural changes (anaemia, etc.); paroxysmal colic (stimulation of the nervous mechanism of the intestines); "drop-wrist" and other muscular paralyses (direct depression of the muscle); central motor stimulations (tremors, "arthralgia"); psychic changes ("encephalopathia"); etc. On withdrawal, these
phenomena generally recede; but the patient is apt to remain in bad health. Prophylaxis is more important than treatment.

**Astringent Actions.**—Lead acetate and subacetate ("lead water") produce more astringent and less irritant effects than other soluble metallic salts. They are effective in diarrhea and catarhal inflammations; but they are so liable to produce chronic poisoning that they should never be used internally nor on open surfaces; and even on the skin their use should not be long continued. "Lead and opium wash" is used in superficial contusions. Saturated alcoholic solution of lead acetate is especially effective in Rhus ("Ivy") poisoning. Emplastra Plumbi—"Diachylon plaster"—acts as a mild irritant.

**ACUTE LEAD POISONING**

This is a rather rare intoxication, generally produced by the acetate or subacetate, sometimes by the carbonate (white lead). The phenomena are at first local and not immediately dangerous, but they are generally followed by chronic poisoning.

The best treatment is the administration of some soluble sulphate (magnesium or sodium), which may save animals from several times the fatal dose (Dauwe, 1907). Tannin, milk and eggs may also be used. The stomach must then be washed and a cathartic administered. Colic is treated symptomatically, as in chronic poisoning.

**Phenomena of Acute Poisoning.**—There is first a sweet, then disagreeably metallic and astringent taste. In a few minutes, sometimes in several hours, there is vomiting (which is often milky with lead chlorid, burning, abdominal pain and thirst; then obstinate constipation or diarrhea with black stools (lead sulphid)). Severer cases show collapse with slow pulse; or muscular cramps and colic. Fatal cases pass into coma with or without convulsions. The fatal dose lies above 50 Gm. Postmortem, there is little characteristic, except the local astringent changes.

Most patients recover, apparently completely, in two or three days; but after a few weeks they show the phenomena of chronic poisoning (also animals, Dauwe, 1907). Application to the surface (lead wash, Diachylon plaster) has rarely if ever caused acute poisoning (Paessler, 1894). Diachy lion pills (as abortifacient) have proven toxic (A. Hall and Ransom, 1906; W. F. Warner, 1907).

**ABSORPTION**

All lead compounds are absorbed slowly but unmistakably; chiefly from the alimentary tract, but also from the lungs and tissues; and with long-continued use even somewhat from the skin (Lewin, 1883).

The skin is probably the least important channel. It probably plays no part in industrial poisoning. The lungs are also of subordinate importance, the toxicity of the lead dust being due to swallowing rather than to inhalation (Carlson and Woelfel, 1913).

**Absorbability of Different Compounds** (Cf. A. Hamilton, 1912).—This is independent of their solubility in water. Lead carbonate and even lead sulphate are dissolved fairly readily by the aid of the gastric juice. Alkalies, including milk, diminish the solution (Carlson and Woelfel, 1913). Alkalies of the concentration of the pancreatic and intestinal juices convert lead sulphate into carbonate and lead carbonate into a mixture of neutral and basic carbonate (Auerbach and Pick, 1913). Lead is also rendered soluble on the bronchial mucosa. Presumably it forms soluble protein combinations. The sulphid was supposed to be inabsorbable, but Woelfel and Carlson, 1914 showed that it is absorbed sufficiently, even from oes, to be dangerous. The toxicity of the various lead pigments is reviewed by A. Hamilton, 1913.

**RETENTION**

Lead disappears rapidly from the blood (the greater part in less than two minutes after intravenous injection; Dauwe, 1907). The main part is deposited in the organs (Kobert); most in the kidneys, then the bones, then the liver and other glands, least in the brain, striped and smooth muscle and the blood. It may be retained for years and be demonstrable at times in the urine. In chronic poisoning of dogs, it exists in the liver as a firm globulin combination (Riva, 1912).
LEAD

EXCRETION

This occurs mainly by the feces (small and large intestines and bile), and to a lesser extent by the urine; traces also by the saliva, sweat and milk.

All is excreted in organic combination, except the unabsorbed fraction in the feces (Erlenmeyer, 1913). The skin is usually credited with some excretion because it gives the black color of lead sulphid when painted with ammonium sulphid; but Milura found that this depends simply on the adherence of lead to the skin.

Lead in Urine in Chronic Poisoning.—Some investigators found it only exceptionally; but L. D. Harris, 1928, found it present in about half the painters that showed clinical signs of plumbism, and in a 1/4 of those that did not show any clinical symptoms. This confirms the opinion of Oliver, 1914, that it is an important aid to diagnosis.

CHRONIC LEAD POISONING

This is very common on account of the extensive industrial use of lead and its indefinite storage and cumulative action. The lead acts independently on the blood, nutrition, muscular and nervous structures; and it is difficult to separate the direct and indirect actions. Similar phenomena may be produced in animals.

Sources of Chronic Lead Poisoning.—Over a hundred industrial processes use lead or one of its salts, and the workers in these—painters, dyers, type-setters and typefounders, plumbers, etc.—are the most frequent sufferers after lead miners and the workingmen in white-lead and red-lead factories. Artisans working with lead paints are by far the most common victims. Automobile factories furnish numerous victims. Amongst painters, about 40 per cent. show active symptoms. Less than half of those who have passed the age of 40 years are free from plumbism. The heaviest incidence is among those who have been painters for 10 years or more (Harris, 1918). Comprehensive reviews of industrial lead poisoning are given by A. Hamilton (potteries, 1912; painters' trades, 1913; lead smelting, 1914).

The occurrence of chronic lead poisoning is by no means confined to these artisans. The metal is so widely distributed that every one is to some extent exposed. Some of the ways in which poisoning has occurred are rather surprising, f.i., by hair dyes.

The smoke and fumes from lead factories contain quite a large amount of the metal. This is deposited on the soil and on the surface of plants, and is also taken up into the tissues of the latter. Cases of poisoning have been referred to the milk of cows fed on these.

The fruit from orchards that have been sprayed with lead arsenate contains traces of lead (Sonntag, 1915); but probably not sufficient, ordinarily to be harmful.

The danger from lead water pipes has been much controverted. At present it seems to be accepted that, if perfectly pure water is allowed to flow through bright and clean lead pipes, poisoning results invariably. In this case the surface of the lead is changed into a hydrate (Cloves, 1900), and this is sufficiently soluble to cause the intoxication. But the danger is very much less with old lead pipes as ordinarily used; these have become lined with a layer of lead oxide, PbO + Pb. This is quite insoluble, and does not readily form a hydrate. The solubility is increased by oxygen and salts, especially by nitrates (Fortner, 1905), but even by sulphates; it is diminished by carbonic acid and carbonates (Paul, etc., 1906).

Ordinarily lead pipes would therefore present but little danger. But even then, if the water is allowed to stand a long time in the pipes, some solution is bound to occur.

On account of this danger, lead pipes should be condemned.

The employment of lead vessels for cooking should, of course, be entirely discarded. Tin-lined vessels, especially tin cans, usually also contain a certain amount of lead in the solder. If the percentage does not exceed a certain limit (10 per cent. for solder, 1 per cent. for tin plate) the lead seems so firmly combined in the alloy as to prevent its solution even by moderately acid liquids, such as vinegar. If it exceeds this quantity, a certain amount will be dissolved, and will exert its toxic action. The addition of some lead is also necessary in tin-foil, such as is used for wrapping articles of food, to make the tin workable. Here, also, it is harmless, if it does not exceed a certain limit. Lead enters into the glazing of earthenware vessels, and is contained in many varieties of glass; but if it exists entirely in the form of silicate of lead, it presents no danger. All these vessels may be easily tested with sufficient accuracy by allowing vinegar or dilute acetic
acid to stand in them for twenty-four hours and then passing a current of sulphuretted hydrogen through the liquid. If there is no precipitate, the amount of lead is below the dangerous limit.

It is somewhat peculiar that lead bullets in a wound do not usually seem to exert the lead action. They probably become incapsulated and oxidized in such a way that none of the metal is absorbed. However, with small shot, which offers a large surface, several cases of severe and fatal poisoning have been reported (Curtet and Lombard, 1912).

**Individual Susceptibility.** — There is no acquired tolerance to lead, but the natural susceptibility, varies greatly as concerns the time, severity and symptoms of poisoning. These differences depend partly on personal and factory hygiene, partly on differences of absorption and excretion; on general health and resistance; and other unknown factors. Anemia and alcoholism are believed to increase susceptibility.

The quantity of lead required to produce poisoning is not definitely known and must vary with the susceptibility. Brouardel believes that poisoning may result from 1 mg. per day; others place it much higher. Guertner claims that symptoms occur in man only after several months with a daily ingestion of 4 to 7 mg., in three to four weeks if the daily dose is 60 mg. (Puegeot and Heffer, 1912).

The length of exposure varies greatly; from a week or less, upward.

**Characteristic Symptoms of Chronic Lead Poisoning** (Cf. Alice Hamilton, 1912). — These have a slow and vague beginning and run an irregular and intermittent course, with paroxysmal symptoms and recurrences. They may develop only some months after stopping work with lead. They are quite independent of the channel of introduction.

The first signs are rather indefinite manifestations of bad health: Pallor, disproportionate to the anemia (spasm of cutaneous vessels); lead-line; foul breath, bad taste, caries of the teeth, gingivitis, often chronic parotitis. Anorexia and various digestive disturbances: Nausea, vomiting, diarrhea or constipation. Loss of flesh, especially in the cheeks. Recurrent attacks of weakness and trembling; increasing loss of strength; spots before the eyes, itching of the eyelids; rheumatic pains.

There is cachexia, with the skin dry, gray or slightly icteric.

**Blood Changes.** — The hemoglobin and red corpuscles are diminished. The latter contain basophilic granules, staining with methylene blue. This "stippling" is an important early and almost constant diagnostic sign (van Emden and Kleerekoper, 1904); although the basophilic granules may occur also in other anemias, and are sometimes absent in lead-poisoning. Many of the corpuscles are destroyed, producing icterus and widely distributed "hemosiderin." Schnitter, 1915, attributes the blood changes to injury of the bone-marrow, involving also the leucoclastic tissue.

The Lead-line. — This consists in a slate-covered margin of the gums where they meet the teeth. It is one of the earliest and most constant signs, and occurs also in animals. It is due to the precipitation of lead sulphide (Ruge). Similar lines are given by bismuth, silver, mercury, iron, and perhaps other metals. It may also be simulated by charcoal tooth-powders.

Other General Phenomena occur later: Fatty degenerations in the kidneys, liver and other glands; and in the intestine, leading to arteriosclerosis.

Gout, with urate deposits similar to those of true gout, but always containing much lead.

Nephritis is common in acute, and invariably present in chronic poisoning. It is primarily vascular, followed by epithelial degeneration, deposition of calcium phosphate, and finally cirrhosis (Bright, 1857). The uric acid and non-protein nitrogen of the blood are increased (Yolcan and Denis, 1911).

The urine flow and chlorids are diminished during the colic, increased after the attack (Nisticò, 1911); the urinary nitrogen increases during the acute attacks, the uric acid is said to be diminished during attacks (Goetz, 1896).
Frequency of Individual Symptoms.—Harris, 1918, found the named symptoms to occur in the following percentage of active cases among painters:

<table>
<thead>
<tr>
<th>Symptom</th>

</table>

Pregnancy.—Lead always exerts an unfavorable influence upon pregnancy. The number of miscarriages in women affected by lead poisoning is very large; and of the children born, by far the largest proportion die during the first year of life (Legge, 1901). Plumbism of Father on Offspring.—The clinical evidence is quite slender. Sterility, stillbirth, and early death of the children are common clinical occurrences. If the children survive, they are particularly liable to various nervous affections (Adami). Experimental feeding of lead acetate to male rabbits and fowl also result in smaller offspring of low vitality (Cole and Backhuber, 1914). Weller, 1914-1916, confirmed this on male guinea pigs fed on lead carbonate; finding sterility or reduction of birth-rate, early death of the fetus, and especially retarded development (underweight), which persists through life.

In most of the lead-fed guinea pigs, there are no demonstrable histological changes in the testes; a few, however, show complete aspermatogenesis, with atrophy and vascular degeneration of the germinal epithelium.

Gradual recovery occurs if the administration of the lead is stopped, indicating that the deleterious action is confined to the maturing cells. The literature of the effects of lead on reproduction is reviewed by Weller, 1915.

Bone-marrow Changes.—These correspond to those produced by mercury, iron, phosphorus; and many infective and wasting diseases. They are perhaps secondary to anemia. At first there is marked increase of leucoblastic cells with disappearance of fat, and sometimes with moderate hyperemia; then, gelatinous degeneration and atrophy of the whole marrow tissue (K. Stockman and Charteris, 1903).

Later Special Symptoms.—These are highly characteristic, but may take various forms; in order of frequency: Colic, arthralgia, paralysis, nephritis, cerebral symptoms and anesthesis.

Colic.—This is preceded by continued minor digestive disturbances; pressure sensation in the epigastrium; anorexia; obstipation; and some abdominal tenderness. The acute attacks consist of paroxysms of intense pain, radiating from the umbilicus, and relieved by pressure. The patient therefore instinctively retracts the abdomen so that this often appears boat-shaped (scaphoid); and he may lie on the face with the fists pressed against the painful region. The skin is very pale and dry; the temperature low; the blood pressure high; the pulse hard, wiry and slowed, often to 40 or 50. The colic is sometimes accompanied by dyspnea (spasm of the bronchial muscles); and sudden severe muscular pains, especially in the flexors of the legs.

After some hours the pain disappears completely; but the constipation lasts some days. Nausea and vomiting are frequent. Relapses are the rule. The colic is very painful but not dangerous. Attacks are more frequent in summer. The action is presumably on the intrinsic nervous mechanism. X-ray examination shows spasmodic contractions of the small intestines (Hertz).
Blood Pressure and Circulation.—It is generally assumed that lead poisoning is accompanied by rise of blood pressure and vasocostriction. This is true for the colic attacks (Riegel and Frank, 1874), where it may be explained by the mechanical displacement of blood from the violent contraction of the intestines; and by pain-reflexes.

Welch and Mail have pointed out that violent contraction of the intestines results in complete exclusion of the blood from the contracted areas. There are few definite data as to the blood pressure at other times. The pallor of the skin points to vasocostriction. In advanced stages the arteriosclerosis and nephritis would raise the blood pressure. Quennell, 1905, believes that the pressure is raised even in acute poisoning.

In his animal experiments Harrack (see below) found no rise or other direct change in the circulation, except with fatal doses. These paralyzed the heart and respiratory muscles in common with the skeletal muscles.

Arthralgia.—This also occurs in paroxysms. After some preceding muscular weakness there are sudden attacks, generally at night, of violent remitting pains and disturbed functions of groups of muscles, especially those of the shoulder and the flexors. Pressure gives some relief. The attacks last generally from five to eight days and often recur. The phenomena are probably due to central motor stimulation.

Droop-twist and Other Muscular Paralyses.—Special groups of muscles, most commonly the extensors of the forearm (distribution of musculospiral below supinator longus), or others most exposed to fatigue, become gradually paralyzed. The condition generally begins with weakness, tremors and disturbed sensation and passes through progressive paralysis, with the "reaction of degeneration" (muscles respond to galvanic and not to faradic stimulation). Finally there is muscular atrophy and contracture. The contracture begins usually at the metacarpo-carpal articulation of the two middle fingers, then the two outer fingers and the thumb, and then the wrist. The action is peripheral and presumably directly on the muscle (see below). There is no pain. Restoration may occur even from advanced stages.

Encephalopathia Saturnalis.—Cerebral symptoms are relatively rare, but especially liable to occur in alcoholics. They indicate a grave prognosis. Hallucinations, illusions, delirium, melancholia, pseudoparalyses, coma, and epileptiform convulsions. (Convulsions may also occur from uremia.) Neurasthenia is very frequent (Hirsch, 1914).

Occasional nervous phenomena are: Neurailgia, anesthesias and hyperesthesias occurring in attacks of eight to eleven days’ duration; amnesia, ambylopa, and deafness.

Experimental Chronic Lead Poisoning in Animals.—This was produced by Harack, 1878, by using an organic compound, lead triethyl, Pb(C₂H₅)₃. It does not cause lead effects directly but only as its lead is liberated in the body. The rapidity and intensity of the action can thus be regulated by the dose and manner of injection. Effects closely resembling those of lead poisoning are secured sufficiently acutely for pharmacologic study. The nutritional and degenerative changes are thereby excluded. This simplifies the phenomena, but for this very reason some judgment must be used in transferring the results to clinical lead poisoning. W. Straub, 1911 and 1912, and Fränkmayer, 1914, have also produced chronic lead poisoning by hypodermic injections of the insoluble salts.

A very typical form occurs in fowls who have swallowed lead-shot. The conditions are especially favorable, since the shot remains in the gizzard; six shots killing a fowl is a few weeks, after muscular paralysis, enaciation, and increased peristaltis (A. Wemore, 1913; Hasslik, 1920).

The actions may be brought under three groups: Direct depression of muscle; stimulation of the central motor system; and stimulation of the intrinsic nervous mechanism of the intestines.

Muscular Actions.—Lead acts directly on all striped muscle, so that this is much more quickly fatigued (especially if moderately warmed, Cash, 1905). Finally the mus-
icle loses its excitability and goes into partial rigor. The phenomena are exhibited by isolated and curarized muscle. This action explains the lead pause and the reaction of regeneration; i.e., a good response to the single galvanic stimulation, and a poor response to the fatiguing technic faradic stimulation. There is no predilection for special muscles so that the peculiar location of lead paralysis must be determined by fatigue (Mellon, 1913).

Central Motor System.—Its stimulation results in ataxia, tremors, twitching and convulsive contractions of the face. The action is presumably located in the mid- and hindbrain. These effects are supposed to represent the clinical encephalopathia and arthralgia; the pain being attributed to muscular twitching. However, the connection is not absolutely clear.

Animals show no sign of pain but this may be because they seem to be much less sensitive to articular pain than man. They also show very little distress if acute articular disease is treated with an acetic acid injection.

Intestinal Effects.—These consist in spasmodic contraction and increased peristalsis. These results in painful colic and generally diarrhea, but sometimes obstipation, according to whether the peristalsis or the spasm predominates. It occurs in all animals and is easily abolished by atropin. The human colic is not so easily influenced by this drug, but otherwise the phenomena correspond very closely and may be explained by stimulation of the intrinsic motor ganglia. Another theory which attributes the colic to spasm of the mesenteric vessels is not supported by evidence. The vessels are indeed constricted; but this is the effect rather than the cause.

Hirschfelder, 1915; describes acute increase of peristalsis and contraction of the intestinal vessels by intravenous injection of lead acetate. Both phenomena are relieved by local or systemic administration of atropin, nicotine, or nitrites. The action of the nitrite is probably both on the vessels and the intestinal muscle.

Experimental colic was produced by F. Wassermann, 1916, by keeping cats in cages sprinkled with sawdust and lead carbonate. Feeding a barley meal after the toxic symptoms had set in, he found by X-ray examination that the gastric movements were practically normal. The small intestines showed apparently less segmentation, but more rapid passage of the food. In the large intestines, the passage was delayed, but there was lively peristalsis, with strong contraction rings, separated by dilated segments.

During the colic attacks, the small intestine contracted to a thread; the large intestine exhibited nothing special.

Wassermann refers the effects to vagus stimulation.

Chronic Nephritis.—This was described in animals by Charcot and Gombault; 1887; and studied especially by Ophuls, 1908 and 1912. It is chiefly interested in, exceptionally, with epithelial changes. Many animals showed hemorrhagic serofibrinous inflammation of serous membranes. Lead administration does not produce atrophicnephritis in dogs (Adler, 1914).

Hepatic Cirrhosis.—This is produced in animals by lethal or slightly sublethal doses of lead (McJunkin, 1913).

Diagnosis of Plumbism.—The chief points may be recapitulated as:

The history of exposure; lead-line; ammonium sulphid reaction on the skin; black stools; especially the chemical demonstration of lead in the stools or urine; pallor, anaemia, stiffening, pinched features, asthma, rheumatic pains, digestive symptoms, colic, obstipation, drop-wrist, recovery when removed from exposure to lead. The concurrence of most of these signs is highly characteristic; but none of them is absolutely constant, and may be simulated individually by other conditions (Linenthal, 1914).

Prophylaxis.—The public and especially the artisans, should be thoroughly educated to the insidious dangers of lead, and the chances of poisoning carefully guarded against.

The sources of danger—lead pipes, etc.—should be eliminated. Tin cans, foil, etc., should be frequently examined by authorized persons. Proper precautions are required in lead factories and in exposed trades. Lead-laden dust is especially dangerous. Since the main channel of poisoning is by the mouth, extreme cleanliness should be encouraged and made possible by liberal facilities for washing. Sulphates are useless (see absorption). Food should not be permitted on the premises, and the
clothing should be changed before leaving the works. More stringent laws are greatly needed.

The Treatment.—Consists in resting the patient in hygienic surroundings until the lead has been eliminated and the general health fairly restored. Tonics are valuable.

Symptomatic measures may be used: Against the pain of colic, morphine is most effective. To this may be added atropin or scopolamin, and hot applications or baths. Amyl nitrite (Riegel, 1878) gives slight and only temporary relief.

Constipation is treated with olive oil enemas; or 200 to 500 c.c. of oil by mouth. This is better than castor oil or calomel, which increase the pain if they do not relieve the constipation. The purges may be treated with strychnin, massage and electricity.

To hasten the elimination of the lead, potassium iodid, baths, sweats, and sulphur internally, are commonly tried; their efficiency is doubtful. The iodid is the most promising: Melsens, 1849, found that it hastened the elimination at first; but it soon appears to lose this effect.

PREPARATIONS—SOLUBLE LEAD COMPOUNDS

Plumbi Acetas (Plumb. Acet.), U.S.P., B.P.; Lead Acetate (Sugar of Lead); Pb(CH₃COO)₂ + 3H₂O.—Colorless or white granular crystals or masses, of faintly aceto odor and sweetish astringent, afterward metallic taste, efflorescent. Freely sol. in water (1:2), sol. in alc. Incompatible with alkalis and carbonates; iodids, chlorides and sulphates. Dose, 0.05 gm., 1 gr., U.S.P.; 0.06 to 0.3 gm., 1 to 5 gr., B.P. Maximum dose, 0.3 Gr., 5 gr.

Pl. Plumb. c. Opia, B.P.—12 per cent. of Oplum; 80 per cent. of Plumb. Acet. Dose, 0.12 to 0.25 Gr., 2 to 4 gr., B.P.

Ung. Plumb. Subacet., B.P.—1:5 per cent. of the Strong Solution.

PREPARATIONS—INSOLUBLE LEAD COMPOUNDS

Plumbi Carbonas (White Lead); (PbCO₃)₂Pb (OH)₂.—Insol. Used as Ointment, 10 per cent., against dermatitis, burns, etc.

Plumbi Indicatus (Plumb. Iod.,) B.P.; PbI₂—An insoluble, bright yellow powder. Used externally as mild counterirritant against glandular swellings, etc., in the form of the Ointment.

Ung. Plumb. Iod., B.P.—10 per cent.

Plumbi Oxidum (Plumb. Oxd.), U.S.P., B.P. (Litharge); PbO.—Heavy, yellowish powder, without odor or taste. Almost insol. in water. Used in making the Subacetate.

(Ump. Plumb., U.S.P., B.P.—See Index).

THALLIUM

The metal is almost as toxic as arsenic. The acetate has been given internally (5 to 10 mg. per day) against the night sweats of phthisis, and both internally and externally as a depilatory. The therapeutic use has repeatedly caused severe poisoning and is scarcely justified. It is not anti-syphilitic (Buschke, 1914).
The toxic phenomena are: stomatitis, diarrhoea, dyspepsia, pain in the extremities, alopecia (also in animals; Buschke, 1900), depression and other neuroses and neuritis, diuresis and persistent albuminuria (Olmer and Tiu, 1900; Swain and Bateman, 1902).

PHOSPHORUS

General Statement.—Phosphorus produces severe acute poisoning, resembling acute yellow atrophy of the liver; characterized by alterations of metabolism and fatty changes of the liver and other organs. Chronic poisoning, as in match factories, results in necrosis of the jaw. Therapeutic doses effect changes in nutrition and bone formation, which are utilized especially in rickets.

Phosphorus acts as such: its actions are not shared by any of its compounds, which are for the most part harmless.

Varieties of Phosphorus.—The element exists in two forms, red and yellow. Red or amorphous phosphorus is non-volatile, insoluble in water or oil, is not absorbed, and is therefore not toxic. The yellow or ordinary phosphorus, while almost insoluble in water, is very volatile and dissolves in fats and bile (Hartmann, 1866), so that it is absorbed, especially when it is finely divided.

Absorption, Fate and Excretion.—Absorption occurs from the intestines; to some extent also by the inhalation of the vapor. It is always slow, and the systemic effects are therefore delayed several days. It is finally excreted in oxidized form (hypophosphoric acid, Poulet, 1872), but its fate is very imperfectly known. Although it oxidizes so readily in the air, its oxidation in the blood requires days (H. Meyer, 1881); perhaps it has an inhibitory action on oxidizing ferments similar to hydrocyanic acid (Schultzen and Ries, 1869). During its action it exists unchanged in the organs and in the expired air.

PHOSPHORUS POISONING

Etiology.—Phosphorus is quite accessible in the form of matches or phosphorus rat paste, so that poisoning, accidental or suicidal, is not uncommon. It also occurs, rather rarely, in the therapeutic use. Infusions of matches have been taken as abortifacient, with serious results. Chronic poisoning of a somewhat different character is seen from its fumes, in phosphorus and match factories. This, as well as the poisoning by matches, has been very greatly diminished since the introduction of amorphous (red) phosphorus.

Phosphorus Matches.—The first phosphorus friction matches were made by De Chaine, Paris, in 1816, but they did not become practical until 1823, when processes for their manufacture were invented in several countries. These all employed yellow phosphorus; each match contains 2½ to 4 mg., so that 10 would be fatal for an adult. The other ingredients are oxidizing agents (potassium chlorate or dichromate; lead oxide or nitrate; manganese dioxide).

The use of the dangerous yellow phosphorus in matches is now prohibited by law in practically all European countries. In the United States, a prohibitive tax has been placed on their manufacture. Phosphorus sesqui sulphide, which is said to be non-toxic, is now used in ordinary matches, which strike anywhere. The "safety-matches" have no phosphorus on the sticks, which are usually headed with Sb₂O₃, K₂O and glass; the red phosphorus is here on the friction surface coating of the box.

The Symptoms of Poisoning.—These have the peculiarity that they occur in two well-defined stages: At first, there is local gastro-intestinal irritation; then more or less complete recovery; then, after two or three days, the phenomena of the systemic actions appear. These are distinguished by fatty enlargement of the liver, intense icterus, and metabolic changes pointing to diminished oxidation. They extend over several days and generally terminate in death by heart failure. Gastric, syncopal, or cerebral phenomena may predominate.

1 Quoted by Blyth.
Acute Symptoms.—These generally start after some hours with gastric pain and burning, intractable with garlic odor, and hourly vomiting, which may be luminous in the dark. Later there is often diarrhea. If treated, there is more or less remission or even complete recovery for two or three days.

The Later Phenomena.—These begin with nausea; then gradually slight icterus; abdominal pain and tenderness; vomiting and soft stools, both often streaked with blood; coated tongue and fetor oris.

The symptoms become gradually more severe; and within two days the area of liver dulness has rapidly increased; the hepatic region is painful and very tender, and the icterus more intense. If death occurs within the first two days of the second stage, there is usually no icterus (Magnus, 1857). All foods and liquids are vomited. The patient becomes profoundly prostrated with insomnia, anxiety, headache, muscle pain and feebleness. The temperature is normal, the skin dry, the respiration increased, the pulse soft but of normal rate. The urine is scanty, acid, with albumin and bile, and contains albumin, casts and abnormal nitrogenous substances. Multiple hemorraghes occur as petechiae or in larger areas, in the skin, mucous, lungs and other viscera.

Agonal Stage.—The pulse becomes thready and intermittent; the heart dilated, with systolic murmurs; the respiration dyspneic or Cheyne-Stokes. Consciousness may be undisturbed, or generally there is somnolence, sometimes delirium and disturbances of temperature, finally coma.

Diagnostic Post-mortem Features.—These are: the icterus; phosphorus odor of opening abdomen; blood tarry and difficulty coagulable; multiple hemorrages; fatty enlargement of the liver and other organs.

The metachromasia of the pancreatic cells, according to W. J. M. Scott, 1816, are the first structures to show changes in phosphorus poisoning.

Course.—This runs from two to fifteen, averaging perhaps eight days.

Fatality.—This is high, about 55 per cent. (Falck); with larger quantities such as are used for abortion, it may reach 85 per cent. (Kobert).

The Fatal Dose.—This may be as low as 20 mg., generally about 100 mg.; but 11 mg. may be severely toxic. It is much more dangerous in solution or when finely divided, than when large. A ten-year-old child has been severely poisoned by therapeutic doses (1.2 mg. distributed over three days; Nebelthau). Magnus, 1914, states that no dangerous effects have ever occurred (in children up to eight years) from 0.5 mg. per day, although there may be some vomiting at first. He states the smallest dose that has exceptionally produced dangerous effects as 1 mg. per day.

Recovery.—This may occur gradually, even from advanced symptoms; but cerebral hemorrhages may leave paralytic after-effects.

Treatment of Acute Poisoning.—Any phosphorus remaining in the alimentary tract should be oxidized and removed. The best antidote is copper sulphate, 0.1 to 0.2 Gm. in water, every ten minutes until emesis. This acts as a prompt emetic, and meanwhile oxidizes the phosphorus and envelopes the globules with a coating of reduced copper which retards absorption (Woehler and Vogel, 1856; Straub, 1903). Gastric lavage with other oxidizing agents may be substituted: KMnO₄ 0.1 per cent. (Bokai and Antal; Koranyi, 1880); H₂O₂ 2 per cent. of the official solution. These should be followed by a saline cathartic. Oils, fats and milk should be avoided while any phosphorus remains in the intestines, since they increase its solubility and absorption. Sodium bicarbonate may be given to prevent acidosis. When the systemic symptoms have set in, these measures are practically useless and the treatment must be mainly symptomatic. Transfusion of blood is said to have given good results.

In phosphorus poisoned animals, the feeding of sugar was found to replenish the hepatic glycogen, and to diminish the other toxic manifestations (Simonds, 1910).

Oil of Turpentine.—0.5 Gm. several times daily for a week may be tried (Anast, 1868; Koehler, 1872) but its beneficial action is doubtful, or at best temporary. They seem to vary with different varieties of the turpentine, the fresh being often as effective as old oxidized samples. The action is not due to simple oxidation of the phosphorus, but to the formation of complex compounds (Busch and Fischer); Koehlert believes that it may be effective even after the phosphorus has been absorbed.
Special Phenomena of Phosphorus Poisoning.—Action on Metabolism.—This is the most interesting feature of phosphorus poisoning from a scientific standpoint. It occurs in chronic poisoning, or as a secondary process after a single larger dose. The phenomena consist in increased tissue destruction with disturbances of synthesis, oxidations and dissociations; increased but incomplete nitrogen metabolism; interference with glycogen deposition; increased lactic acid and ammonia excretion; and inhibition of other synthetic processes; deposition of fat in the liver.

The Mechanism.—This is not understood. It appears to involve interference with certain ferment actions, primarily with some of those involved in carbohydrate metabolism.

Nitrogen Metabolism.—This is very greatly increased. The urinary nitrogen may rise by 500 per cent. (Storch, 1862.) The excretion of phosphate and sulphur is also increased, while the chlorides are diminished by the inaction (Welsch, 1852). All the nitrogenous metabolites may participate in the increase (v. Jaksh, 1903); but not to the same extent (Muenzer, 1894). The urea is not nearly as much increased as the others and may even be diminished. It is to a large extent replaced by ammonia. This may be attributed to an increased production of sarcolactic and other organic acids. The uric acid excretion does not show characteristic changes; and the creatinin output is scarcely affected (Lusk). The hippuric synthesis of excised kidneys is checked (Hauser, 1895).

The blood of dogs poisoned with phosphorus shows increase of non-protein nitrogen, urea and amino-acids; and generally a terminal acidosi (E. K. Marshall and Rowntree, 1915). The protein cleavage products may play a part in the production of the symptoms (Moriani, 1916).

A very important phenomenon is the appearance in the urine of amino acids; leucin, tyrosin, cystin; and peptone-like substances (Schultzen and Ries, 1890). Clinical cases may not show the tyrosin. The peptone-like substances are present especially in the early stages. Their nature is not known (Harnack, 1893).

Fatty Changes.—Extensive deposition of fat occurs particularly in the liver cells, whose fat-content may reach three or four times the normal; but it is seen also in practically all other cellular organs: muscle, skeletal smooth and cardiac; kidneys; blood vessels; epithelium of stomach and intestine, etc. The fatty changes are preceded by "cloudy swelling," which is probably an intermediate stage. They are followed by proliferation of interstitial connective tissue (cirrhosis).

Similar fatty changes occur in poisoning by: Phosphin, arsenic, antimony, many volatile oils, the alcohol group, benzoil, phallin, etc., in starvation, etc.

The Mechanism of the Fatty Degeneration.—This has been studied especially in the liver. It was originally assumed that the fat was formed in situ, by true degeneration of the protoplasm of the liver cells (Bauer, 1878). However, Lebeicht, 1883, disproved this, finding that fat is deposited in the liver only if the fat store of the body is ample; and that if some foreign fat is introduced into the subcutaneous tissue, the fat deposited in the phosphorus liver agrees in composition with this foreign fat. This suggests that the liver fat is merely transported from the fat depots. These observations have been confirmed by Rosenfield, 1897; Pflueger, 1898; and others. They apply also to other poisons that cause "fatty degeneration" of the liver. The conclusion was strengthened by the observation of Atyanadu, 1898, that the total fat of the body is not increased by phosphorus. In fat it is rather diminished (Shibata, 1911). The increased fat of the liver must therefore have been drawn from other parts of the body so that the process is one of infiltration.

Lusk finds that the combustion of fat in phosphorus poisoning is not changed. Some of the "fat" consists partly of other lipoids (Dastre and Morat, 1897); Heffter, 1896, claims that the percentage of lecithin is decreased. The fat in the heart (studied by Rosenfield, 1906) is also infiltrated (Liek and Winkler).

Leathers, 1909, showed that the liver affects certain changes in the depot-fats (de-saturation, increasing the iodine-number). He believes that this is a necessary preliminary to the utilization of the fats in metabolism. Fatty infiltration of the liver would therefore represent an excessive attempt at such conversion. Accordingly, it is found in all conditions in which there is a high need for fat (starvation, etc.). If such animals are freely fed, the fatty infiltration of the liver may disappear within a day (Mottram, 1915).

Carbohydrate Metabolism.—Phosphorus causes the disappearance of glycogen from the liver. This is not due to increased glycolysis, for the percentage of sugar in
the blood is generally not increased, and in the later stages it is even decreased. Phosphorus must therefore inhibit glycogen synthesis, especially from non-carbohydrate sources (E. Franck and Isaak, 1911). This would explain the prevention of epinephrin glycosuria by phosphorus; and the non-combustion of lactic acid. According to v. Fueth, 1912, lactic acid appears in the urine only when the rabbits are fed on an excess of sugar. Dextrose also is not converted into glycerogen (E. Neubauer, 1900); thus explaining the occurrence of glycosurias when carbohydrates are fed. Glycogen may be still formed from levulose. The tolerance for galactose and levulose is lowered (E. K. Marshall and Rowntree, 1912).

The increase of nitrogen excretion may be due to carbohydrate disturbance: Franck and Isaak, 1911, believe that this interference with glycogen synthesis is the primary action of phosphorus; they attribute the increased protein destruction to the necessity of making up for the lessened supply of energy material. The rapid translocation to the liver could be similarly explained.

Accordingly Rettig, 1914, found that a diet rich in carbohydrates prevents the increased protein catabolism and the fatty changes. Ray, McDermott and Lusk, 1890, also showed that with dogs rendered glycosuric by phloridzin, phosphorus does not increase the nitrogen excretion; again indicating that the nitrogen excretion is not due to direct destruction of the protoplasm, but is in some way connected with the disturbed carbohydrate metabolism. Lusk, 1907, suggests that the primary action is to inhibit the ferment which burns lactic acid; and that the nitrogen changes are due to the resulting acidosis.

Oxygen Consumption.—The metabolic effects of phosphorus resemble those of oxygen deprivation (e.g., Porges and Pribram, 1908); and it has been suggested that phosphorus renders the cells less capable of utilizing oxygen. However, it is also possible that the metabolic changes in both cases are the secondary result of some other common factor. Indeed, Lusk, 1907, has shown that the oxygen consumption is not diminished but rather somewhat increased, partly by fever, and probably also by the toxic action of increased protein destruction.

Autolysis.—In advanced phosphorus poisoning, the postmortem autolysis of the liver is greatly accelerated (Jacoby, 1900; Porges and Pribram, 1908); probably by decreased resistance of the liver cells to the normal autolytic ferments (Wells). It is not clear what, if any, part this plays in the liver and systemic changes during life.

Direct addition of phosphorus to excised normal liver does not hasten autolysis (Jacoby). The phenomena are probably analogous to those of late chlorform poisoning.

Bile and Icterus.—The swelling and subsequent cirrhosis of the liver obstruct the bile capillaries, so that the bile secretion is diminished or suppressed; and the gall-bladder contains only a little mucous fluid. The retention of the bile constituents produces the characteristic intense icterus. It was formerly believed that the formation of bile was also increased by the destruction of the blood; but there is no evidence for such destruction.

The Effects on the Liver.—These may therefore be summarized as: disappearance of glycogen; incomplete combustion of lactic acid; increased excretion of ammonia; increased protein destruction with incomplete desamidization of certain amino-acids; fatty infiltration; mechanical interference with bile formation; increased postmortem autolysis; decrease of fibrinogen.

The excretion of p-s-phtalein is delayed (Whipple and Sperry, 1915). The liver, heart, ganglion and other nerve cells show degenerative changes similar to those of chloroform intoxication (Lissauer, 1914).

Changes in the Blood; Red Corpuscles.—It was formerly believed, on the basis of experiments on birds (Franckel and Roehmann), that these were rapidly destroyed in man and animals (Tawass, 1862; v. Jacckeb, 1863), however, no destruction occurs even in severe poisoning. In fact the corpuscles are often increased (Ragazzi, 1910; Leonardi, 1914) and this is the typical effect of therapeutic doses.

In phosphorus poisoning not only the absolute volume, but also the viscosity (Lissauer) of the blood are increased by the polycythemia; and remain so until death approaches, when they suddenly decrease. The osmotic pressure of the blood was found increased.
by Bottazzi, 1895; unchanged by Ragazzii. The alkalinity is diminished. The catalase action is moderately decreased (Duncker and Jodlbauer, 1911). The statements as to the leucocytes are confused; Ragazzii describes increase of the polymuclear, and disappearance of eosinophiles. According to Leoncini, the leucocytes are at first diminished, then sometimes moderately increased.

The coagulability of the blood is diminished. This is probably due to the destruction of fibrinogen or of fibrin ferment; or possibly to the production of peptone bodies by the destruction of proteins (Cevigalli, 1902). Denny and Minto, 1915, also find the antithrombin content of the blood diminished.

The hemorrhagic tendency is explained by the lessened coagulability of the blood and by the fatty changes in the capillary endothelium.

The ebolic action which occurs with fatal doses may be referred to degeneration of the blood vessels. However, phosphorus also passes to the fetus in sufficient amount to produce fatty hepatic degeneration.

Circulation.—Phosphorus appears to have direct toxic effects on the heart-muscle; for with intravenous injection this is paralyzed before anatomic degeneration has set in (Meyer, 1881). In the collapse, splanchnic stimulation is ineffective. In clinical poisoning, the syncopal cases may be due to this cardiac paralysis, but generally the circulation suffers but little until the agonal state.

Muscle and Nerve.—These are not directly affected.

The Central Nervous System.—This plays a subsidiary rôle, but is said to show histologic changes (Rossi, 1897).

Local Actions.—Irritation of the mucous is shown by the early acute symptoms, but phosphorus is not corrosive.

Chronic Phosphorus Poisoning.—This is seen especially in match factories using yellow phosphorus. The most common manifestation is necrosis of the jaw; sometimes bronchitis, to which tolerance is acquired; and cachexia resembling mild acute poisoning.

Strict prophylaxis should be enforced. The manufacture of yellow phosphorus matches has been prohibited in most civilized countries. Exposed persons should attend to ventilation, cleanliness and strict oral hygiene (Ivy, 1911).

The necrosis of the jaw begins with salivation, suppurative ulceration of the gums, and ends in very profound periodontitis, involving the whole jaw. It usually starts in carious teeth. The lower jaw is more often affected. The only treatment is excision of the diseased bone.

Identical necroses in the teeth and other bones have been produced experimentally (Wegner, 1872), by prolonged exposure of rabbits to phosphorus vapor, after laying bare the periosteum. The bone changes are probably allied to those seen in the therapeutie use, but intensified by the more direct contact and by secondary infections.

Phosphorus Burns.—These are no more dangerous than other burns of similar extent and do not produce any of the symptoms of phosphorus poisoning.

Bone Changes by Prolonged Administration of Small Doses.—These stimulate bone formation (Wegner, 1872); in growing animals, the epiphyses form compact instead of spongy bone; in adults, the Haversian and marrow canals are gradually filled with dense bone. This has the normal chemical composition and structure. Larger doses increase the vascularization of the bone (Kassowitz).

THERAPEUTIC USES

The stimulation of bone formation led to the use of phosphorus in rickets, osteomalacia, and delayed healing of fractures (Kassowitz, 1884). The clinical evidence of its usefulness is contradictory; the best results are reported in rickets, in which it is said to improve not only the bone changes, but all the other symptoms. The improvement should be seen in about four weeks.
MANUAL OF PHARMACOLOGY

Themister, 1918, found its clinical use to produce distinct stimulation of bone formation, provided that calcium deposition had not been markedly deranged by the disease. Phosphorus would therefore be useful mainly during the "healing stage," when improvement has already started.

The dose is usually about 1 mg. per day, with meals; best dissolved in olive or cod liver oil (0.01:200 c.c.). The solution should be freshly made. A pill (0.6 mg.) is also official. It is coated with Tolu to prevent oxidation.

The administration of phosphorus generally causes some gastrointestinal disturbance; sometimes the jaw necrosis; and rarely typical phosphorus poisoning. It must therefore be carefully watched and stopped if any gastric or intestinal effects appear.

Stability of Phosphorus Preparations—Engelhardt and Winters, 1915, find the pills and spirit fairly stable, but not always. Compound elixirs are less stable.

Phosphorus in Nervous Diseases.—It has been advised as a tonic in alcoholism, neurasthenia, neurasthenic neuralgia, neurasthenic neuritis, neurasthenic neuritis, tuberculous neuritis; and in chlorosis and anemias. There is little scientific support, either experimental or clinical, for this use.

Zinc Phosphide.—This has been suggested as a therapeutic substitute (Vigier, 1876); there is very little scientific information about it.

Amorphous or Red Phosphorus.—This is non-volatile, incombustible and therefore non-poisonous when taken by mouth; but since it may contain traces of ordinary phosphorus (to 0.6 per cent.—Blythe), large doses could become toxic. Intravenous injections (Nasse, 1883) produced the effects of ordinary phosphorus.

Phosphated Hydrogen.—This gas (Phosphine—PH₃) is a violent poison; 0.025 per cent. in air is harmful after a time; and 0.2 per cent. is quickly fatal, producing dyspnea, fainting, lowered blood pressure, slowed heart; nausea and vomiting; convulsions and paralyses; coma and asphyxia. Postmortem examination shows pulmonary congestion and exudation. Industrial poisoning occurs from its pressure in acetylene and ferrosilicon.

Phosphorus Pentachlorid.—Poisoning is described by Roch, 1914.

PREPARATIONS—PHOSPHORUS

Phosphorus (Phosphor), U.S.P.; B.P.—A translucent waxy substance of distinctive odor. Melts about 44°C. Oxidizes (ignites) on exposure to air. Practically insol. in water, but slightly sol. in alc. (1:400). Sparingly sol. in oils. Sol. in fat solvents. Dose, 0.5 mg., 5/12 gr., U.S.P., 0.6 to 2.5 mg.; 5/8 to 5/4 gr. B.P., as pill or oily solution. These must be currently prepared. Maximum dose, 0.5 mg., 5/4 gr. Oleum Phosphorum (Ol. Phosphor.), B.P.; 1 per cent. in olive oil. Dose, 0.06 to 0.3 c.c., 1 to 5 minims. B.P., in almond or cod liver oil, or in capsules.

Pil. Phosphor., U.S.P.—0.6 mg., 5/10 gr.; coated with Tolu to retard oxidation. Pil. Phosphorii, B.P.—1 per cent. (formerly 2 per cent.) Dose, 0.06 to 0.25 Grn., 1 to 4 gr., B.P.

PHOSPHORUS COMPOUNDS IN NUTRITION

LECHEIN, GLYCEROPHOSPHATES, HYPOPHOSPHITES, ETC.

General Statement.—Phosphorus compounds are important constituents of animal and vegetable cells, and especially of nervous tissue. Preparations of phosphorus have therefore been used as tonics and "brain foods" in all sorts of depressed conditions: Scrofula, incipient phthisis and cachexia; neurasthenia and tabes; neurites and nervalgias, etc.

With the possible exception of lecithin, there is no experimental evidence of their value; the clinical evidence also is too indefinite and contradictory to establish their position. With lecithin, positive results are claimed by some investigators but even these are denied by critical observers. The ordinary diet furnishes a very free supply of lecithin and other phosphorus compounds, and it is difficult to see how the small qua-

1 A very full review of these subjects, with bibliography, is given by Forbes and Keith, 1914.
PHOSPHORUS COMPOUNDS IN NUTRITION 949
tivities added in the form of more or less expensive medicines could have any other than psychic effects.

Occurrence of Phosphorus in Body.—Phosphorus is found as inorganic phosphate, mostly in the bones and teeth as bone ash, and as organic phosphate in the fluids and cells. The cells also contain the organic compounds, nucleins, lecithins, and phosphatides. The organic phosphorus compounds of the serum are almost exclusively phospho-ribos (Greenwall, 1910; Bloom, 1919; Meigs et al., 1910).

Quantitative Distribution.—The total phosphorus content of the body (young dog) is equivalent to about 0.7 per cent. of P. Of this, three-fourths is in the bones; the muscles contain more than the combined total of the central nervous system, skin, liver and kidneys (Heubner, 1914).

Organic Phosphorus Constituents or Tissues.—It may be well to premise the discussion of phosphorus metabolism by some chemical data.

Structure and Occurrence of Lecithins.—These are esters of fatty acids, glycerophosphoric acid, and a nitrogenous base (mainly choline). Their structure will be understood by the following formula, in which $R$ represents fatty acid—oleic, stearic, palmitic or other. The part to the right of the dotted line represents choline.

$$\text{CH}_2\text{O} - \text{P} - \text{O} - \text{H}$$
$$\text{CH}_2\text{O} - \text{P} - \text{O} - \text{R}$$
$$\text{CH}_2\text{OH}$$
$$\text{CHOH}$$

Glycero phosphoric acid.

Lecithin.

The various lecithins differ according to the fatty acid, etc. They occur in animal (not in vegetable) cells, generally combined with proteins. Their place may be taken by related compounds or "phosphatides" which are but little understood.

Lecithins are conveniently isolated from brain substance or egg-yolk ("vitellin"). The commercial products are quite impure. They contain 3.8 to 4.2 per cent. of phosphorus. The purest are those obtained by Erlandsen’s method. (Bibliography of Lecithins, Merck’s Report, 20: 26.) H. MacLean, 1915, states that ordinary lecithin is really a mixture of cephalin (which tends to become insoluble in alcohol), and true lecithin (which remains alcohol-soluble).

Barbieri, 1910 and 1917, threw doubt on the existence of lecithin; contending that this is merely a mixture of fats, phosphates and dializable nitrogen without any choline. However, this has been disproven by Levene and West, 1917, 1918. They isolated from egg, brain and other tissues, absolutely pure lecithin, and established its composition as conforming to that generally accepted.

Properties.—Lecithin is a white to orange-colored substance, usually amorphous and waxy when dry. It is very hygroscopic, softening to a semifluid mass in the air. It also oxidizes readily, becoming darker. It dissolves in alcohol or most fat-solvents (not in acetone). It is insoluble in water, but readily takes up water, swelling to a gelatinous mass and finally to a colloidal solution, from which it is precipitated by certain acids and salts; while other salts prevent the precipitation (W. Koch). It is decomposed by prolonged contact with water; alkalies sapontize it readily into choline, fatty acid, and glycero phosphoric acid. Further cleavage results in ordinary phosphoric acid. The cleavage with dilute acids is quite slow.

Kephalin.—This is a highly unsaturated monamino-monophosphatid. Its nitrogenous base is probably not cholin (W. Koch, 1902); otherwise it is closely related to lecithin.

Koch and Woods, 1915, believed that it is distributed as widely as lecithin.

Other Phosphatides.—The number of these is probably very limited; the various phosphorized fats prepared from different tissues being probably mixtures of lecithin and kephalin, with closely related homologous fragments (Levene and Komatsu, 1919).

Plant Phosphatides.—These were formerly considered identical with lecithin, but are now known to be quite distinct. They usually contain a sugar molecule.

Phythin.—This is a calcium-insolent phosphate, occurring abundantly in plant seeds.

Absorption, Fate and Elimination of Phosphorus Compounds.—The inorganic phosphates are absorbed as such, mainly from the upper portions of the small intestines. Phosphates that are insoluble in water generally
dissolve readily in the gastric juice. They are excreted by the urine and feces. Hypophosphites are also absorbed, and for the most part are excreted unchanged. Glycerophosphates and all organic phosphorus compounds are almost completely hydrolyzed in the digestive tract (Pflimmer, 1913), and absorbed and excreted as inorganic phosphate (Oeri, 1909). Opinions differ as to the importance of the small fraction (if any) that escapes decomposition. Further details will be given under the individual drugs.

The absorbed phosphorus is utilized in the construction of bone and in the synthesis of the various forms of organic phosphorus compounds in the body. These can be constructed completely from inorganic phosphates. The greater part of the normally excreted phosphate is derived from the metabolism of the tissues and therefore generally varies in the same direction as the nitrogen excretion, although they are not necessarily proportional. *Phosphaturia* is the deposition of phosphates in the urine, is due to alkaline reaction of the urine, and not to increased phosphate excretion; indeed, the excretion is generally diminished.

The path of phosphate excretion is markedly influenced by the calcium of the food. With a high calcium income, the phosphate is excreted mainly by the feces as calcium phosphate; whereas the urinary phosphates increase with a lime-poor diet (Zuelzer, 1905).

**Phosphorus Compounds of Urine.**—Practically all the phosphorus of the urine is normally in the form of inorganic mono- and di-hydrogen phosphates. A variable fraction may exist in organic form, as glycophosphoric and phosphobacitic acid.

The organic phosphorus is increased in fasting, chloroform anesthesia, morphine poisoning, and some pathologic conditions.

**Phosphorus Compounds of the Feces.**—These are derived partly from unabsorbed phosphates, from intestinal secretions, and from the bacteria. They include various organic forms, nucleins, lecithins, etc.; as well as calcium and other inorganic phosphate.

**Rôle of Organic and Inorganic Phosphate Compounds in Nutrition.**—Animals which receive an adequate supply of inorganic phosphates require very little, if any, organic phosphorus compounds (Review, Marshall, 1915). The presence of some organic phosphorus in the food appears in favor nutrition; but this may be due to the association of some "vitamin" or similar substance.

**Synthesis of Lecithin.**—Miescher, 1866, deduced that the production of roe and milk in the fasting salmon must involve the synthesis of large amounts of phosphorized fats from inorganic phosphorus compounds. Roehm, 1908, showed that mice can be maintained for two generations on lecithin-free food; and Fingerling, 1912, and McCollam, Halpin and Drescher, 1912, demonstrated that the organic phosphorus of egg-yolks can be formed from inorganic phosphorus compounds, since it is not diminished if birds are kept on a diet free from organic phosphorus. Pflimmer, 1913, came to the same conclusion. Macallum found no phosphate ions in the nucleic, so that the nucleins are probably not formed here.

**Daily Phosphorus Requirements.**—Under ordinary conditions, the daily phosphorus excretion of normal human adults is equivalent to about 1.5 to 1.75 Gm. of P, or about 3.5 Gms. of PO₄. This must be replaced by a corresponding income to preserve a balance.

The ordinary diet contains about this amount (from 1.52 to 2.88 Gm., average 2 Gms., of PO₄ (Sherman, Mettler and Sinclair, 1910)). Under special conditions of diet, equilibrium may be preserved temporarily with 0.0 Gm. of P. This is also the average daily excretion in fasting.

**Phosphorus Balance.**—Increased intake of phosphorus compounds is followed by increased elimination: in carnivora mainly by the urine; in herbivora mainly by the feces; in omnivora by either, according to the diet. A portion of the excess is retained, especially in growing animals or after wasting diseases. The retention is diminished by deficiency of calcium or excess of magnesium in the food. The bones constitute important depot for a phosphate reserve. The deposition of phosphate in them is hindered by the oxalic acids, calcium-precipitating ions, or high potassium or low sodium content of the ration.
Cows during lactation lose considerable phosphate. This may be corrected by the addition of bone and calcium carbonate to the food (Forbes et al., 1915).

Excision of the parathyroids is followed by marked retention of phosphorus, increasing its concentration in the blood (Greenwald, 1916).

Deficient Phosphorus Income.—If this falls below the normal requirement, the excretion, and finally the phosphorus content of the tissues, is diminished. The phosphorus of the plasma, both organic and inorganic varies rather widely and is influenced by the food (Meigs et al., 1910). Its diminution soon leads to disturbances of growth and nutrition, the spongy tissue of the bones being most affected (Masslow, 1914). The bones become soft and flexible when their phosphorus content has fallen by one-sixth (Houbner, 1914). In fasting, the loss of phosphorus is considerable.

Growth that has been interrupted by phosphor-deficiency, is resumed when phosphorus compounds are added. Inorganic phosphates are perfectly efficient for this purpose (Osborne and Mendal, 1913).

Phosphorus Compounds as "Tonics."—As was pointed out in the introductory paragraph, the extensive employment of phosphate compounds as tonics, particularly as "nerve foods," was based on mistaken theoretical conceptions.

With the doubtful exception of lecithin, it lacks all experimental or reliable clinical foundation.

Phosphorus in Nervous Tissue.—Phosphatids, especially lecithin, are contained in glands, cell membranes (especially of the red corpuscles), and nerve tissue, where they subserve important physical and chemical functions. Nervous tissue is rich in phosphorus (1.5 per cent. of moist; 1.5 per cent. of dry); but not more so than glandular organs. Its phosphatid content (27 per cent. of dry), however, is three times or more that of glands. Its importance therefore can not be doubted; but the percentage of phosphorus is not decreased even in severe nervous diseases (dementia precox). Nervous diseases are therefore not due to deficiency of lecithin (W. Koch, 1909).

Even in menorrhagia, where the nervous tissue, particularly lecithin, is lacking rapidly, an abundance of phosphorus compounds is supplied by the food. Moreover, Hart, 1908, showed that even in extreme phosphorus starvation the tissues keep up their phosphorus content by drawing on the phosphatides of the bones. The effects of withholding or adding inorganic and organic phosphorus compounds to the food of growing dogs was studied by Durflach, 1913.

The lecithin content of different tissues was studied by Cruikshank, 1913; it is also discussed in Mercer's Reports, 16:6.

LECITHIN

General Statement.—This is probably the most promising of the phosphorus tonics. There is at least some experimental evidence that its administration favors growth, although this is open to suspicion. It has not achieved a secure place in therapeutics. The occurrence, composition and properties have been sufficiently discussed in the preceding paragraphs.

Lecithin Content of Food.—The ordinary mixed diet contains at least 5 Gm. of lecithin daily; and this can be doubled by adding a couple of eggs (egg-yolk contains 6.8 per cent. of lecithin); or by liver or sweetbreads, which are also rich in phosphorus.

In comparison with this, the phosphorus content of medicines is ridiculously small; for instance, the daily dose of lecithin amounts to only 0.2 Gm. Milk, however, is rather poor in lecithin (1 pint contains 0.3 to 0.4 Gm.) (W. Koch, 1905); but the organism is able to synthesize its lecithin from inorganic phosphates.

Fate of Lecithin.—Modern investigators agree that little, if any, lecithin is absorbed as such (contrary to the opinion of Bunge); but that the fat-splitting enzymes of the intestines split off the glycerophosphoric acid, which is further decomposed into phosphoric acid before it is absorbed (Bokay, 1877; Pasquali, 1863; Plimmer, 1913).

Possibly a fraction of the glycerophosphoric acid, and even of undecomposed lecithin, is absorbed before the cleavage is completed. In this case, or if the lecithin is introduced parenterally, the cleavage occurs in the tissues; the excretion being entirely as inorganic phosphates.

Effects on Growth.—Danilewsky, 1895 and 1896, believed that feeding isolated lecithin stimulates the processes of growth, producing increase of red corpuscles and accelerated physical development as compared with control animals. The growth of plants was also increased. The division-rate of parrancium is slowed by lecithin.
Since the experimental quantities were too small to have much food value, they would have acted as true stimulants. However, a critical attitude toward these statements appears justified. It is rather remarkable that the addition of these small doses of isolated lecithin should have effects which are not produced by the much larger quantities in the ordinary diet. Moreover, several recent investigators (Goldfarb, 1917; Yoshimoto, 1910) were unable to confirm the experimental data. They obtained negative results even with long-continued administration.

On the other hand, the lipins of egg-yolk or butter-fat have a positive effect on the growth of rats kept on a uniform artificial diet (McCollum and Davis, 1914; Osborne and Mendel), but this is not due to phospho-lipins.

When lecithin is administered to lactating mice, the growth of the sucklings is slightly retarded (Robertson and Cutler, 1916).

Effectson Metabolism.—The statements are similarly contradictory. Tunnicliffe, 1906, and Slowtonoff, 1906, described retention of nitrogen and phosphoric acid.

The Clinical Data.—These are even more unsatisfactory than the experimental, although apparently successful toxic and hemorhagic effects have been described (Serono, 1897; Oesnheim and Mueller, 1905, etc.).

Carcinoma.—Hydropenic injection retards the growth of rat-carcinoma; oral administration is not effective, presumably because the lecithin is decomposed before absorption (Robertson and Burnett, 1910).

Action on Circulation.—Danilewsky, 1906, Michalowski, 1910; and Katsnelson, 1910, state that the heart of frogs and rabbits is stimulated by diurese, depressed by concentrated solutions. Lischitz, 1910, describes rise of blood pressure and cardiac stimulation. Lawrow and Woronow, 1912, produced a marked antagonistic effect to cardiac poisons (chloral and other lipolytic narcotics) in mammals, by the intravenous injection of 0.5 Gm. per kilogram, 3 g per cent. emulsion. Much larger doses were harmless. The results were still more marked in excited hearts. They attribute the effect partly to direct cardiac stimulation, partly to disinfection of the lipolytic poisons. Hauschmidt, 1913, confirms that intravenous injection is harmless and lessens the toxicity of the lipolytic narcotics and also of curare, strychnin and morphin; but that it is not the toxicity of the rich.

Rôle in Fat-Assimilation.—Bloor, 1915, et seq., found that the lecithin content of the blood increases by 10 to 25 per cent. during the absorption of fats, generally parallel to the increase of blood fat. The accumulation of lecithin is greatest in the corporcles, which contain about twice as much as the plasma. The cholesterol content (which is about equal in the muscles and plasma) is not increased by feeding fats. These data indicate an important rôle of lecithin in fat assimilation. Bloor believes that lecithin is a regular stage in fat metabolism, through which all fats must pass before they are assimilated. The formation of lecithin probably occurs in the liver.

Lecithin on Cutaneous Absorption.—Borsch, 1912, claimed that small amounts, rubbed into the skin before the application of a potassium iodid solution increases its absorption; while large amounts have the reverse effect. Glucose, salicylic acid and tetanus toxin were not absorbed.

Administration.—Commercial lecithin may be administered as pills, 0.1 to 0.2 Gm., 1 to 2 g. per day; for infants, one-third of this dosage. It has also been given hypodermically, 1 c.c. of 5 per cent. in oil; but in view of the impurities, this is not advisable. It is incompatible with alkalies (Details of administration; Merck's Report, 26:42).

PHYTIN

This consists of the salts (usually calcium) of an organic phosphoric acid, probably containing inositol (presumably inositol-hexaphosphoric acid). It is widely distributed in plants (bibliography, A. R. Rose, 1912). It is prepared from plant seeds, and has been proposed as a substitute for lecithin. It is absorbed and metabolized, but must be decomposed before it can be used by the tissues. Abundant amounts are contained in ordinary food; and there is no clear evidence that it is superior to inorganic phosphates.

GLYCEROPHOSPHATES

These are absorbed in part unchanged, but for the greater part are decomposed in the intestines into ordinary phosphates (Flinik, 1913). The excretion is entirely as phosphate.

Since lecithin is split into glycerophosphates in the intestines it was suggested by Pasquale, 1884, Buelow, 1884, and Robin, 1894, that the direct administration of the cheaper glycerophosphates (especially the calcium salt) should accomplish the same results. However, according to Willstaetter, the synthetic glycerophosphoric acid is
not identical with that formed from lecithin. In any event, the evidence of its usefulness is less convincing than for lecithin (Report, Counc. Pharm. Chem., 1916, J. A. M. A., 67, 1933).

A proprietary compound of glycerophosphates and casein has been widely and extravagantly advertised as "Sanatogen." It is a very costly food, in no sense superior to ordinary casein, such as cottage cheese (Street, 1914).

PREPARATIONS—GLYCEROPHOSPHITES

Cali. Glycerophosphates (Calc. Glycerophosphates). U.S.P.—the normal calcium salt of glycerophosphoric acid (C,H,OH).PO,Cl).—The most commonly used glycerophosphate. Fine, white powder; odorless and almost tasteless, somewhat hygroscopic. Sol. in water (1:50); insol. in alc. Solutions of glycerophosphates are decomposed on heating. Dose, 0.25 Gm., 4 gr., U.S.P.

Sod. Glycerophate, U.S.P.—Not less than 98 per cent. of C,H,OH).PO,Na. White plates or scales, or powder; saline taste. Very sol. in water; nearly insol. in alc. Dose, 0.25 Gm., 4 gr., U.S.P.

Liq. Sod. Glycerophate, U.S.P.—Not less than 90 per cent. of Na,C,H,OH).PO,. Dose, 0.35 cc., 6 minims, U.S.P.

HYPOPHOSPHITES

General Statement.—These were introduced by Churchill, 1855, against tuberculosis, on the theory that phthisis is caused by lack of oxidation and that this would be stimulated by organic phosphorus; and that the hypophosphites would be converted into this “phosphatide element.” On the basis of this fantastic theory, they have been used considerably as tonics in tuberculosis. The clinical evidence is too indefinite and the experimental evidence is generally negative (Marriott, 1916). (Report Counc. Pharm. Chem., 1916, J. A. M. A., 67, 766.)

The hypophosphites are excreted rapidly and almost completely unchanged (85 per cent.) Marriott, 1916) by the urine (Paquelin and Joly; Boddaert, 1805; Massol and Gamaud, 1909,) but may possibly be oxidized (Delaini, 1911). (Pitto, 1910, claims that only a fraction is excreted unchanged.) They are not diuretic.

The unscientific status of the hypophosphites is reflected in the polypharmaceutical syrups in which they are generally prescribed, such as the Syrupus Hypophosphitum, U.S.P., containing four (different hypophosphites, dose 10 c.c.;) and the Syrupus Hypophosphitum compositus (dose 10 c.c.), containing six hypophosphites besides quinin and strychin; there is also an emulsion of cod liver oil with hypophosphites. The hypophosphite is easily soluble in water; dose, 0.1 ti 1 Gm.; 1 to 15 gr.

The calcium salt is probably the most important.

PREPARATIONS—HYPOPHOSPHITES

Calcii Hypophosphat (Calc. Hypophosphat), U.S.P.; B.P.; Ca(H,PO,).—Colorless, transparent prisms, or small lustrous scales, or a white, crystalline powder; odorless, nauseous, and bitter taste. Freely sol. in water (1:6.5); insol. in alc. Dose, 0.5 Gm., 8 gr., U.S.P.; 0.2 to 0.6 Gm., 3 to 10 gr., B.P.

Rad. Hypophosph., U.S.P.; KPHO,.—Very sol. in water (1:25). Dose, 0.5 Gm., 8 gr., U.S.P.

Sod. Hypophosph., U.S.P.; B.P.; NaHPO, + H,O.—Saline taste. Freely sol. in water (1:27); sol. in alc. Dose, 1 Gm., 15 gr., U.S.P.

Syrupus Hypophosphitum (Syr. Hypophos.) U.S.P.—Contains a mixture of calcium, potassium and sodium hypophosphites (total, 7.5 per cent.), acidulated with hypophosphorous acid. Dose, 10 c.c., 25 grains, U.S.P.

Syrupus Hypophosphitum Compositus, N.F.—Contains the above, also the hypophosphites of Fe and Mn, with quinin and strychin. Dose, 10 c.c., 2 drams; contains 11 mg. (1/4 gr.) quinin; 1.1 mg. (1/4 gr.) strychin.
## APPENDIX

### APPENDIX A.—TABULATION OF AVERAGE DOES

The following list may aid in memorizing the subject. The drugs have been divided into four groups, according to the order of their practical importance. It is not advisable that medical students should trouble themselves with group D; nor very much with group C.

APPENDIX B.—CHECK-LIST FOR THE STUDY OF PREPARATIONS

Introductory.—The student should keep a separate notebook, ruled in columns as illustrated in the schema, into which the names of the drugs and the relevant data are entered as they are studied. The preparation of these tables is probably the most efficient method of learning the subject. The synonyms, origin, miscibility, dose, and remarks will be found in the text. The appearance, odor, and taste should be studied directly from the specimen. It is highly desirable that the physician should be somewhat familiar with the physical characters of the principal drugs, if for no other reason than that it will give him some confidence, save him some embarrassment, and guarantee the proper dispensing of his prescriptions. This knowledge may be of vital importance for the prompt diagnosis of poisoning.

Those drugs which may be readily recognized by their physical characters are marked with an *asterisk*. It is expected that the student will learn these so that he can identify the unlabelled specimens. The other specimens should be learned sufficiently, so that the student is able to decide whether or not an unlabelled sample may or may not be whatever is suggested. For instance, whether a white powder may be arsenic trioxide; whether a colorless fluid may be Tincture of Nux Vomica, etc. The drugs which are bracketed in the list are for inspection only. No data need be entered for them.

The *Materia Medica Museum* should contain the drugs mentioned in the following exercises. These may be duplicated for large classes. It will be found convenient to arrange the drugs in the order of this list.

The labels should give the name of the drug; whether it is for identification, important, or unimportant; and whether it may be tasted. Separate gummed slips, distinguished by colors, are very handy for this purpose.

**White Labels**

- **Strong Poison!** Do Not Taste. (Red Label)
- **Poison!** Taste Cautiously. (Blue Label)
- **Practically Harmless.** (Green Label)

**Red Print**

- **Identification.**

**Blue Print**

- **Important.**

**Black Print**

- **Unimportant.**

Other drugs—especially crude specimens—are valuable for reference, but may be dispensed with. Illustrations and herbarium specimens of important and domestic medicinal plants are also profitable.
### SCHEMA FOR THE TABULATION OF MATERIA MEDICA NOTES

<table>
<thead>
<tr>
<th>Average dose (U.S.P.)</th>

</tbody>
</table>

Explanatory:

(1) Enter the full Latin name and the abbreviation. Synonyms or English Names need be entered only if they differ markedly from the Latin name.

(2) The origin need be given only for drugs or preparations derived from the organic kingdom.

#### CHECK LIST OF IMPORTANT PREPARATIONS

"H" means that the drug is harmless.
"C" that it may be tasted cautiously.

Clavip. 428
Clavicepsin. 428
Climate. 721
Cloves. 169
Cinus. 420
Coagulability of blood. substances increasing. 193
Coal oil. 113
tar. 585
dyes. 605
Cobalt. 219
Cobra venom. 501
Coca. 250
Coca folla. 313
Cocain. 313, 310, 320, 327
group. 306 to 314
hyperthermia. 518
substitutes. 306 to 314
Coca. 313
Cocain. 250, 247
Coccs. 64
Cochineal. 64
Cocumas. 222
Cocum. oleum. 110
Cod liver oil. 102
Colest. 259 to 288, 542

codeine. 288
Coffee. 244 to 258
Oil. 257
Cognac. 659
Coal. black. 197
blue. 500
Cola. 257
Collapse. 28
Colchicina. 330, 517
Colchicum. 517 to 519
Collapse. 543
Collargol. 915
Cold. external. 539
Cold. 283
Colloidin. 375
Collodion. 40
Colloium. 120
Colloidal solutions. 784
Lazatives. 216
Metals. 857 to 858
Colloidal solutions. 619, 725 to 730
Colloids. 108
and edema. 755
Carbohydrate. 449
on absorption. 88
on diuresis. 784
on uterus and intestine. 526
Colocynthis. 212, 214, 215
diarrhea. 508
Colombo. 106
Colophony. 114
Coloring. 64
Columbian spirits. 660
Combined action of drugs. 95
Comm. 24
Concentration. 88
and actions. 77
effect of. 70
Condiments. 104
Conditions influencing drug action. 92 to 96
Condurango. 197
Confections. 31
Conin. 339
Conium. 379
Conjuunctiva. 85
Constitution. on action. 75
Convallaria. 460 to 461
Convulsant poisons. 214
Convulsants on temperature. 548
Convolutions. 281
Copaiba. 171, 172
Copper. 916 to 917
Corandrum. 68
Coriaria and coriarymyrtin. 239
Cor. 18
Corn. 17
Cori. 413
Corinum. 418
Corpus luteum. 451
Correction. 58
Corrosion. 122
Corrosive effects. 130
poisoning. 131
Sublimate. 924
Cortex. 17
